	Control	Cafeteria
+ Albumin (5 mg ml^{-1})	32.3 ± 2.0	42.7 ± 2.6*
+ GDP (1 mM)	20.2 ± 1.2	18.7 ± 2.3 NS
+ FCCP (5 μM)	35.3 ± 2.6	38.3 ± 3.4 NS

The age and weight of the rats used were similar to those in Table 1. Mitochondria were prepared by the method of Slinde *et al.*[16], and oxygen consumption was measured at 25 °C in a Clark-type oxygen electrode (Rank Brothers) using the conditions described by Nicholls[7]. Mitochondrial protein was measured as in Table 1. Results are mean values ± s.e.m., $n = 8$. NS, Not significantly different ($P > 0.05$) from controls.

*$P < 0.01$.

The action of purine nucleotides on mitochondrial respiratory control in BAT is due to inhibition of the proton conductance pathway[2]. This inhibition is associated with the binding of the purine nucleotides to an inner membrane protein (molecular weight 32,000) unique to brown adipose tissue mitochondria. Changes in mitochondrial GDP binding have been used to study the capacity of the proton conductance pathway during cold-adaptation in rats[8,9], and during early development in both rats[9] and guinea pigs[10], as well as to investigate abnormalities in heat production in brown adipose tissue from genetically obese (*ob/ob*) mice[11]. In view of the similarities between non-shivering thermogenesis and diet-induced thermogenesis an experiment was carried out to compare the purine nucleotide binding capacity of brown adipose tissue mitochondria isolated from cafeteria- and stock-fed rats maintained in warm and cold environments.

Similar rats to those used in the first experiments were housed at either 24 °C (warm-adapted) or 4 °C (cold-adapted) and fed the stock diet for 15 days, after which time half the animals at each environmental temperature were allowed access to the cafeteria diet. We have previously shown[12] that

Table 3 Purine nucleotide (GDP) binding to interscapular brown adipose tissue mitochondria from cafeteria and control rats maintained at either 24 °C (warm) or 4 °C (cold)

	Warm control	Warm cafeteria	Cold control	Cold cafeteria
Animal weights (g)	326.3 ± 18.1	306.0 ± 25.5	296.6 ± 11.8	327.4 ± 21.2
Mitochondrial protein recovered (mg)	5.7 ± 0.9	8.7 ± 0.9*	17.2 ± 1.4‡	21.0 ± 1.3‡
GDP binding (pmol GDP per mg mitochondrial protein)	52.6 ± 7.4	135.3 ± 24.0†	249.8 ± 17.8‡	237.5 ± 14.6‡
n	7	5	5	5

The rats used in these experiments were aged approximately 10 weeks. Mitochondria were prepared by the method of Slinde *et al.*[16], and the protein content of each preparation was determined colorimetrically by a modified Lowry assay[19] using bovine serum albumin as a standard. Mitochondrial GDP-binding was measured essentially as described by Nicholls[20] with the modifications of Desautels *et al.*[6]; ^{3}H-GDP and ^{14}C-sucrose (both Radiochemical Centre) incubations were carried out for 7 min at room temperature. Results are mean values ± s.e.m.

*$P < 0.05$; †$P < 0.01$; ‡$P < 0.001$, compared with warm controls.

cafeteria feeding in the warm produces quantitatively similar increases in metabolic rate, noradrenaline sensitivity and brown adipose tissue mass, to those seen with cold-adapted stock-fed controls. In the present study, animals were killed after 10–20 days on the experimental diets and brown adipose tissue mitochondria prepared for determination of GDP-binding capacity. Details of the methods used and results obtained are shown in Table 3.

Cafeteria feeding in the warm environment resulted in a significant 2.5-fold increase in GDP-binding per mg mitochondrial protein compared with warm-adapted controls. Thus, the high diet-induced thermogenesis resulting from cafeteria feeding apparently leads to a marked increase in the proton conductance of brown adipose tissue mitochondria, similar to that observed with cold-adaptation. It is unlikely that the increased GDP binding of cafeteria-fed rats over that of the controls was due to the isolation of a different population of mitochondria or to differences in the purity of the preparations, because the specific activities of the two respiratory enzymes (cytochrome oxidase and α-glycerophosphate dehydrogenase) were almost identical for both groups.

Cold-adaptation produced a greater than fourfold increase in GDP binding per mg mitochondrial protein in both stock- and cafeteria-fed rats. The results for the cold-adapted control group are similar to those reported by Desautels *et al.*[8], and although an additive effect of cold and cafeteria feeding on metabolic rate and noradrenaline sensitivity has been seen in earlier experiments[12], this is not reflected in the GDP-binding results for the cold-adapted cafeteria group in the present study.

The present results are the first report of an effect of diet and energy intake on the capacity of brown adipose tissue mitochondria for thermogenesis. They support our earlier suggestion[1] that the mechanisms of diet-induced thermogenesis and non-shivering thermogenesis are similar, and are consistent with the improved cold tolerance of overfed rats[12].

Genetically obese animals (*ob/ob* and *db/db*) have impaired thermogenesis[13–15], which has been associated with a lowered purine nucleotide binding in their brown adipose tissue mitochondria[11]. This finding, together with the results of the present study, suggest that brown adipose tissue has an important regulatory role in energy balance, as well as in body temperature.

Insulin stimulates sugar transport in giant muscle fibres of the barnacle

P. F. Baker & A. Carruthers

Department of Physiology, University of London King's College,
Strand, London WC2R 2LS, UK

Insulin stimulates sugar transport in vertebrate skeletal muscle but the mechanism of insulin action is unknown[1]. It has been reported that Na transport in giant muscle fibres of the barnacle (*Balanus nubilis*) is sensitive to insulin[2] but no one has examined the sensitivity of sugar transport to insulin in this preparation. We show here that insulin does, indeed, stimulate sugar transport in barnacle muscle. The great advantage of barnacle muscle over all other muscles used so far for investigating the mechanism of insulin action is its large size, which facilitates measurements on single cells and permits the experimenter to control the intracellular environment of the muscle fibre by the technique of internal dialysis[3]. Using single muscle fibres it is possible to show that acceleration of sugar transport by insulin is associated with a fall in ionized Ca, a fall in cyclic AMP and a rise in cyclic GMP. Working with internally dialysed muscle fibres we find that insulin only increases sugar transport when the dialysis solution contains ATP. In the absence of insulin, sugar transport in dialysed muscle is increased by a rise in ionized Ca, a fall in cyclic AMP and, when the internal Ca is elevated, by a rise in cyclic GMP.

D-Glucose is taken up and metabolised by barnacle muscle fibres. For this reason, the non-metabolised sugar 3-*O*-methylglucose was used throughout the present study. In addition to their sensitivity to insulin, 3-*O*-methylglucose fluxes in barnacle muscle show several features in common with sugar transport in mammalian tissues. Sugar uptake and exit consist of two components: a saturable component (apparent $K_m = 5\,\mathrm{mM}$, $V_{max} = 17\,\mathrm{pmol\,cm^{-2}\,s^{-1}}$) which is reduced by both phloretin (apparent $K_i = 10^{-4}\,\mathrm{M}$) and cytochalasin B (apparent $K_i = 5 \times 10^{-6}\,\mathrm{M}$), and a component which increases linearly with sugar concentration and is insensitive to phloretin or cytochalasin B.

Porcine insulin stimulates reversibly the rate of sugar uptake and exit in isolated muscle fibres in a concentration-dependent manner (half-maximal stimulation seen at $1.2\,\mathrm{U\,ml^{-1}}$). Barnacle muscle fibres bind ^{125}I-insulin: this can be displaced by cold insulin, and in the presence of $1\,\mathrm{U\,ml^{-1}}$, the insulin space of single fibres is about five times greater than that of mannitol or sucrose. Both insulin binding and the activation of sugar transport become saturated at roughly the same concentration of insulin and on the assumption that all the radioactivity is bound to the surface of the muscle, the number of insulin binding sites is 600 per μm^2. These findings suggest that barnacle muscle fibres have receptors for insulin but we do not know whether barnacles possess endogenous insulin or an insulin-like peptide. The stimulatory action of insulin is confined to the phloretin- or cytochalasin B-sensitive component of sugar transport. In the presence of these inhibitors, insulin has no effect on sugar fluxes but in their absence it increases the rate of sugar uptake 2.4-fold and the rate of sugar exit approximately 2.5-fold. Denatured insulin, $ZnCl_2$ ($60\,\mu\mathrm{M}$) and albumin ($0.5\,\mathrm{mg\,ml^{-1}}$) are unable to mimic the effect of native insulin. Analysis of the kinetics of sugar uptake shows that insulin increases the V_{max} with little or no effect on the apparent K_m.

Insulin has been claimed to exert its action on sugar transport through changes in cyclic nucleotide levels or ionized Ca[1,2,4–6]. These possibilities can be examined directly using single barnacle muscle fibres. The effect of insulin on cyclic nucleotide levels is shown in Fig. 1. Insulin ($5\,\mathrm{U\,ml^{-1}}$) elicits a roughly simultaneous rise in cyclic GMP and fall in cyclic AMP levels which can be detected as early as 2 min after

0028-0836/80/290276-04$01.00

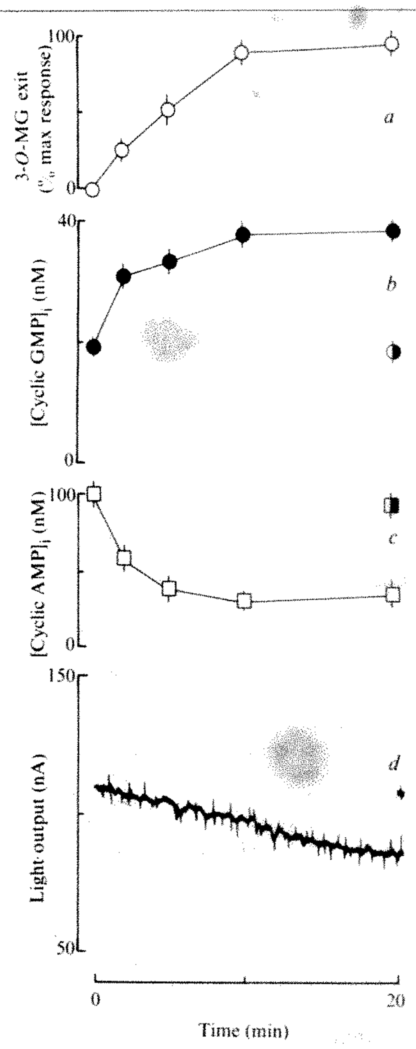

Fig. 1 *a–d* The effects of insulin ($5\,\mathrm{U\,ml^{-1}}$) on 3-*O*-methylglucose (3-*O*-MG) exit, cyclic nucleotide levels and aequorin light output in barnacle muscle. *a*, Time course of the stimulation of sugar exit in single muscle fibres by insulin Fibres were bathed in seawater, composition (mM): NaCl, 442; KCl, 10; $MgCl_2$, 53; $CaCl_2$, 11; Tris, 10, *p*H 7.6. Each point consists of four or more fibres. Mean fibre diameter, 1,326 µm; temperature, 11 ± 1 °C. *b*, Time course of the rise in cyclic GMP levels caused by insulin. Each point consists of six separate determinations. The concentration of cyclic GMP following 20 min incubation in insulin-free seawater (◑) is shown below the points. Temperature, 12 °C. Recovery of exogenous cyclic GMP added to barnacle muscle homogenate was 89.2%. *c*, Time course of the fall in cyclic AMP levels caused by insulin. Each point consists of five or six separate determinations. Cyclic AMP levels corresponding to 20 min incubation in seawater (◨) are shown above the points. Temperature, 12 °C. Recovery of exogenous cyclic AMP added to barnacle muscle homogenates was 93.4%. *d*, Time course of the change in intracellular free Ca as a result of exposure to insulin. The fibre was injected with aequorin and left in flowing seawater for 2 h to allow the aequorin to diffuse uniformly across the cell. The figure is a tracing of the photomultiplier output as displayed on a pen recorder. The light output was stable before application of insulin. Above the record at 20 min is shown the level to which light output recovered after 20 min in insulin-free seawater. Fibre diameter, 984 µm; temperature, 11 °C.

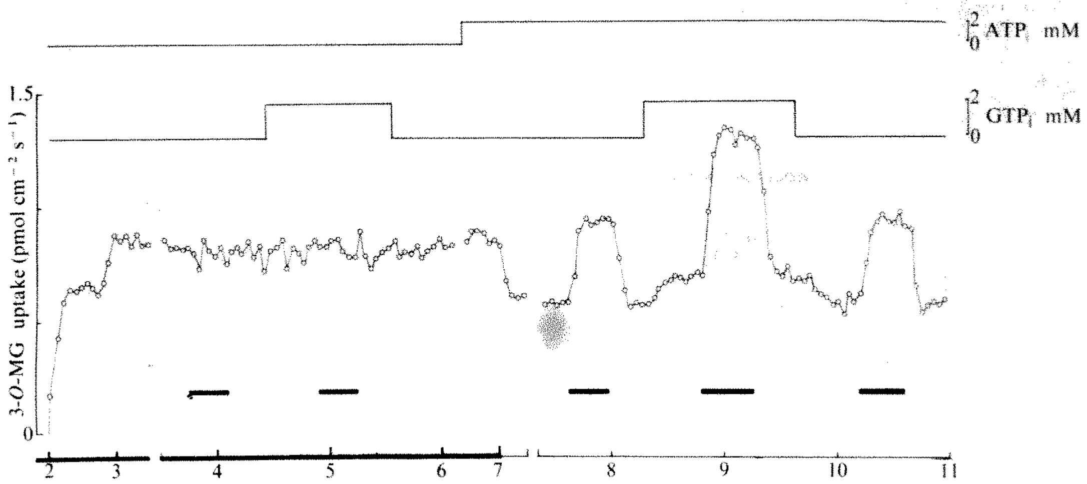

Fig. 2 The effect of insulin on 3-*O*-methylglucose uptake in an internally dialysed muscle fibre. The fibre was dialysed with a solution of the following composition (mM): K aspartate, 150; NaCl, 32; $MgCl_2$ (in excess of ATP), 10; $CaCl_2$, 1.5; EGTA, 5; HEPES, 5; PIPES, 5; NaCN, 2; ECCP, $2\,\mu\mathrm{g\,ml^{-1}}$; phenol red, 2, *p*H 7.0. The osmolarity was adjusted to 975 mosM with sucrose. ATP was added to the solution as MgATP. In calculating the concentration of ionized Ca, the log of the stability constant for Ca-EGTA at *p*H 7.0 was taken as −6.723. Internal ATP and GTP concentrations are shown above the points. External application of insulin ($5\,\mathrm{U\,ml^{-1}}$) is indicated by the solid bars. The external 3-*O*-methylglucose concentration was 2 mM in all dialysis experiments. The fibre was dialysed for 2 h with a solution containing 0 ATP before external application of isotope. Fibre diameter, 985 µm; temperature, 10 °C. As in Fig. 4, sugar uptake is expressed as $\mathrm{pmol\,cm^{-2}\,s^{-1}}$.

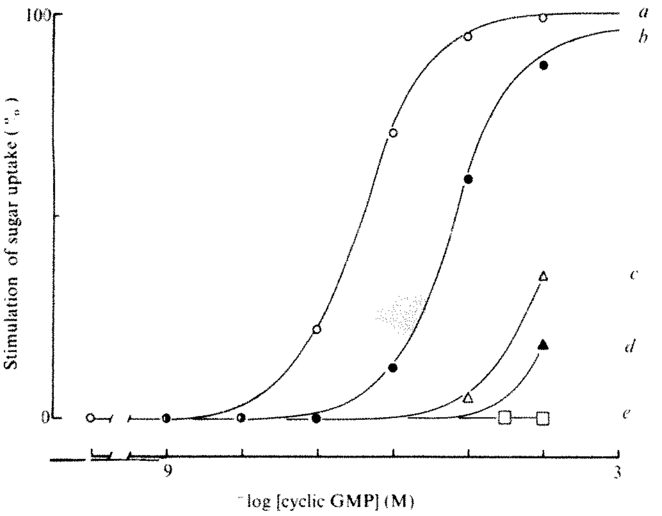

Fig. 3 The effect of raised internal free Ca on the activation of 3-*O*-methylglucose uptake by cyclic GMP. The data are pooled from six fibres. Each curve shows the cyclic GMP-dependent activation of sugar uptake at different Ca levels. The small activation caused by raising the internal ionized Ca concentration is subtracted from each point. The ionized Ca levels are 0.91, 0.5, 0.41, 0.27 and 0.12 μM for curves *a*–*e*, respectively. Curves *a*–*c* are calculated by Lineweaver–Burk analysis, on the assumption that the maximum stimulation in all cases is 100%. The apparent Michaelis constants for cyclic GMP are: curve *a*, 4.12×10^{-7} M; curve *b*, 6.92×10^{-6} M; curve *c*, 1.9×10^{-4} M. Curves *d* and *e* are drawn by eye. Mean fibre diameter 1,241 μm; temperature, 10 °C.

adding insulin to the medium. The changes in cyclic nucleotide levels seem to precede the change in the rate of sugar exit; this is not inconsistent with the possibility that insulin increases sarcolemmal sugar permeability through alterations in cyclic nucleotide levels.

The hypothesis that insulin acts in muscle by mobilizing intracellular Ca can be tested directly in the barnacle muscle fibre using the Ca-sensitive photoprotein aequorin. Fibres were injected axially with aequorin and the light emitted passed along a fibre optic system to a photomultiplier (EMI, 9635 B) the output of which was displayed on a pen recorder. Resting light output was calibrated by use of a variety of Ca-EGTA buffers[7] and, on the assumption of an internal ionized Mg of 4 mM (ref. 8) and *p*H of 7.2 (ref. 9), the light output was found to correspond to a free internal Ca of 70 nM. On exposing fibres loaded with aequorin and isotopic 3-*O*-methylglucose to insulin (5 U ml^{-1}), there was a simultaneous increase in the rate of sugar exit and a small, but reproducible, fall in the resting light output (Fig. 1). This effect on light output was not mimicked by $ZnCl_2$ (60 μM), denatured insulin or albumin (0.5 mg ml^{-1}). A fall in light output was rather unexpected in view of the claims that insulin may increase intracellular ionized Ca. It is well known that intracellular ionized Ca can be manipulated by altering external Ca or replacing external Na with Li, and the effects of these manoeuvres on sugar fluxes were examined. Removal of external Ca reduced light output by some 70% and replacement of Na by Li increased light output eight-fold; however, sugar exit in both conditions was unaffected. We conclude that although insulin seems to reduce internal free Ca in barnacle muscle, its effect on sugar transport in this preparation seems not to be related in any simple way to the myoplasmic ionized Ca concentration.

Another way to examine this problem is to use internally dialysed muscle fibres[3]. With this technique it is possible to clamp the ionized Ca to some predetermined level using Ca-EGTA buffers; if a change in ionized Ca is a prerequisite of insulin action, it should be impossible to elicit any response to insulin in conditions of dialysis with solutions containing EGTA buffers. This was certainly not the case. Figure 2 shows that, provided ATP was in the dialysis solution, insulin stimulated the rate of sugar uptake in the presence of a buffered Ca concentration of 120 nM and the stimulatory effect of insulin was enhanced when GTP (2 mM) was also included in the internal solution. This action of insulin was not seen in dialysed fibres exposed to cytochalasin B. These observations suggest that although intracellular ATP is essential for insulin action, alterations in internal ionized Ca are probably not necessary.

Figure 2 also shows that ATP *per se* has an effect on sugar fluxes. In the nominal absence of ATP the uptake of sugar increased. This is consistent with the well known effects of metabolism and anoxia on sugar fluxes in muscle cells[6]. The concentration of ATP which produced half-maximal inhibition of 3-*O*-methylglucose uptake was 0.4 mM.

Using the dialysed muscle fibre it is possible to examine whether any of the alterations in cyclic nucleotide levels or ionized Ca brought about by application of insulin are capable

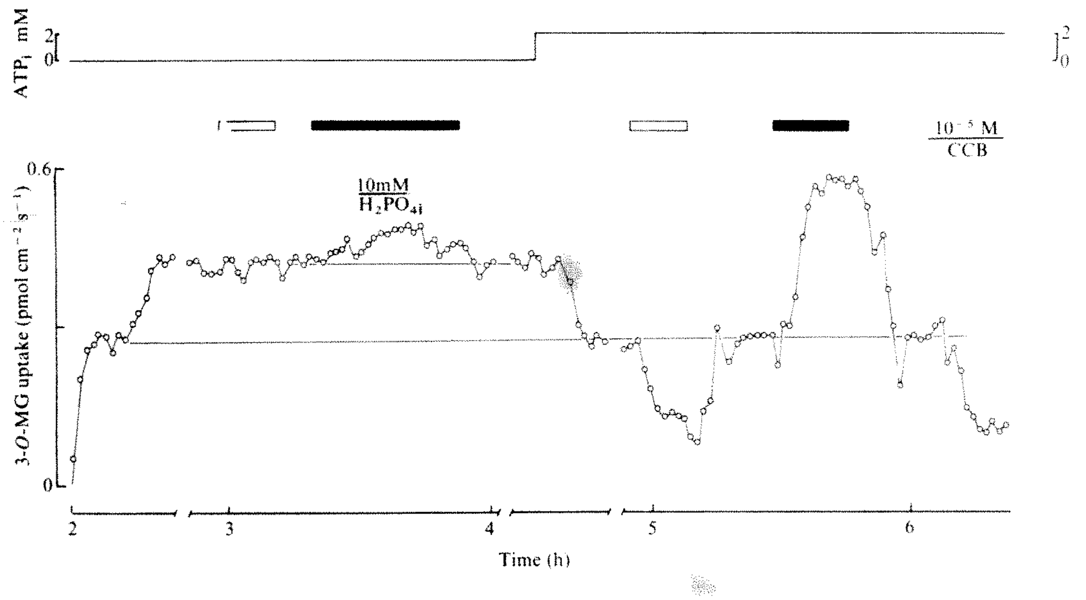

Fig. 4 Effect of cyclic nucleotides on sugar uptake in dialysed muscle. Internal solution as in Fig. 2. Internal ionized Ca = 0.91 μM. The internal ATP concentrations are shown above the points. Internal application of cyclic AMP (10^{-6} M) and cyclic GMP (10^{-4} M) are indicated by the open and closed bars, respectively. Cytochalasin B (CCB) was applied externally at the end of the experiment. Fibre diameter, 1,098 μm; temperature 10 °C.

themselves of mimicking the action of insulin on sugar fluxes. Raising internal Ca from 0.12 to 0.91 μM produced a small increase in the rate of sugar uptake averaging 1.27-fold. It follows that a fall in ionized Ca as seen after application of insulin should, if anything, reduce sugar uptake.

Internal application of cyclic AMP reduced the rate of sugar uptake in dialysed muscle. When cyclic AMP (100 μM) was added to an internal solution containing 2 mM ATP and a free Ca of 0.12 μM, 3-*O*-methylglucose uptake was reduced to 29.1 ±4.5% of control values ($n=5$). This inhibition of uptake was half maximal at 10^{-6} M cyclic AMP_i and was independent of the internal free Ca concentration.

When the internal free Ca was low (0.12 μM), internal application of cyclic GMP had no effect on the rate of sugar uptake. On raising the internal ionized Ca from 0.12 to 0.91 μM, however, cyclic GMP_i (100 μM) rapidly and reversibly stimulated the rate of 3-*O*-methylglucose uptake 2.13-fold ($n=4$). Raising internal free Ca seemed to increase the affinity of the system for cyclic GMP. Thus, increasing internal free Ca from 0.5 to 0.91 μM reduced the concentration at which cyclic GMP stimulated the rate of sugar uptake from 6.9×10^{-6} to 4.2×10^{-7} M (see Fig. 3). Figure 4 shows that ATP_i must be present for both cyclic AMP and cyclic GMP to influence the rate of sugar transport.

These results show that sugar uptake can be affected by changes in ionized Ca, cyclic AMP and cyclic GMP; however, can the measured changes in these parameters in intact muscles account quantitatively for the observed stimulation of sugar fluxes in dialysed muscles? Although the changes are somewhat smaller than those needed to alter sugar fluxes in dialysed fibres, it is unlikely that cyclic nucleotide levels are uniform across the fibre. Bearing in mind the peripheral location of adenylate cyclase in the plasma membrane, it is very possible that cyclic AMP is at appreciably higher concentrations in the myoplasm close to the sarcolemma. If this is the case, a fall in cyclic AMP could certainly play a part in mediating the increase in sugar transport brought about by insulin. The experiments on dialysed fibres suggest that alterations in cyclic GMP could be important when the background level of ionized Ca is raised, for instance during exercise; however, it is possible that dialysis removes some small molecular weight factor that is synergistic with cyclic GMP.

Evidence for two insulin receptor populations on human erythrocytes

Victoria Herzberg, J. Mark Boughter, Sandra Carlisle & Donald E. Hill

Department of Pediatrics, University of Arkansas for Medical Sciences, Little Rock, Arkansas 72201

Human erythrocytes specifically bind ^{125}I-insulin in a manner similar to cells in which insulin exerts a physiological response[1]. In addition, erythrocytes are of practical value for correlating *in vitro* insulin binding with *in vivo* carbohydrate intolerance[2,3]. The competitive binding of labelled and unlabelled insulin to erythrocyte receptors is typically curvilinear when plotted according to Scatchard[4]. The curvilinear nature of the Scatchard plot describing insulin binding to membrane receptors, although originally attributed to heterogeneous sites[5], has been more recently interpreted as negative cooperativity between homogeneous sites[6]. Evidence reported here, however, suggests that there are two populations of insulin receptors on erythrocytes. Specific concentrations of concanavalin A (Con A), a lectin which mimics insulin activity[7], are shown here to inhibit one population of receptors leaving another population unaffected.

As Fig. 1 shows, Con A competes with labelled insulin for the erythrocyte receptors. After increasing the concentration of Con A to 5 μg ml^{-1}, a 50% reduction in ^{125}I-insulin binding was observed. Concentrations of Con A greater than 20 μg ml^{-1} presented problems with cell agglutination.

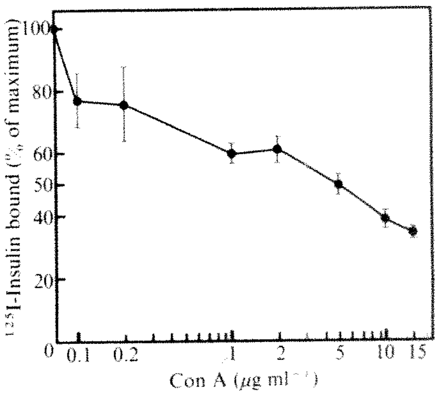

Fig. 1 Effect of Con A on the specific binding of ^{125}I-insulin to human erythrocytes. Data from five normal adult volunteers are expressed as mean ± 2s.d. Blood was collected in EDTA, and erythrocytes were purified on Isolymph (Gallard-Schlesinger) gradients[10], yielding a relatively homogeneous population of mature erythrocytes (0.01% granulocytes; ≃1% reticulocytes). Crystalline porcine insulin (Lilly) was labelled with ^{125}I to a specific activity of 125–150 μCi per μg (refs 16, 17). 1.5×10^{9} erythrocytes were added to a series of tubes in which ^{125}I-insulin (0.2 ng ml^{-1}) and increasing amounts of Con A (Sigma, grade IV) were mixed with Tris-HEPES buffer (*p*H 8.0, 284 mosmol per kg) to give a final volume of 0.5 ml. The erythrocyte receptor assay was as described before[1], with the following modifications: (1) ^{125}I-insulin was repurified on Sephadex G-50 immediately before use; (2) cells were incubated for 4 h (15 °C) to attain equilibrium binding, and (3) non-specific binding was determined in the presence of unlabelled insulin (10 μg ml^{-1}) and was subtracted from all data points before analysis.

In Fig. 2*a*, the individual curvilinear Scatchard plots obtained by the competitive binding of labelled and unlabelled insulin to erythrocyte receptors are illustrated with the 'best fit' line derived by 'Ligand' (ref. 8), a computer program designed to consider simultaneous analysis of n ligands binding to m classes of binding sites. In this instance, a single ligand (insulin) was investigated. The broken lines represent two heterogeneous, non-interacting binding sites mathematically derived from the 'best fit' line, illustrating each binding species as though the other were not present. The slope of each line represents the affinity (K_1, K_2) while the abscissa intercepts (R_1, R_2) approximate the maximum binding capacity of the two receptor populations. One receptor population (I) has a high affinity and low capacity for insulin, whereas the other (II) has a low affinity and high capacity for insulin. These lines may also be derived graphically as described by Rosenthal[9].

The experimentally determined insulin binding data obtained in the presence of Con A (Fig. 2*b*) approximate the mathematically derived site II. Variations in the concentration of Con A which proved optimal for linearization of the Scatchard plot were noted when erythrocytes from different

0028–0836/80/290279–03$01.00

individuals were tested; however, in all cases, a linear component whose correlation coefficient varied from −0.90 to −0.98 was observed. Insulin binding in the presence of Con A therefore demonstrates complete inhibition of binding site I and clearly delineates site II. The suppression of insulin binding at site I by Con A may result from steric hindrance by the larger Con A molecule binding to a contiguous site, direct competition for the same site, or indirect competition for a necessary binding component. The disclosure of site II indicates that this site may be physically removed and (or) biochemically distinct from site I.

Table 1 compares the values for the affinity and maximum binding capacity obtained by Ligand analysis of the individual Scatchard plots. Both the experimental (+Con A) and the theoretical (−Con A) binding values for site II mathematically approximate the same line. The affinity reported here cannot be directly compared with published values of average affinity constants which are based on receptor occupancy and the negative cooperativity model[6]. The maximum binding capacity, used to determine the number of sites per cell, varies considerably in the literature depending on the highest concentrations of ligand chosen by the investigator for extrapolation of the Scatchard plot to provide an abscissa intercept; for example, reported values for erythrocytes vary from 34 (ref. 10) to 2,000 (ref. 1) sites per cell. There are approximately 11 sites per cell calculated from the R2 value in Table 1, and R1 represents an average of approximately one site per cell; yielding a total of 12 insulin binding sites per erythrocyte when analysed by a two-site model. In view of these data, the difficulty in documenting a physiological response to insulin in erythrocytes is understandable.

Experimental parameters investigated in these experiments describe receptor characteristics well within the normal physiological range of circulating insulin concentrations (0.2–20 ng ml^{-1} = 5–475 μU ml^{-1}). As insulin concentrations are increased beyond this range, experimental data demonstrate that trace amounts of labelled insulin continue to be bound, accounting for the asymptotic nature of the Scatchard plot. This nonsaturable component can be treated mathematically by the Ligand program.

Erythrocytes demonstrate both enhanced dissociation[1] and, as shown here, heterogeneous populations of receptors. Enhanced dissociation of ^{125}I-insulin from receptors in the presence of excess unlabelled insulin has been explained by negative cooperativity between homogeneous receptors[6]. However, the phenomenon of enhanced dissociation cannot be explained by the presence of non-interacting, heterogeneous sites[11]. It is thus possible that there are site–site interactions among receptors of a single type, as suggested for adipocyte insulin receptors[12], or that one receptor population consists of an aggregated form of the other receptor population.

There are several interesting parallels between membrane receptors for Con A and insulin. Con A erythrocyte receptors are associated with physical particles on the membrane which influence glucose flux[13], and a specific minor membrane glycoprotein known to influence anion permeability[14]. Both of these transmembrane functions are stimulated by insulin in hormone-sensitive cell types. Insulin has also been shown to interfere with Con A binding sites on myoblasts, thus inhibiting the Con A-stimulated formation of myotubules[15]. Although these observations seem to favour a common or physically adjacent site for Con A and insulin membrane receptors, it is also possible that these molecules compete for the component(s) necessary for aggregation of receptor sites, a phenomenon observed for both Con A[14] and insulin[18] receptors. The data reported here augment these important similarities between Con A and insulin receptors and also provide evidence for heterogeneous populations of insulin receptors on human erythrocytes.

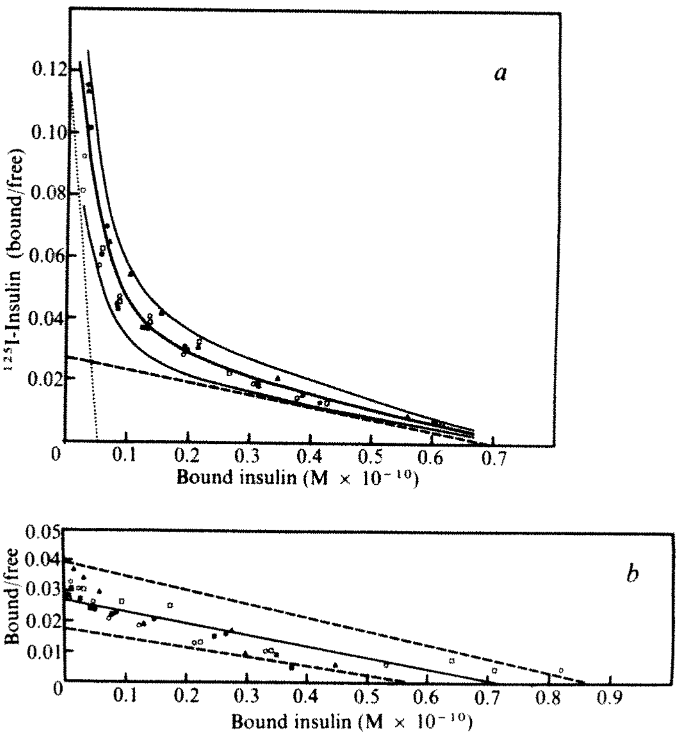

Fig. 2 Scatchard plots of insulin binding to erythrocytes from five individuals (as in Fig. 1) in the absence (*a*) and presence (*b*) of Con A. The ratio of bound to free insulin is plotted as a function of the molar quantity of bound insulin. Insulin concentrations varied from 0.2 to 100 ng ml^{-1} in the absence of Con A and from 0.2 to 20 ng ml^{-1} in the presence of Con A. *a*, Computer resolution of the curvilinear Scatchard plot, shown as the best fit line ± 2s.d. yields high affinity (......) and low affinity (– – – –) components. *b*, Data points obtained in the presence of Con A (5–10 μg ml^{-1}) are shown in comparison to receptor site II (——) ± 2s.d. (----) as determined by computer analysis of data in the absence of Con A.

Table 1 Comparison of binding parameters between Scatchard plots in the presence and absence of Con A

	Site I		Site II	
	K_1	R_1	K_2	R_2
	$\times 10^{10}$ M^{-1}	$\times 10^{-12}$ M	$\times 10^{8}$ M^{-1}	$\times 10^{-11}$ M
No Con A*	2.25 ± 1.07	5.39 ± 1.6	3.83 ± 0.81	7.11 ± 0.72
+Con A†	Undetectable		3.95 ± 0.56	7.03 ± 0.90

The values for affinity (*K*) and maximum binding (*R*) were determined from data illustrated in Fig. 2 and averaged to determine the mean ± s.e. (*n* = 5).

*From experimental data points shown in Fig. 2*a*.

†From experimental data points shown in Fig. 2*b*.

We thank Dr Dan Sheehan for verifying the original Rosenthal analyses, Drs David Rodbard and Peter Munson for helping us implement the 'Ligand' program; Drs David Straub and Jim Norris for reviewing the manuscript, and Dr Sanford Roth for initial suggestions. An effect of chloride on (Na+K) co-transport in human red blood cells

A. R. Chipperfield

Department of Physiology, University of Dundee,
Dundee DD1 4HN, UK

In certain conditions, internal K can stimulate active Na:K transport as well as Na:Na exchange through the ouabain-sensitive Na, K exchange pump[1]. When the exchange was examined during a study of the action of internal K, it emerged that the removal of K_o (the main requirement for Na:Na exchange[2,3]) reduced the ouabain-insensitive Na efflux. Thus, in eight experiments done variously with outdated cells or high and low $[K]_o$, PCMBS-treated cells, the K_o-dependent Na efflux ranged from 0.18 to 0.70 µEquiv per ml cells per h. This conflicts with the well established view that the K_o-dependent and ouabain-sensitive components of Na efflux are identical[3,4]. However, the K_o-dependent, ouabain-insensitive Na efflux was found to go through the (Na+K) co-transport system, which was further found to show a dependence on chloride ions.

In a further eight experiments, specifically designed to test the effect of K_o on the ouabain-insensitive Na efflux, the same pattern emerged. The K_o-dependent, ouabain-insensitive efflux varied from 0.16 to 0.96 µEquiv per ml cells per h (or from 8 to 41% of the total). But why did this happen in this study and not before? The reason seems to be because Ca, Mg and phosphate are absent in the external medium (this unusual feature derives from an earlier study of the kinetics of the pump[5] where any possible interference was to be avoided; this does not affect the sensitivity to ouabain). Thus, when any of the ions Ca, Mg or phosphate were present the effect of K_o was reduced and with all three present it was abolished. Moreover, it was not seen when Na_o was replaced by Li or by Mg. Thus, there may be several reasons why a K_o-dependent, ouabain-insensitive Na efflux has not been seen before.

Table 1 Tracer ^{24}Na efflux from human RBC in the presence of ouabain

External medium	Na efflux (µEquiv per ml cells per h) With 150 mM $[Cl]_o$	 With 30 mM $[Cl]_o$
Complete	2.19±0.31	1.73±0.12
K-free	1.74±0.14	1.78±0.14
Complete+ furosemide (1 mM)	1.48±0.12	1.59±0.14
K free+ furosemide (1 mM)	1.65±0.17	1.65±0.14

Tracer ^{24}Na efflux from outdated human RBC was measured as described elsewhere[1–5] in a medium containing 142 mM NaCl, 8 mM KCl, 8 mM Tris–Cl, *p*H 7.5, 10 mM inosine[16] and 0.1 mM ouabain. When K was omitted, KCl was replaced by NaCl external [Cl] was reduced by replacing NaCl, KCl and Tris–Cl by the corresponding nitrates. The results of this and the other four similar experiments show that the K_o-dependent, ouabain-insensitive flux in 150 mM external chloride is statistically significant (Student's *t* test, $P<0.003$); in contrast, this component of Na influx is not significant in media containing 30 mM $[Cl]_o$, furosemide or both. Results are the means of three determinations (±s.e.m.)

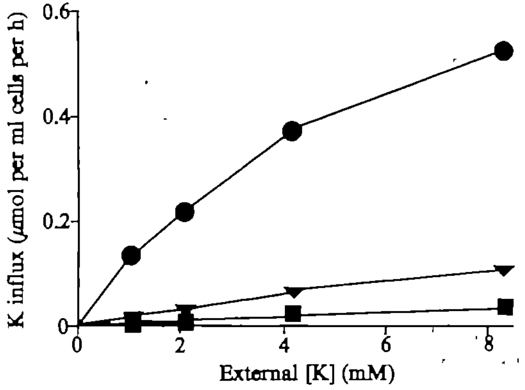

Fig. 1 External [K] dependence of ouabain-insensitive K influx into human RBC. K influx was measured as described in Table 2 (experiment 2): each point is the mean of two determinations (errors, which are not shown were comparable to those in Table 2). ●, Control: 150 mM $[Cl]_o$; ▼, 30 mM $[Cl]_o$; ■, 150 mM $[Cl]_o$ with 1 mM furosemide (the results for 30 mM $[Cl]_o$ with 1 mM furosemide (not shown) were the same as for 150 mM with furosemide).

If there is a ouabain-insensitive, K_o-dependent component of Na efflux, it is most likely to be related to the furosemide-sensitive (Na+K) co-transport system identified in RBC by Wiley and Cooper[6]. If so, is it related to the furosemide-sensitive, external Cl-dependent K:K exchange in ascites cells[7,8]? The results of one of five experiments designed to test these possibilities are shown in Table 1. Three features were noted: (1) furosemide inhibited the ouabain-insensitive, K_o-dependent efflux, (2) on replacing most of the Cl_o with nitrate, Na efflux was reduced and (3) the ouabain-insensitive, K_o-dependent efflux was smaller in nitrate-containing media.

These results, taken together with the studies mentioned before[6–8], are consistent with the idea that a large part of the Na efflux goes by a (Na+K+Cl) co-transport system. If this is so, then the furosemide-sensitive K influx should be reduced on lowering $[Cl]_o$. The results of the first experiment in Table 2 (leaving aside, for the moment, the tests with phloretin) bear out this prediction.

The results of the second experiment in Table 2 show that similar results were obtained when K influx was assessed using ^{86}Rb as tracer (this was also true for Rb influx). Accordingly, this technique was used in further comparisons with earlier work. Thus, the saturable, furosemide-sensitive passive K influx[2,3,6] was reduced on lowering $[Cl]_o$ (Fig. 1). There was a roughly linear dependence on $[Cl]_o$ (ref. 8) of K influx (Fig. 2). With anions other than nitrate, there was a substantial furosemide-sensitive K influx with bromide but not with

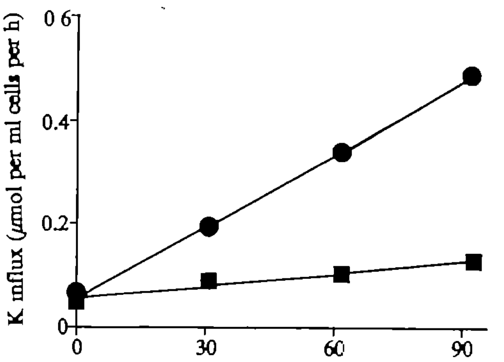

Fig. 2 External [Cl] dependence of ouabain-insensitive K influx into human RBC. K influx was measured as described in Table 2 (experiment 2): each point is the mean of three determinations (errors (not shown) were comparable to those in Table 2). ●, Control; ■, with 1 mM furosemide.

0028-0836/80/290281-02$01.00

Table 2 K influx into human RBC in the presence of ouabain

External medium	Experiment 1 K influx (tracer ^{42}K) (μEquiv per ml cells per h) Control	 With furosemide	Experiment 2 K influx (tracer ^{86}Rb) (μEquiv per ml cells per h) Control	 With furosemide
Complete	0.83 ± 0.04	0.26 ± 0.00	0.99 ± 0.00	0.25 ± 0.00
30 mM [Cl]	0.36 ± 0.01	0.25 ± 0.02	0.36 ± 0.05	0.29 ± 0.01
Complete + phloretin	0.46 ± 0.04	0.24 ± 0.03	0.64 ± 0.01	0.24 ± 0.00
30 mM [Cl] + phloretin	—	—	0.28 ± 0.01	0.24 ± 0.02

K influx into outdated human RBC was measured as described elsewhere[1–5] in the same conditions (and with the same changes) as those given in Table 1; the concentration of phloretin used was 0.1 mM. The results shown are the mean of three determinations (± s.d.).

sulphate or acetate: bicarbonate raised both the furosemide-sensitive and furosemide-insensitive components of K influx. These new observations on cation and anion affinities fit the previous findings[2,3,6,8]. It was also shown that passive K influx was half-maximally inhibited by 5×10^{-6} M furosemide.

Three other sets of results should be mentioned. First, experiments on fresh cells: here, the effects of furosemide and $[Cl]_0$ reduction on Na efflux were the same but K_0 had no effect (giving another reason why this flux has not been seen before). Second, experiments with phloretin: this drug reduced, but did not abolish, the K_0- and Cl_0-dependent Na efflux and likewise for K influx (Table 2). Moreover, furosemide and phloretin together inhibited no more than furosemide alone. Evidently, the co-transport system is the same as the phloretin- and furosemide-sensitive (Na-Li) counter-transport system identified in RBC by Tosteson and co-workers[9]. Third, there is the extensive work by Wieth on anion and cation effects on passive fluxes in RBC[10,11]; some of his results, for example, an increase in Na influx in 120 mM nitrate, seem to conflict with mine. The most likely explanation for these discrepancies is that his media contained Ca, Mg and phosphate, all of which may alter the results (see above) as well as bicarbonate, which alters passive permeability too[10].

(Na + K) co-transport[6] is clearly affected by chloride but direct evidence for Cl^- transport by the same system in RBC is lacking. On the other hand, furosemide-sensitive co-transport (or counter-transport) for each pair of ions has been found in several tissues and often these are invoked to explain ion distributions that do not seem to be in equilibrium[6–9,12–14]. Is it reasonable to speculate that some of these share the same pathway? Certainly, this view would be consistent with the idea that 'dissipative' fluxes may be coupled to uphill movements of another species[15].

I thank Mrs C. J. Hall for technical assistance, the Scottish Hospitals Endowments Research Trust for financial support and Hoechst UK Ltd for the gift of furosemide.

Note added in proof: A recent, independent study by Dunham *et al.*[17] also bears on the chloride dependence of furosemide-sensitive fluxes.

Schnittspahnstrasse 10, D 6100 Darmstadt, FRG

Martin G. Peter

Institut für Organische Chemie und Biochemie, Rheinische Friedrich-Wilhelms-Universität Bonn, Gerhard-Domagk-Strasse 1, D 5300 Bonn, FRG

Insect juvenile hormones (JH) maintain larval characteristics of insects during growth and development. At high JH titres the larval hypodermis is programmed to secrete larval cuticle in the following moult[1]. Generally, the molecular events preceding the response of a target cell to a hormonal stimulus involve binding of the hormone to specific receptor molecules. There are little data available on the primary mechanism of action of JH at the molecular level. We have demonstrated the specific uptake and retention of JH-I in the cytosol of larval *Drosophila hydei* integument *in vitro* (G.K. and H.E., in preparation). We now report the discovery of high-affinity, high-specificity JH-binding principles that exhibit characteristic properties of hormone receptors, in the cytosol of early third instar *D. hydei* larval integument.

Because it has been established that receptors for steroid hormones in vertebrates[2] and invertebrates, especially the fruitfly *Drosophila*[3,4] and the crayfish *Orconectes*[5], exist in the cytosol of target cells in only very low concentrations, we started our search for receptors of the non-steroid JH using competition experiments with standard techniques. A large excess of nonradioactive racemic (2*E*,6*E*)-10,11-*cis*-JH-I was competed with either racemic or optically pure preparations of JH-I (ref. 6) labelled with tritium at high specific activity. The results are shown in Fig. 1: the presence of competible (specific) JH-I binding sites becomes apparent from the competition curves for both racemic and optically active preparations of radiolabelled JH-I. However, remarkably different results were obtained; first, the enantiomerically pure, naturally occurring (10*R*,11*S*)-JH-I is bound to cytosol

Table 1 Competitive displacement of [*methoxy*-^{3}H](10*R*,11*S*)-JH-I from partially purified high-affinity JH-binding sites by enantiomerically pure (10*R*,11*S*)-JH-I and racemic JH-I, respectively

Competitor (ng per test tube)	% Displacement of [*methoxy*-^{3}H](10*R*,11*S*)-JH-I by (10*R*,11*S*)-JH-I	 Racemic JH-I
0.4	24.7	1.7
1.3	48.8	10.0
9.1	54.8	20.9

High-affinity JH-binding sites were prepared by gel filtration of cytosol through Sepharose 6-B, equilibrated with TMG-buffer, *p*H 7.2, at 0 °C. The specific JH-binding sites were contaminated with nonspecific JH-binding sites. 8,600 c.p.m. [*methoxy*-^{3}H](10*R*,11*S*)-JH-I (0.32 ng per test tube = 1.1 nM) were incubated for 1 h at 4 °C with the indicated concentrations of (10*R*,11*S*)-JH-I or racemic JH-I. Bound radioactivity was measured in 100-μl aliquots by the charcoal adsorption technique. The enantiomerically pure (10*R*,11*S*)-JH-I was extracted from 3–4 day old *Hyalophora cecropia* accessory glands. The purification method of extracts includes low temperature precipitation of lipids, TLC on silica gel, chromatography on Sephadex LH-20, and HPLC on LiChrosorb Si 60 and Si 100. Purity was controlled by analytical HPLC on LiChrosorb Si 100.

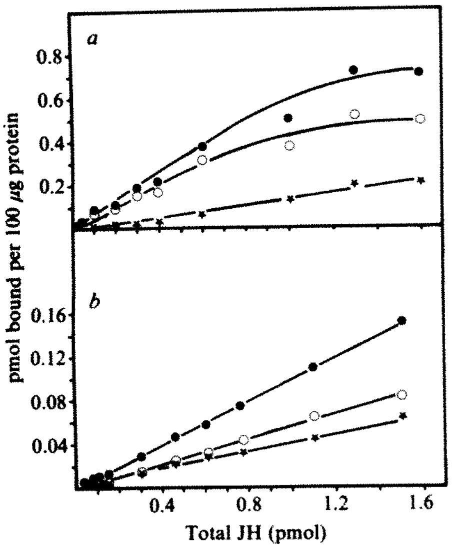

Fig. 1 Binding of *a*, enantiomerically pure [*methoxy*-^{3}H] (10*R*,11*S*)-JH-I (specific activity ~58 Ci mmol^{-1} (ref. 6)) and *b*, racemic [10-^{3}H]-JH-I (specific activity 11.5 Ci mmol^{-1}, NEN) to cytosol components. Larval integuments from early third instar larvae (120 h) were prepared and homogenized as described elsewhere[14]. Cytosol (120,000*g* supernatant) was prepared in TMG-buffer, *p*H 7.2, consisting of 10 mM Tris(hydroxy-methyl)-aminomethane, 15 mM β-mercaptoethanol, 20% glycerol, 1 mM EDTA, 50 mM KCl (all from Merck, Darmstadt), and 0.43 mM Trasylol (Bayer). JH metabolism was inhibited with 1 mM *p*-hydroxymercuribenzoate (Serva)[14]. Samples (100 μl) (containing 80–120 μg protein as determined in aliquots by the Lowry method[15]) of the cytosol were equilibrated for 30 min at 4 °C with increasing concentrations of [*methoxy*-^{3}H](10*R*,11*S*)-JH-I (0.02–1.6 pmol per 100 μl sample) or racemic [10-^{3}H]JH-I (0.04–1.5 pmol per 100 μl sample) in the absence (●) and presence (★) of a 100-fold excess of unlabelled racemic JH-I (Eco-Control), respectively. Bound and free radioactivity was separated by the charcoal adsorption technique with 0.42% dextran-coated charcoal (Serva)[8]. 100 μl of the supernatant (bound radioactivity) were measured by liquid scintillation counting using Aqualuma (Baker) as scintillation cocktail. The means of two duplicates, normalized on the basis of 100 μg cytosol protein are plotted. Specific binding (○) was considered as difference of total binding (●) and nonspecific binding (★).

constituents with a higher affinity than the racemic JH-I, even if the possibility is considered that 50% of the latter, represented by the (10*S*,11*R*) enantiomer, which does not occur naturally, is not bound at all. Second, in the concentration range tested, only the tritiated (10*R*,11*S*) enantiomer seems to be able to saturate the specific JH binding sites of the cytosol completely. It may be important to consider that with 1.6 pmol JH-I per test tube the limit of solubility is nearly reached in our buffer system on addition of the excess unlabelled JH-I. Third, the ratio of specific to nonspecific JH binding sites seems to depend on the optical purity of the hormone tested. Using tritiated (10*R*,11*S*)-JH-I it is 2.5, whereas it is only 1.5 using tritiated racemic JH-I.

Equilibrium dissociation constants (K_D) of JH binding sites were first determined in equilibrium conditions. Figure 2 shows the Scatchard[7] plots of binding data obtained with [*methoxy*-^{3}H](10*R*,11*S*)-JH-I and with racemic [10-^{3}H]JH-I. Increasing concentrations of the enantiomerically pure tritiated (10*R*,11*S*)-JH-I reveal the presence of two binding components with different affinities for the JH-I molecule. The apparent equilibrium dissociation constant (K_{De}) for the high-affinity JH-binding sites is 3.6×10^{-9} M. Similar equilibrium dissociation constants have been described for the macromolecular binding sites for ecdysteroids in *D. melanogaster* imaginal disks[3] and K_c cell lines[4]. The second JH-binding component exhibits a much lower affinity for JH-I ($K_{De}\approx10^{-7}$–10^{-6} M). Normalizing the data on the basis of protein content in the cytosol and correcting for low-affinity binding sites, a concentration of 7.7 pmol per mg cytosol protein is calculated for the free high-affinity JH-binding sites. With tritiated racemic JH-I (Fig. 2, inset), four JH-binding components are detectable. One of them shows a similar K_{De} value (4×10^{-9} M) to the high-affinity binding sites, detected with the enantiomerically pure JH-I. The additional binding components show apparent K_{De} values of 2×10^{-7} M, 8×10^{-7} M, and 10^{-5} M, with one of them ($K_{De}=2\times10^{-7}$ M) corresponding well to the haemolymph carrier protein ($K_{De}=1\times10^{-7}$ M)[8]. As it is essential to clarify whether this component results from contamination of the tissue preparation with haemolymph or whether it truly represents an intracellular constituent, we injected third instar larvae with ^{14}C-inulin solution. Following preparation of integuments 30 min after injection, the amount of label present was 0.65% of the total administered. Taking the concentration of the free JH-carrier protein into account[8], it is thus established that less than 4% of the 2×10^{-7} M JH-binding component found in the cytosol preparation results from contamination with haemolymph. It is therefore of interest first to isolate and characterize this JH-binding component for comparative studies with the haemolymph JH-carrier protein, and second, to investigate the possible role of the JH-carrier protein in the process of JH uptake into target tissues. An interesting analogy might be represented in this context by the mechanism of uptake of the diterpenoids retinol and retinoic acid in vertebrate target tissues[9].

An additional method was applied to obtain K_D values by measuring association and dissociation kinetics at 4 °C, using racemic [10-^{3}H]JH-I. The association of JH-I with cytosol constituents, shown in Fig. 3, follows second-order kinetics. Equilibrium between association and dissociation is reached after 30 min. Transformation of binding data into linear form (Fig. 3, inset) yields the association rate constant (k_{+1}) for total JH-binding sites. From the slope of the straight line, a k_{+1} of 2×10^6 M$^{-1}\times$min^{-1} is calculated. After reaching equilibrium the cytosol was chased with a 500-fold excess of non-labelled racemic JH-I. At appropriate times, bound radioactivity was measured in cytosol aliquots. From those data (not shown) a half-life time of approximatively 8 h at 4 °C for the hormone–macromolecule complex and a dissociation rate constant (k_{-1}) of 6.5×10^{-4} min^{-1} was calculated. The kinetic data are not impaired by a measurable loss of binding activity during the incubation period, due to the pronounced stability of the competible JH-binding sites at low temperatures; even after maintaining the cytosol for 2 days in

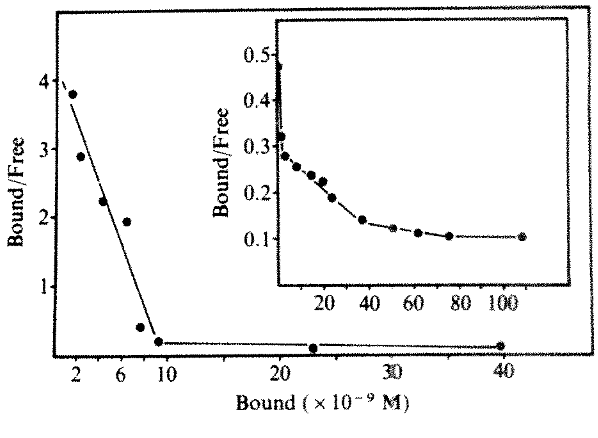

Fig. 2 Scatchard[7] analysis of ^{3}H-JH-I binding to cytosol components. Samples (100 μl) of larval integument cytosol, prepared as in Fig. 1, were equilibrated for 30 min at 4 °C with increasing concentrations of [*methoxy*-^{3}H](10*R*,11*S*)-JH-I (2–300 nM) or racemic [10-^{3}H]JH-I (1–1,100 nM) (inset), respectively. Bound radioactivity was measured as in Fig. 1. Each point represents the mean of duplicate experiments. Repeat experiments gave similar results.

ice, no change in binding behaviour was detectable. From the kinetic data an equilibrium dissociation constant (k_{-1}/k_{+1} $= K_D$) of 3.2×10^{-10} M results for the JH-binding sites, which is one order of magnitude lower than that obtained from the equilibrium binding data. Such differences are not uncommon in studies with protein–ligand complexes[10]. In any case, the K_D values obtained from both kinetic and equilibrium data clearly prove the presence of high-affinity JH-binding sites in the cytosol of *D. hydei* integument.

We do not know the biological significance of JH-binding sites showing different affinities for the JH molecule. We believe that the high-affinity binding sites might serve as JH receptors in the cytosol, comparable to those described for steroid hormones. Further support for this assumption is presented by experimental approaches towards this binding component. A molecule serving as JH receptor should meet the following requirements:

(1) receptors must be macromolecules. Gel filtration of crude cytosol preparations on Sephadex G-25 and on Sepharose 6-B, equilibrated with TMG-buffer, pH 7.2, without glycerol, revealed the macromolecular nature of specific JH-binding sites. Heating the macromolecular cytosol fractions for 10 min at 60 °C completely destroys the competible binding activity. (2) Receptors must show a high specificity for the natural hormone. The potential of some JH homologues and analogues to compete with [*methoxy*-^{3}H](10*R*,11*S*)-JH-I and racemic [10-^{3}H]JH-I for JH-binding sites was studied with crude cytosol. Among the compounds tested, racemic JH-I and JH-III were the most effective competitors of [*methoxy*-^{3}H]-(10*R*,11*S*)-JH-1 and racemic [10-^{3}H]JH-I bound to cytosol components (Fig. 4). The capacity to compete with the binding of [*methoxy*-^{3}H](10*R*,11*S*)-JH-I decreases in the following order: JH-I > JH-III > ethyl ester analogue of JH-III ≫ methyl farnesoate > ZR515. The sequence of competition efficiency with [10-^{3}H]JH-I is: JH-I ≈ JH-III > ethyl ester analogue of JH-III ≫ ZR515 > methyl farnesoate. Alterations in the structure of the JH-III molecule (the absence of the epoxy group as in methyl farnesoate or the presence of a ethyl ester group instead of a methyl ester group) markedly reduce the competing efficiency. It is of interest that the highly potent insect growth regulator ZR515, which has been used in pest control[11], indeed competes only very poorly with the JH-binding sites.

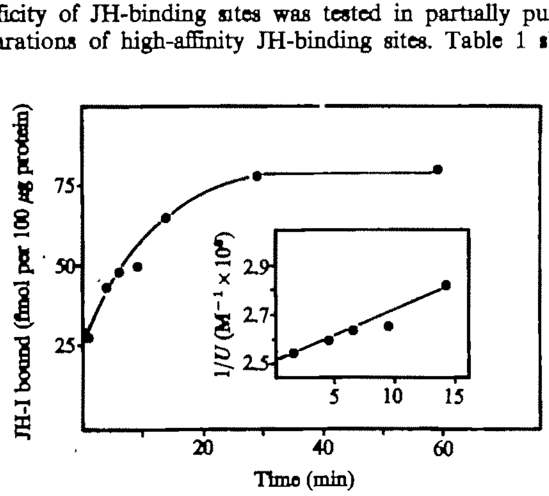

Fig. 3 Association kinetics of racemic [10-^{3}H]JH-I binding to cytosol components. Samples (100 µl) of larval integument cytosol, prepared as in Fig. 1, were incubated with 4 nM racemic [10-^{3}H]JH-I at 4 °C for the incubation periods indicated and bound radioactivity was measured as stated above. The means of two duplicates, normalized on the basis of 100 µg protein, are plotted. Inset, the inverse of unbound hormone concentration (1/*U*) is plotted as a function of time. The association rate constant (k_{+1}) for total JH-I binding is calculated from the slope of the straight line.

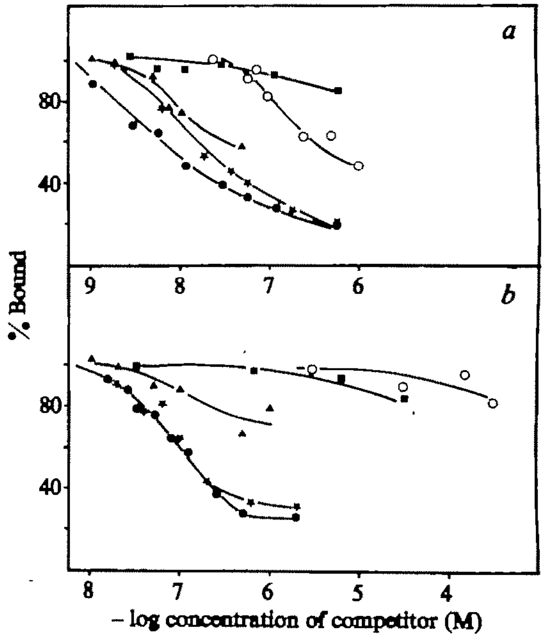

Fig. 4 Specificity of JH-binding sites in the cytosol of early third instar larvae integument. Samples (100 µl) of the cytosol, prepared as in Fig. 1, were equilibrated for 30 min at 4 °C with: *a*, 1.1 nM [*methoxy*-^{3}H](10*R*,11*S*)-JH-I (8,600 c.p.m. specific activity ~70 Ci mmol^{-1}) or *b*, 6.5 nM racemic [10-^{3}H]JH-I (8,600 c.p.m., specific activity 11.5 Ci mmol^{-1}) and increasing concentrations of competitors. Bound radioactivity was measured as stated above. Each point represents the mean of two to four duplicates. Tritiated JHs and unlabelled competitors were purified by HPLC on Porasil columns (Waters Associates) with *n*-hexane/8% ethyl acetate or 8% diethylether as solvent system and/or by TLC on silica gel plates with benzene/ethyl acetate (7:1). ZR515 (Zoecon) was 96.8% pure. ●, JH-I (methyl-2*E*,6*E*-*cis*-3,11-dimethyl-7-ethyl-10,11-epoxy-2,6-tridecadienoate) ★, JH-III (methyl-2*E*,6*E*-3,7,11-trimethyl-10,11-epoxy-2,6-dodecadienoate), ▲, (JH-III-E, ethyl-2*E*,6*E*-3,7,11-trimethyl-10,11-epoxy-2,6-dodecadienoate (a gift of H. Rembold, MPI f. Biochemie, Martinsried)); ○, FME (methyl-2*E*/*Z*,6*E*/*Z*-3,7,11-trimethyl-2,6,10-tridecadienoate), ■, ZR515, (isopropyl-2*E*,4*E*-11-methoxy-3,7,11-trimethyl-2,4-dodecadienoate).

Enantioselectivity as another means of determining the specificity of JH-binding sites was tested in partially purified preparations of high-affinity JH-binding sites. Table 1 shows that optically pure unlabelled (10*R*,11*S*)-JH-I competes with binding of [*methoxy*-^{3}H](10*R*,11*S*)-JH-I better than the racemic unlabelled JH-I, thus demonstrating enantioselective JH binding to the high-affinity JH-binding sites. Similar results have been reported previously for JH-specific haemolyph carrier proteins of *Manduca sexta*[12] and *Locusta migratoria*[13]. Surprisingly, especially at low competitor concentrations the unlabelled naturally occurring (10*R*,11*S*) enantiomer competes with the tritiated (10*R*,11*S*) enantiomer much better than the theoretically expected factor 2, when compared with the racemate. Considering only the data of Fig. 1, it may be suggested that the specific activity of the two radioactive JH-I preparations would have to be determined more carefully. This point, however, is of minor importance in the competitive binding studies depicted in Table 1. Clearly, there is a difference in binding behaviour of the racemate and the optically active preparation, the magnitude of which cannot be explained with our rationale on simple stereochemical arguments. A factor of 3 has been observed for the difference of binding of racemic and optically active JH-III preparations to the JH-carrier protein from larval *M. sexta* haemolymph[12]. Furthermore, in the *Galleria* bioassay, (10*R*)-JH-III is about three times more active than the racemate[12]. Due to the lack of more conclusive data, we have to consider the possibility that presently unknown effects govern the binding of radiolabelled JHs to their receptors.

The experiments performed so far present unequivocal evidence that high-affinity, high-specificity receptor-type JH-I binding sites are present in the cytosol of larval *D. hydei* integument. According to the general concept of hormone action, further work should analyse the interaction of these binding sites with other cellular components (nuclei) in order to investigate their physiological significance in more detail.

Molecular heterogeneity of benzodiazepine receptors

Werner Sieghart & Manfred Karobath

Department of Biochemical Psychiatry, University of Vienna,
Lazarettgasse 14, A-1090 Vienna, Austria

Benzodiazepines exhibit reversible, stereospecific high affinity binding to mammalian brain membranes, and the respective binding sites for ^{3}H-flunitrazepam represent pharmacologically and clinically relevant receptors for benzodiazepines[1–3]. Recently it has been demonstrated that reversibly bound ^{3}H-flunitrazepam becomes irreversibly attached to a specific membrane protein with apparent molecular weight of 50,000 when incubations were performed in the presence of UV light[4,5]. Irreversible binding of ^{3}H-flunitrazepam to this protein had pharmacological properties similar to reversible benzodiazepine receptor binding, indicating that ^{3}H-flunitrazepam is a photoaffinity label for the benzodiazepine receptor[5]. Using irreversible binding of ^{3}H-flunitrazepam and subsequent electrophoretic separation of the labelled proteins in SDS-gels followed by fluorography[6], we found that in hippocampus and several other brain regions at least two different types of benzodiazepine receptors exist. Each seems to be associated with a γ-aminobutyric acid (GABA) receptor.

Membranes from several rat brain regions were incubated with 10 nM ^{3}H-flunitrazepam at 0 °C for 90 min, and the samples were then irradiated with UV light for 10 min. Membranes were collected by centrifugation, dissolved in SDS and subjected to SDS-polyacrylamide gel electrophoresis and fluorography.

^{3}H-flunitrazepam irreversibly binds to a single protein band with an apparent molecular weight of 51,000 (P_{51}) in cerebellum (Fig. 1). Similarly, most of the ^{3}H-radioactivity bound to membranes from other brain regions is associated with a protein band with the same apparent molecular weight. The extremely weak labelling of this protein band in spinal cord agrees with the very low specific reversible binding (data not shown) of ^{3}H-flunitrazepam to membranes from this tissue. Thus, P_{51} seems to be identical to the labelled benzodiazepine receptor described previously[5]. However, in other brain regions in addition to P_{51} several other protein bands with apparent molecular weights of 53,000 (P_{53}), 55,000 (P_{55}) and 59,000 (P_{59}) are labelled with variable intensity. The most prominent of these additional bands is P_{55} which is most highly labelled in hippocampal membranes.

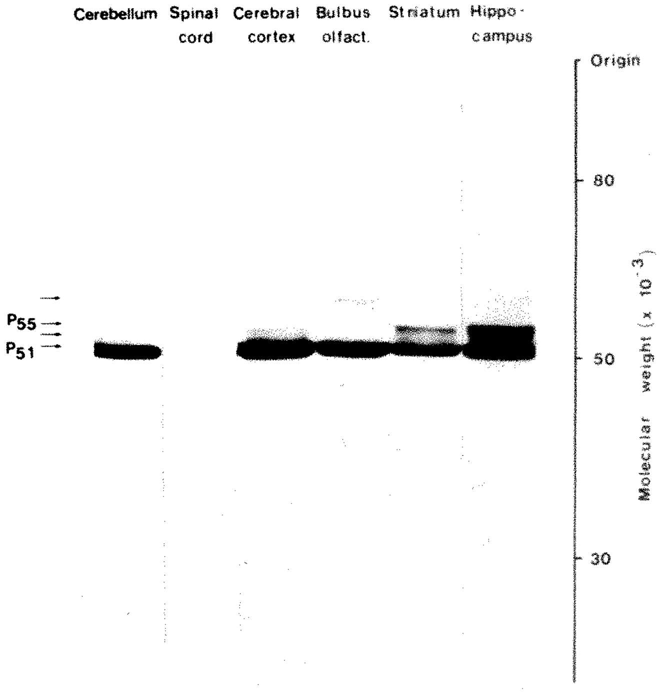

Fig. 1 Fluorography illustrating irreversible ^{3}H-flunitrazepam binding to membrane proteins from several rat brain regions. Tissues from several rat brain regions were homogenized with an Ultra Turrax for 30 s in 50 vol of 50 mM Tris–citrate buffer, *p*H 7.1, and centrifuged for 10 min at 48,000*g*. Pellets were washed four times by resuspension and recentrifugation in the same volume of buffer and stored at −20 °C for at least 18 h. After thawing, aliquots of membranes derived from 6 mg tissue wet weight were incubated with 10 nM ^{3}H-flunitrazepam (84.3 Ci mmol^{-1}, NEN) in a solution containing 50 mM Tris–citrate buffer, *p*H 7.1, and 150 mM NaCl (ref. 9). Incubations were performed at 0 °C for 90 min and the samples were then irradiated with UV light[5] for 10 min. Membranes were centrifuged at 48,000 g for 10 min, resuspended in 100 µl H_2O and 50 µl SDS stop solution (10% SDS (w/v), Tris–HCl 100 mM, *p*H 7.4, β-mercaptoethanol 5 mM, sucrose 0.1 g ml^{-1} and bromophenol blue tracking dye 0.02 mg ml^{-1}) and placed in a boiling water bath for 5 min. Electrophoresis on 10% SDS-polyacrylamide slab gels and protein staining of the gels was performed as described previously[10]. After treatment with PPO, gels were dried and subjected to fluorography at −70 °C on Kodak X-Omat R film[6] for 6 days. All radioactive bands disappeared after incubation of the samples with pronase but not after three extractions with chloroform–methanol (3:1), and thus represent proteins. The apparent molecular weights of the labelled protein bands, indicated by the arrows (59,000: P_{59}; 55,000: P_{55}; 53,000; P_{53} and 51,000: P_{51}) were determined by calibrating the gel with standard proteins of known molecular weight. The pattern of bound radioactivity was unchanged in cerebellar or hippocampal membranes isolated and labelled in the presence of the protease inhibitor phenylmethylsulphonyl-fluoride (PMSF, 100 µM). Furthermore, co-homogenization of cerebellum and hippocampus and irreversible binding of ^{3}H-flunitrazepam to the resulting mixed membranes revealed a pattern of labelled protein bands which was additive and did not show any enhanced degradation of the hippocampal bands. This indicates that the heterogeneity of ^{3}H-flunitrazepam binding proteins cannot be explained by regional differences in the degradation of a single protein with higher molecular weight. As the efficiency of labelling of the different protein bands is not necessarily identical, no attempt was made to estimate the quantitative contribution of the various bands to irreversible benzodiazepine receptor binding.

To characterize the pharmacological properties of irreversible ^{3}H-flunitrazepam binding to P_{51} and P_{55}, membranes from cerebellum and hippocampus were

Table 1 Influence of GABA and CL 218 872 on reversible and irreversible binding of ^{3}H-flunitrazepam to membranes or membrane proteins from rat cerebellum and hippocampus

	Specific ^{3}H-flunitrazepam binding (% of control)		
	Reversible	Irreversible	
		Membranes	Proteins
Cerebellum			
+ 10 μM GABA	200.7 ± 8.3	201.0 ± 0.2	251.7 ± 13.3
+ 1 μM CL 218 872	10.8 ± 1.5	16.9 ± 0.7	14.3 ± 0.4
Hippocampus			
+ 10 μM GABA	211.1 ± 2.9	198.8 ± 11.4	211.7 ± 11.1
+ 1 μM CL 218 872	45.9 ± 4.2	47.7 ± 0.2	49.9 ± 3.1

Cerebellar or hippocampal membranes were incubated with 0.4 nM ^{3}H-flunitrazepam either without additions (control) or in the presence of 10 μM GABA, 1 μM CL 218 872 or 2 μM diazepam as described in legend to Fig. 1. For the estimation of reversible binding, samples were then rapidly filtered as described previously[9]. For the estimation of irreversible binding to membranes samples were irradiated for 10 min with UV light after the 90 min equilibration period. In these conditions, irreversible binding of ^{3}H-flunitrazepam to membranes was about 30% of reversible binding. Exposure to UV light for a longer time period resulted in a higher percentage of irreversible binding but did not yield additional labelled protein bands. In this experiment the short irradiation time was selected because longer irradiation times change the kinetic properties of irreversible binding. After irradiation, 2 μM diazepam was added and samples were incubated at 30 °C for 60 min to remove non-irreversibly bound ^{3}H-flunitrazepam from membranes. Samples were then filtered and bound radioactivity was estimated as described previously[9]. For the estimation of irreversible binding to proteins, samples were treated as described in the legend to Fig. 2. As separation of the hippocampal proteins was not sufficient to allow for separate quantitation of the proteins in the gel system used, the region in the gel containing P_{51} to P_{55} was identified by fluorography, cut out and oxidized with a Packard Model 306 sample oxidizer to recover ^{3}H-radioactivity for liquid scintillation counting. Nonspecific binding (estimated in the presence of 2 μM diazepam) was subtracted from total binding to yield specific binding. Results are expressed as per cent of control binding (mean ± s.e.m.; $n = 3$). Control binding given in d.p.m. per mg wet weight was 1,643 and 3,170 (reversible binding), 579 and 1,046 (irreversible binding to membranes), 264 and 533 (irreversible binding to proteins) for cerebellum and hippocampus, respectively.

investigated. As can be seen in Fig. 2, irreversible binding of ^{3}H-flunitrazepam to P_{51} in cerebellum and to P_{51} and P_{55} in hippocampus is completely inhibited by diazepam, a centrally active benzodiazepine. In contrast, binding to these proteins is not inhibited by Ro 5-4864, which selectively inhibits binding to peripheral benzodiazepine binding sites[7] (data not shown). Furthermore, irreversible binding of ^{3}H-flunitrazepam to P_{51} in cerebellum and to P_{51} and P_{55} in hippocampus is stimulated by 10 μM GABA to a similar extent as is found with reversible binding to membranes from cerebellum or hippocampus (Fig. 2, Table 1). This stimulation by GABA is bicuculline sensitive (Fig. 2) indicating that GABA exerts its stimulatory effects on the labelling of the protein bands by way of a GABA receptor. These results indicate that irreversible binding of ^{3}H-flunitrazepam to P_{51} as well as that to P_{55} is similar to reversible benzodiazepine receptor binding. Thus, in different brain regions different types of benzodiazepine receptors may occur which are modulated by GABA receptors.

A heterogeneity of benzodiazepine receptors has been suggested previously when reversible benzodiazepine receptor binding was investigated in the presence of CL 218 872 (ref. 8). This substance, a triazolopyridazine, has anxiolytic but only weak sedative properties[8]. In contrast to benzodiazepines it inhibits reversible benzodiazepine binding with K_i values and Hill coefficients which differ in various brain regions[8]. We therefore investigated a possible differential effect of CL 218 872 on the irreversible binding of ^{3}H-flunitrazepam to the different binding proteins. Figure 2 shows that CL 218 872 inhibits irreversible binding of ^{3}H-flunitrazepam to P_{51} more strongly than binding to P_{55}. Such a selective effect can account for the different quantitative inhibition by CL 218 872 of reversible[8] and irreversible binding of ^{3}H-flunitrazepam in cerebellum and hippocampus (Table 1). These results seem to indicate that P_{55} is or is part of a pharmacologically different type of benzodiazepine receptor which is unrelated to that which contains the P_{51} protein. Both of these receptors seem to be associated with a GABA receptor. It should be emphasised, however, that additional types of benzodiazepine receptors could exist since the role of P_{53} and P_{59} in benzodiazepine receptor binding has not yet been investigated. In addition, each labelled band could consist of more than one labelled protein which differ in structure and properties but not in apparent molecular weight.

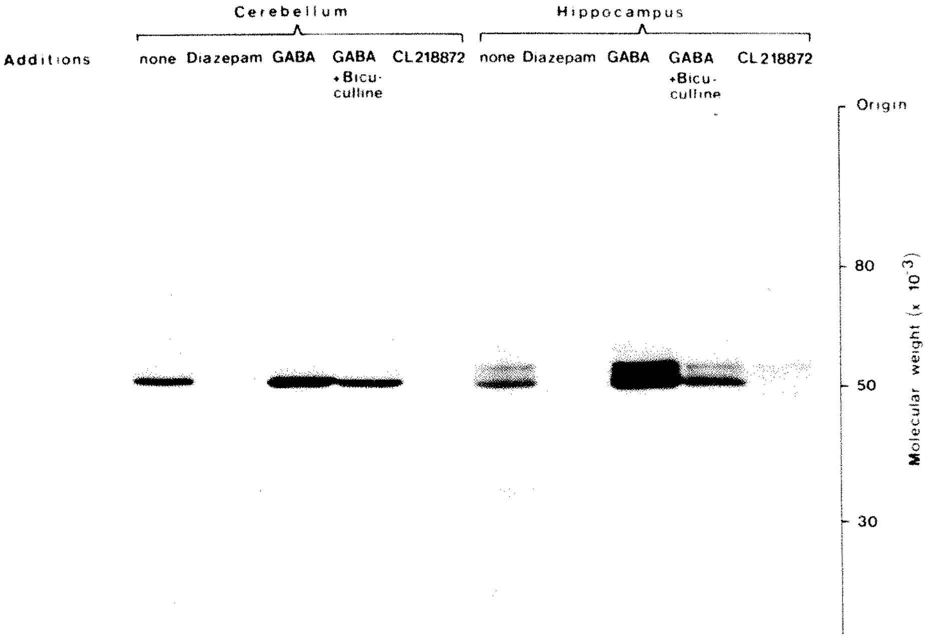

Fig. 2 Fluorography illustrating the influence of several drugs on irreversible ^{3}H-flunitrazepam binding to membrane proteins from cerebellum and hippocampus. Cerebellar or hippocampal membranes were incubated with 0.4 nM ^{3}H-flunitrazepam either without additions (lanes 1 and 6) or in the presence of 2 μM diazepam (lanes 2 and 7), 10 μM GABA (lanes 3 and 8), 10 μM GABA plus 10 μM bicuculline-methiodide (lanes 4 and 9), 1 μM CL 218 872 (lanes 5 and 10) or 1 μM Ro 5-4864 (experiment not shown). Incubation and irradiation of the samples as well as SDS-gel electrophoresis of the membrane proteins and fluorography of the gels was performed as described in the legend to Fig. 1.

Thus, this investigation indicates for the first time not only a pharmacological but also a molecular heterogeneity of benzodiazepine receptors. Using the present approach of irreversible labelling of benzodiazepine receptors followed by electrophoresis and fluorography, it seems possible to separate and isolate the different receptors. Furthermore, this technique can be used to develop new drugs which, in contrast to benzodiazepines, have selective effects on different types of benzodiazepine receptors.

Axoplasmic transport of muscarinic receptors

Pierre Laduron

Department of Biochemical Pharmacology, Janssen Pharmaceutica, B-2340 Beerse, Belgium

The reality of axoplasmic transport is widely accepted; various neurotransmitters[1–3], enzymes[2–4], labelled proteins[5] and peptides[6] are known to move rapidly along the axons of different nerve fibres. In the terminals of sympathetic nerves, noradrenaline release is controlled by various regulatory mechanisms which imply the occurrence of presynaptic receptors[7]. In this regard, there is considerable indirect physiological evidence for the existence of muscarinic cholinergic receptors in the sympathetic nerve endings[7–9]; the stimulation by acetylcholine of such presynaptic receptors elicits an inhibitory effect on noradrenaline release[8,9]. We now provide direct biochemical evidence for the occurrence in dog splenic nerve of muscarinic receptors which seem to move along the axon as suggested by their rapid accumulation on either side of a ligature.

Ligature experiments were carried out in mongrel dogs anaesthetized with pentobarbital (30 mg per kg, intravenously). Splenic nerve fibres were dissected from the splenic artery near the bifurcation, and a silk thread ligature was tied round the splenic nerve[10]. At 18 and 48 h, and 11 days after the operation, 1-cm segments of the nerve were removed, two above (proximal to) and below (distal to) the ligature. Coeliac ganglia were also removed and control splenic nerves were taken from unoperated dogs. After clearing connective tissue from the nerve fibres, the segments were weighed and then homogenized in 50 volumes of ice-cold distilled water by means of an ultraturrax. The samples were further diluted to 1:200 with 0.05 M phosphate buffer, *p*H 7.4. Binding assays were carried out using 2 ml of tissue preparation with 2 nM ^{3}H-dexetimide (specific activity 17.5 Ci mmol^{-1}, IRE Fleurus, Belgium) or 2 nM ^{3}H-levetimide (specific activity 19 Ci mmol^{-1}, Janssen) as described previously[20]. After incubation for 20 min at 37 °C, 3 ml of cold buffer was added and the samples were then rapidly filtered on Whatman GF/B glass filters. Stereospecific binding was taken as the difference between binding measured in the presence of 2×10^{-7} M levetimide (inactive enantiomer) and 2×10^{-7} M dexetimide (blank value).

To characterize the ^{3}H-dexetimide binding sites in dog splenic nerves, various concentrations of dexetimide and levetimide were tested *in vitro* using a total homogenate. Figure 1 shows that dexetimide displaced the labelled ligand in the nanomolar range whereas levetimide was only effective in a micromolar concentration. This indicates the stereospecific nature of the binding which represents 50% of the total binding. Table 1 gives the IC_{50} values for different compounds; atropine, an antimuscarinic drug which belongs to a different chemical class from dexetimide, also competed with ^{3}H-dexetimide in the nanomolar range. Moreover, there was a good correlation between the IC_{50} values of muscarinic antagonists, oxotremorine and levetimide, in dog splenic nerves and rat brain. As nicotine is not active, but antimuscarinic drugs and oxotremorine are, ^{3}H-dexetimide binds in dog splenic nerves to receptors which have the characteristics of the muscarinic receptor. Further control experiments were carried out using ^{3}H-levetimide as ligand; here, there was no stereospecific displacement and the value of the total binding corresponded to the blank values in the ^{3}H-dexetimide binding. From these data, we conclude that the ^{3}H-dexetimide binding sites in dog splenic nerves are of muscarinic nature.

Stereospecific ^{3}H-dexetimide binding was measured in the proximal and distal part of dog splenic nerve at different times after ligature. Figure 1*a* shows that 18 h after constriction, the segments close to the ligature, P_1 and D_1, revealed more than a twofold increase in binding sites as compared with control nerves. In contrast, segments located 1 cm more proximally (P_2) or more distally (D_2) to the ligature and samples of the coeliac ganglion did not differ significantly from the control nerves. This accumulation in P_1 and D_1, so near the ligature, was still more pronounced 48 h after the operation (Fig. 2*b*). At that time the increase in binding sites was more than five times higher than control values in the proximal as well as in the distal part of the splenic nerves. This suggests a bidirectional transport of muscarinic receptors along the axon.

In contrast, the accumulation of noradrenaline was only detectable in the proximal segment, indicating a unidirectional transport for the biogenic amine, and confirming our earlier finding[10]. Interestingly, the increase of noradrenaline in the P_1 segment was of the same order of magnitude as the increase in muscarinic receptors measured in the binding assay. Here again, control experiments were carried out using ^{3}H-levetimide as ligand; there was no increase in binding in the P_1 and D_1 segments even 48 h after ligature and again the total binding corresponded to the blank value of ^{3}H-dexetimide binding.

To assess the origin of muscarinic receptors in the splenic nerves, ^{3}H-dexetimide binding was assayed in proximal and

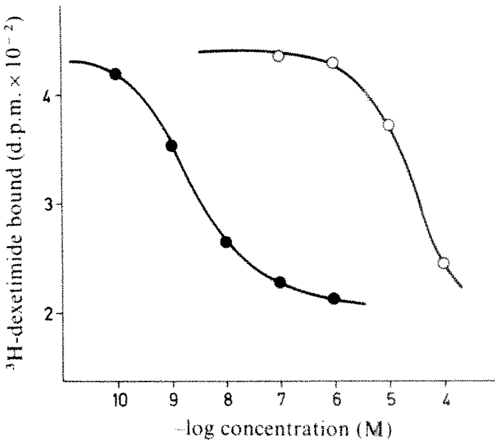

Fig. 1 Dose–response inhibition of dexetimide ((+)benzetimide) (●) and levetimide ((−)benzetimide) (○), expressed as −log concentration, in ^{3}H-dexetimide assay using a total homogenate from dog splenic nerves.

0028–0836/80/290287–02$01.00

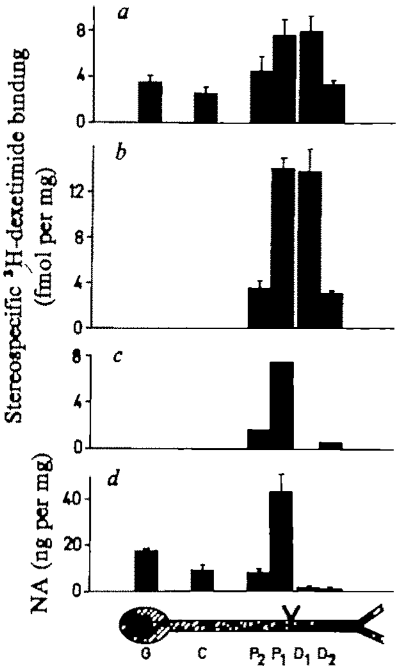

Fig. 2 Stereospecific ^{3}H-dexetimide binding and noradrenaline content in different segments of dog splenic nerves 18 h (*a*) 48 h (*b*, *d*) and 11 days (*c*) after ligature. Binding was assayed in duplicate; the results represent the mean (± s.e.m.) obtained from five or six animals except for *a* ($n=3$) and *d* ($n=1$). Noradrenaline was measured according to the method of Coyle and Henry[21] G = coeliac ganglion, C = control nerve from non-operated animals, P_1, P_2 and D_1, D_2 are, respectively, the proximal and distal part of ligated splenic nerves

distal segments 11 days after ligature Stereospecific binding sites were practically undetectable in the distal part, even in the segment closest to the constriction. In contrast, a clear-cut accumulation of binding sites remained detectable in the P_1 segment although to a lesser extent than that observed 48 h after the operation. This suggests that muscarinic receptors, like noradrenaline storage vesicles[1,10,11], originate from the perikarya of sympathetic neurones, in this case, in the coeliac ganglion

The above results provide biochemical evidence for the presence of muscarinic cholinergic receptors in sympathetic nerves, giving more support to the concept of presynaptic or prejunctional receptors. In the heart, a substantial fraction of muscarinic receptors have been identified biochemically at the presynaptic sites in the sympathetic nerve terminals[12].

The most interesting finding here is the rapid accumulation in dog splenic nerves of muscarinic receptors both above and below a ligature, suggesting a bidirectional axonal flow for such binding sites The fact that the rate of transport, about 1 mm h^{-1}, is practically the same as that previously found in similar conditions for noradrenaline storage vesicles, implies that muscarinic receptors are probably also associated with vesicle-like structures. Nevertheless, the rate of transport should be more precisely measured in smaller nerve pieces, this could provide a new approach to studying the turnover of receptors, as already reported for noradrenergic vesicles[13,14].

Table 1 Inhibition of stereospecific ^{3}H-dexetimide binding

	IC$_{50}$ (nM)	
	Dog splenic nerves	Rat striatum*
Dexetimide	2.2	1 4
Atropine	6 3	6.8
Oxotremorine	3,200	6,500
Levetimide	28,000	6,500
Nicotine	> 100,000	> 100,000

*The values were taken from refs 19 and 20

How these prejunctional receptors are transported along the axon remains unclear. However, the following sequence of events can be considered: synthesis of receptors like the proteins[15] and their association with subcellular organelles[11] in the perikarya; anterograde flow in the axon, at the terminals externalization of receptors by exocytosis, which makes the receptor available to ligand and thus functional, internalization by endocytosis (see ref 16), back to perikarya by retrograde axonal flow and recycling or degradation[17]. If this is the correct process, most of the binding sites in the perikarya, in the axon and partly in the nerve ending would be silent receptors. If such a view is transposed to the central nervous system, this could provide a plausible explanation for the very limited increase in binding sites in supersensitivity phenomena[18] when compared with the more pronounced pharmacological reactivity.

Evidence against presynaptic α-adrenoreceptor modulation of cardiac sympathetic transmission

James A. Angus & Paul I. Korner

Baker Medical Research Institute, Commercial Road, Prahran, Victoria, Australia 3181

In addition to its well known actions on postsynaptic adrenoreceptors, noradrenaline released at the sympathetic nerve endings is now believed to modulate subsequent transmitter release through its actions on presynaptic receptors[1-7]. Much evidence in support of this hypothesis has been obtained from overflow studies in which labelled noradrenaline and metabolites released into the bathing solution are used as an assay of transmitter release. According to Langer[4] and Rand, McCulloch and Story[6], evidence to favour the existence of such a presynaptic mechanism includes the demonstration that α-adrenoreceptor antagonists produce enhanced transmitter overflow in steady-state conditions of sympathetic stimulation. They also suggest that α-adrenoreceptor-mediated potentiation of transmitter release would not be expected in response to a

0028–0836/80/290288–04$01 00

single pulse, as a threshold concentration of released noradrenaline is required to activate presynaptic inhibition of further release. In the myocardium both conditions have been obtained in the presence of phenoxybenzamine[5,6]. Surprisingly, although phentolamine is also a potent α-adrenoreceptor antagonist, the potentiation of transmitter release was less than the increase due to phenoxybenzamine[6]. Studies of transmitter overflow have generally been made with supraphysiological sympathetic stimulation of 5 Hz continuously for 30 s or 4 Hz for 60 s (refs 6, 7). We have used more closely physiological stimulation parameters delivered only during the atrial refractory period. We have now shown that phenoxybenzamine markedly potentiates the chronotropic response to a single pulse and also responses up to maximum stimuli. By contrast, phentolamine and yohimbine were totally without effect even at high concentration. The action of phenoxybenzamine was largely accounted for by its effect on uptake blockade. Taken together, our studies provide evidence against a physiological role of presynaptic α-adrenoreceptors in the heart

Guinea pig right atria were placed horizontally in Krebs' solution (composition in mM: Na^+ 144, K^+ 5.9, Ca^{2+} 2.5, Mg^{2+} 1.2, HCO_3^- 25, Cl^- 128.7, $H_2PO_4^-$ 1.2, SO_4^{2-} 1.2, EDTA 0.04, glucose 11) in a 50-ml organ bath at 37 °C with 1 µM atropine. Two Teflon-coated stainless steel wires, bared only at the tip, were placed on the surface of the atrium approximately 2 mm apart to record the surface electrogram. Following amplification, this signal was used to trigger a microprocessor-controlled period meter with an accuracy of better than 2 ms in the entire system. The cycle to cycle period (interval) was continuously displayed on a chart recorder. When required, intramural sympathetic nerve fibres were stimulated by applying square wave field pulses (2 ms duration, 100 mA) across the atrium from a pair of platinum electrodes. Field pulses were delivered from a Grass S88 stimulator following a 5-ms delay after the upstroke of the atrial electrogram signal (during the refractory period) to prevent arrhythmia[8]. Either a single field pulse or a train of four field pulses (one pulse following each of four consecutive atrial electrograms) were used as stimuli.

In control conditions, these low stimulation frequencies produced a marked tachycardia, that is, a decrease in the succeeding atrial period as measured from the P–P intervals of the atrial electrogram. After a single field pulse applied during the refractory period, atrial period fell by 30 ms, with the fall beginning at the next interval. The tachycardia then declined over the next 20 s. The mechanism underlying the time course of response is assumed to depend on the concentration of released noradrenaline in the synaptic cleft. The transmitter will activate postsynaptic β-adrenoreceptors to increase both rate and force of contraction until the concentration falls below the threshold level necessary to activate these receptors. The mechanisms responsible for the lowering of the biophase noradrenaline are a 'neuronal uptake mechanism' (or uptake$_1$) and an extraneuronal mechanism (uptake$_2$)[9,10]. After four pulses the fall in atrial period was approximately 150 ms. Maximum fall in atrial period was 200–250 ms observed with

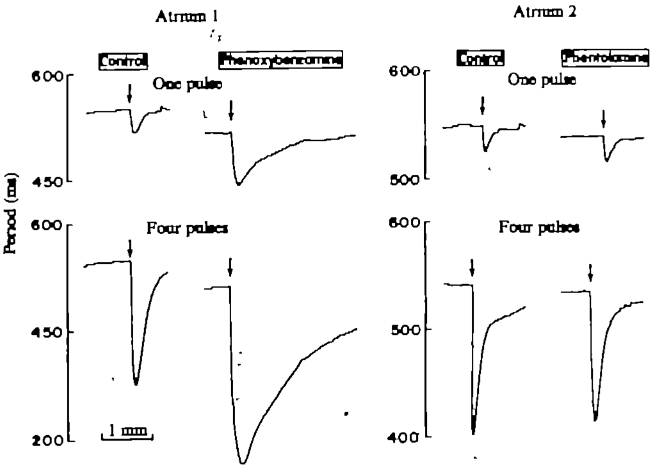

Fig. 1 Chart recordings of right atrial period from two tissues. Top: responses to sympathetic nerve stimulation effected by one square wave field pulse (2 ms duration, 100 mA) delivered during the refractory period in the presence of 1 µM atropine. Bottom: period responses to four field pulses delivered as a train of one pulse immediately after each of four spontaneous electrogram signals. Phenoxybenzamine (10 µM) was equilibrated with atrium 1 for 15 min followed by repeated washing for 30 min before restimulation. Phentolamine (10 µM) was left in contact with atrium 2 for 30 min before, and during, field stimulation. Both the peak fall in period and the duration of the tachycardia were significantly prolonged by phenoxybenzamine treatment but not by phentolamine.

Table 1 Effects of phenoxybenzamine, phentolamine, yohimbine and uptake block on the tachycardia response to sympathetic stimulation in guinea pig atria

Peak responses are the maximum fall in period (ms) following either a single pulse or a train of four pulses of square wave field stimulation (2 ms duration, 100 mA) delivered across the atrium by two platinum electrodes during the refractory period of spontaneous sino-atrial rhythm. Area responses are the integrated change in atrial period over the whole response, that is, until the atrial period returns to resting values. The chart record of period was integrated by weighing. Logarithmic units of area were used to obtain homoscedastic observations. Mean values for peak and area responses before and after drug treatment are given together with s.e.d. within atria for each comparison. P values are the level of significance (n is the number of atria in each treatment). Phenoxybenzamine was left in contact with the atria for 15 min followed by repeated washing for 30 min before further field stimulation. Phentolamine, yohimbine and uptake block (combination of desipramine 0.1 µM and 17β-oestradiol 5 µM) were equilibrated with the atria for 30 min and left in the bath during stimulation.

*Considering log (peak) to avoid heteroscedasticity the difference was significant $P < 0.01$.

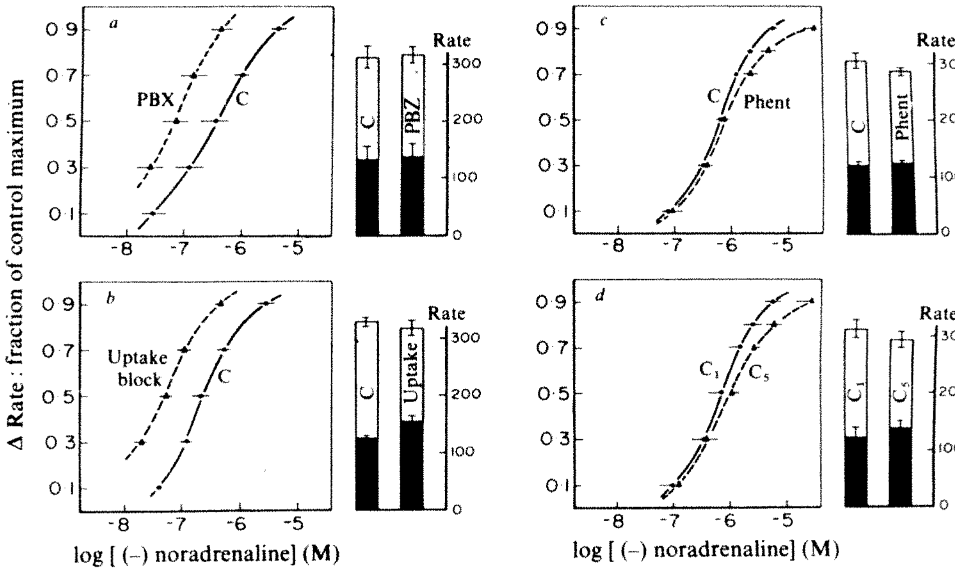

Fig. 2 Effect of phenoxybenzamine (PBX), phentolamine (Phent.) and uptake block to chronotropic response to exogenous (−)noradrenaline. Graphs: ●, first cumulative concentration–response curve to (−)noradrenaline; ▲, second curve after equilibration of test drug. For each atrium, curves were constructed by first expressing the change in atrial rate as a fraction of the maximum change obtained in the first curve. Mean ± s.e.m. values of log EC_{10}, EC_{30}, EC_{50}, EC_{70}, EC_{80} and EC_{90} values were determined from four atria. Histograms: black columns, resting atrial rate (beats min^{-1}) just before starting the noradrenaline curve; white columns, maximal atrial rate obtained with noradrenaline. Values are mean + 1 s.e.m. for four atria. *a*, Phenoxybenzamine (10 μM); 15 min equilibrium followed by 30 min washing before second curve. *b*, Uptake block; 30 min equilibration with 0.1 μM desipramine and 5 μM 17β-oestradiol before second curve. *c*, Phentolamine (10 μM), 30 min equilibration before curve. This curve was the fifth curve on each atrium; the previous curves were in the presence of 0, 0.3, 1 and 3 μM phentolamine and were similarly without significant effect on the noradrenaline responses. *d*, Control curves. C_1 refers to the first control curve and C_5 was the fifth curve to noradrenaline in each of four atria. Curves 2, 3 and 4 all lay between these two curves.

8–16 pulses. These findings indicate that the present method of atrial stimulation leads to immediate release of substantial amounts of sympathetic transmitter. Evidence that this transmitter was released from nerves was obtained by the observations that 0.1 μM tetrodotoxin completely blocked the response to one and two field pulses and almost abolished the response to four pulses without significantly altering resting atrial rate.

Pretreatment with phenoxybenzamine resulted in a marked potentiation in relation to the control response in both the peak and its duration after either one or four pulses (Table 1 and Fig. 1). If we assume that the tachycardia response is directly related to the synaptic cleft concentration of noradrenaline, the area under the atrial period response record will be a function of the concentration and duration of noradrenaline released by nerve stimulation. The peak responses to a single pulse doubled after phenoxybenzamine whereas the area increased by 2.4- and 4.9-fold after 3 and 10 μM, respectively (Table 1). In contrast, phentolamine, in concentrations that significantly antagonized α-adrenoreceptors in guinea pig aortic strips, did not increase the tachycardia response with respect to peak or duration to either one or four pulses, nor was there a significant depression of resting atrial period (Table 1 and Fig. 1). Yohimbine, which has been classified as being a more selective presynaptic α-adrenoreceptor antagonist than phentolamine[11], was also without significant effect on the response to sympathetic stimulation (Table 1).

Applying four field pulses within one refractory period (that is, four pulses over 40 ms equivalent to a frequency of sympethetic stimulation of ~100 Hz) decreased the atrial period by the same magnitude as four pulses delivered as one pulse following each atrial beat for four beats. However, phentolamine and yohimbine failed to potentiate the responses to either stimulation pattern. These findings contrast with some reports of an increase in the tachycardia response to sympathetic stimulation after phentolamine and yohimbine[12–15].

To explore the possibility that phenoxybenzamine potentiated the response to a single pulse by its well established property of uptake inhibition[9,16], we investigated the effect of a combination of desipramine and oestradiol, drugs classified as potent inhibitors of $uptake_1$ and $uptake_2$ (refs 17, 18). In the guinea pig heart the $uptake_2$ mechanism is of minor significance[19] and this was confirmed in the present study by the finding that desipramine alone potentiated the responses to field stimulation as much as did desipramine combined with oestradiol. The potentiation of response to a single pulse in the presence of the combination of the uptake blocking drugs was very similar to the potentiation observed following phenoxybenzamine (Table 1). Moreover, tachycardia responses to cumulative dose–response curves to exogenous noradrenaline were potentiated to a similar degree by phenoxybenzamine and uptake blockade (Fig. 2). By contrast, phentolamine at 0.3–10 μM had no significant effect on the resting atrial rate or the dose–response curves to noradrenaline (Fig. 2). Therefore, we conclude that uptake

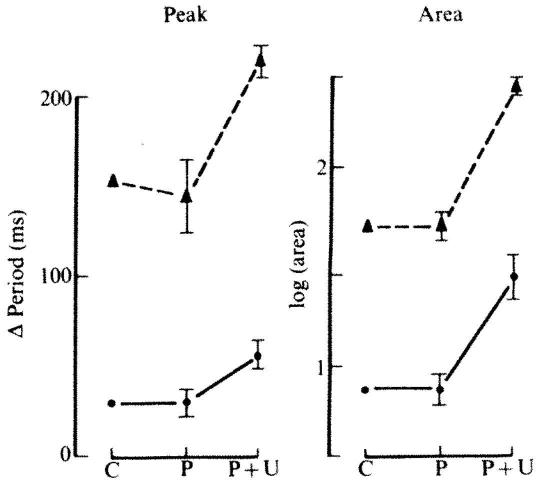

Fig. 3 Potentiation of right atrial period responses to sympathetic stimulation by uptake block in the presence of phentolamine. For each atrium responses were measured to one (●) and four (▲) field pulses in three conditions: (1) C, control, (2) P, in the presence of 10 μM phentolamine, and (3) P + U, in the presence of 10 μM phentolamine and uptake block (0.1 μM desipramine and 5 μM 17β-oestradiol). Points represent mean values from five atria; bars indicate ± 1 s.e.d. within atria between adjoining means. All values during P + U were significantly higher than either P or C ($P < 0.05$). Peak and area defined in Table 1 legend.

blockade is more likely to be the underlying mechanism of the phenoxybenzamine potentiation than α-adrenoreceptor antagonism.

The failure of phentolamine to enhance the chronotropic effect of sympathetic nerve stimulation despite a considerable increase in transmitter overflow has been previously observed[7,20]. However, Langer, Adler-Graschinsky and Giorgi[7] suggested that phentolamine had a veratramine-like direct depressant action on the sino-atrial node which (1) lowered the resting atrial rate, (2) attenuated the chronotropic response to exogenous noradrenaline and (3) prevented the tachycardia to sympathetic nerve stimulation. We can find no evidence for this depressant action of phentolamine on the resting atrial rate or on exogenous noradrenaline dose–response curves. Moreover, in the presence of a high phentolamine concentration (10 μM), uptake block treatment potentiated the response to one and four pulses of sympathetic stimulation to a similar degree to uptake block alone (Fig. 3). Similarly, pretreatment with 10 μM phenoxybenzamine in the presence of 10 μM phentolamine, still potentiated responses as before (area responses to one field pulse, log units: phentolamine 0.88, phenoxybenzamine 1.46, s.e.d. = 0.097, $t = 5.88$, $P < 0.01$, seven experiments).

In conclusion, our results indicate that phenoxybenzamine potentiates not only the response to a train of sympathetic nerve pulses but also markedly accentuates the effects of a single pulse. By contrast, the α-adrenoreceptor antagonists phentolamine and yohimbine did not potentiate the effects of either stimulus trains or single pulses. It seems likely that the potentiation produced by phenoxybenzamine was not due to its α-adrenoreceptor antagonist action but to its property of uptake block. This suggests that presynaptic α-adrenoreceptor modulation by synaptically released noradrenaline plays no part in cardiac sympathetic transmission, at any rate, at the physiological stimulus levels of the present experiments which were generally lower than those used in overflow studies.

We thank Mrs E. Anderson and Mr M. Lew for technical assistance and Mr M. Percy for the period meter. J.A.A. is a holder of an NH and MRC of Australia C.J. Martin Fellowship.

Open time of channels activated by binding of two distinct agonists

Alain Trautmann & Anne Feltz*

Laboratoire de Neurobiologie, Ecole Normale Supérieure 75230 Paris Cedex 05, France

At the frog endplate, acetylcholine (ACh) causes depolarization by opening synaptic channels, and it is generally assumed that more than one molecule must bind to open one channel. This interpretation, proposed to explain the sigmoidicity of the dose–response curve[1,2], also accounts for the potentiating effect of pipette-released ACh on the response to nerve-released ACh[3]. We have described a similar cross-potentiation between ACh and carbachol (CCh)[4,5]. The response to simultaneous application of these two agonists is larger than the sum of the responses to separate application, and we have assumed that this reflects the binding of both ACh and carbachol to individual receptor molecules. One approach to an understanding of the molecular basis of transmitter action is to study the mean time a channel remains open in its presence. Because this mean 'open time' depends on the nature of the agonist used to activate a given receptor, we have measured this parameter in order to understand better the mechanism underlying the cross-potentiation. We compared the 'open times' observed when the two agonists were applied separately with those obtained when both were applied together. In each case, when a 'faster' agonist (one inducing 'short' open times) and a 'slower' agonist (one inducing 'long' open times) are applied together, the channels opened by combined activation have a short mean open time, as if these were only controlled by the faster agonist.

The open time of a channel at the frog endplate (τ) can be measured directly (by single-channel recording[8]), or it can be estimated indirectly from the relaxation of the endplate current when displaced from equilibrium. Displacement can be spontaneous, appearing in the form of fluctuations of thermal origin around a mean, and in that case noise analysis is used[6]; it can be caused by a concentration jump, in which case the decay of the endplate current is measured[7]; or, as τ is voltage-dependent, it can be caused by voltage jumps[9–11]. The estimation of τ is effectively independent of the method used, at least at a low concentration of agonist. We used the last method, where τ is given by the time constant of relaxation of the agonist-induced current after an instantaneous voltage jump.

Experiments were carried out on the frog endplate at a low temperature (3–5 °C) to reduce the rate of desensitization[5,12]. Membrane potential was controlled by a conventional two-electrode voltage clamp on an endplate region located under Nomarski optics. Identical voltage jumps were performed before (control) and after application of various agonists. Pure agonist-induced current was obtained by subtracting from the current measured in the presence of the agonist (before, during and after the voltage step) the 'nonsynaptic' current measured during a control jump[9–11]. Figure 1*a* (top trace) shows the CCh-induced current obtained by such a subtraction. Before the jump, at −90 mV, the agonist induced a current of 20 nA. After hyperpolarization to −140 mV, the CCh-induced current first increased as expected from the change in driving force on the channels that were open before the jump. The current then relaxed towards a new steady level. When the membrane potential was returned to the initial holding potential, the CCh-induced current first decreased rapidly, then more slowly, eventually returning to the value measured before the voltage step.

A semilogarithmic plot of current against time (Fig. 1*b*) shows that after reaching the new voltage (−140 mV), the

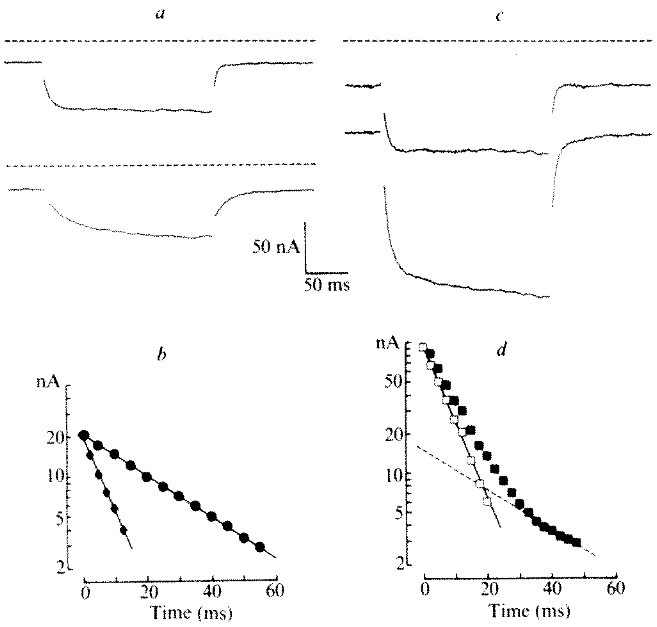

Fig. 1 Agonist-induced currents during a voltage jump lasting 205 ms from a −90-mV to a −140-mV holding potential. The voltage jump was performed before, then during agonist application. After subtraction of the control jump, the nonsynaptic contribution disappears, leaving the current flowing through the synaptic channels opened by the agonist. Each trace is an averaged signal on eight jumps. Dotted lines give the zero synaptic current. *a*, Current induced by the application of 10 μM CCh (top trace) and 37 nM SubCh (bottom trace). *b*, Semilog plot of the CCh-induced current (rhombs) and SubCh-induced current (circles) against time, after a jump at −140 mV. Both currents decay exponentially, with time constants of 7.6 ms and 27 ms respectively. *c*, The bottom trace shows the 'total current' resulting from the simultaneous application of 37 nM SubCh and 10 μM CCh, and the top trace shows the difference between the total current and the sum of the two currents given in *a*. *d*, Semilog plot of the total current (black squares) against time after a jump at −140 mV; the foot of the curve is fitted with an exponential (dotted line) of time constant 27 ms as in *b*. The difference between the total current and this slow component is given by the open squares, which can be fitted by an exponential with time constant 7.5 ms. The time constant of the 'difference' shown in *b*, top (semilog plot is not shown) is 5.7 ms. This figure is somehow shorter than the fast component, but this difference was not systematic in the various experiments (see text). The base line slopes slightly on all records; its time constants of several hundreds of ms are easily separable from the values we are studying. The perfusing medium was cooled at 3 °C to reduce desensitization. In the same line, a Ca-free Ringer was used, with the following composition (mM): NaCl, 115; KCl, 2; $MgCl_2$, 5; HEPES 2 mM and *p*H adjusted to 7.2. All data were recorded on a tape recorder Racal M4 and later analysed on a Hewlett Packard 9825A desk computer. Note the increase in noise level in *c* (compared with *a*): the phenomenon was recorded at a low gain (to avoid saturation on the tape), and reamplified later, with a resulting increase of the background noise from the tape.

current relaxed exponentially to a steady level, enabling us to estimate, at this potential, the mean open time of the channels controlled by CCh ($\tau_{\rm CCh}$).

Similar records obtained during the application of suberyldicholine (SubCh) show slower relaxations (Fig. 1*a*, bottom trace). In the voltage range studied, $\tau_{\rm CCh}$ and $\tau_{\rm SubCh}$ differ by a factor of 3–4, in good agreement with previous data[6,11]. Both values increase with hyperpolarization, and both double over a 50-mV range.

At the holding potential of −90 mV, separate applications of 10 μM CCh• and 37 nM SubCh resulted in an inward current of 20 nA and 25 nA, respectively. During simultaneous application of both agonists (10 μM CCh + 37 nM SubCh) cross-potentiation was observed: instead of the 45-nA current expected from purely additive effects, a total current of 87 nA developed. Moreover, when SubCh and CCh were applied together, the relaxation following a voltage jump was no longer exponential, but biphasic. The extra current produced by cross-potentiation was calculated by subtracting both the CCh-induced current and the SubCh-induced current shown in Fig. 1*a* from the agonist-induced current which developed during simultaneous application. Figure 1*c* (top trace) shows that this extra current relaxed along a single exponential with a time constant almost identical to that observed with CCh alone.

The subtraction of the two single-agonist relaxations from the double-agonist relaxation is justifiable only if the number of receptors bound by two molecules of a given agonist is the same when that agonist is applied alone and when it is applied in combination with the second agonist of the pair—a criterion that can be assumed to be met if the fraction of receptors activated by the agonist is small. In our experimental conditions, clearly only a small proportion of the receptors were activated, because the doses used induced a current of only 20 nA (10 μM CCh), whereas the current expected from activation of all the receptors (assuming a total of more than 10^7 receptors per endplate[13] and an elementary conductance of 25 pS[14]) is 1,000 times greater. Furthermore, because low concentrations of agonist and low temperatures were used, desensitization developed very slowly.

Given our experimental conditions, it thus seems possible to conclude that the receptor population was far from saturated and that desensitization was avoided, so that we could assume that the additional current seen with combined agonist application was due to the recruitment of a new group of receptors, each bound by one CCh and one SubCh molecule. Even if receptor saturation and desensitization were not completely avoided, neither of these factors would be expected to alter our principal finding—that the extra channels controlled by combined agonist application are opened for a short time.

The same conclusion as that drawn from subtracting the two relaxations can be reached directly from a semilog plot of the relaxation of the combined agonist-induced current against time (Fig. 1*d*). Two exponentials appear, with time constants the same as those obtained by separate application of the two agonists. Whereas the amplitude of the slow component remained equal to that obtained with SubCh alone, that of the fast component was four times larger than in the relaxation seen with CCh alone. This again suggests that the channels opened by combined application of SubCh and CCh behave as CCh-activated channels.

To investigate whether our observations were generally applicable, we looked at the characteristics of the channels during cross-potentiation between ACh and acetylthiocholine, SubCh, or CCh. These experiments were all performed after irreversible inactivation of acetylcholinesterase by *O*-ethyl-S_2-diisopropyl-amino-ethyl-methyl-phosphonothionate (MTP)[5]. In all cases, the agonist, which alone would have led to the shorter open time, $\tau_{\rm short}$ (so called faster agonist), seemed to determine the open time of the channels controlled by two agonists ($\tau_{\rm pot}$). In 12 experiments $\tau_{\rm pot}/\tau_{\rm short}$ was 1.08 ± 0.31 (± s.d.).

Our data thus suggest that the binding of a receptor molecule by two different agonists leads to channel opening for a time determined in most cases, if not always, by the faster of the two agonists. These results have to be taken into account in schemes describing normal channel activation. It has often been suggested that sequential binding of two agonist molecules is followed by isomerization of the receptor–channel complex and subsequent channel opening (see ref. 14 for a review). Our data are not easily interpreted with respect to such a model: if isomerization is the rate limiting step, it has to be assumed that for a mixed activation, isomerization depends only on the faster agonist, and that is not very satisfying. On the other hand, if binding is the rate limiting step, one can predict that the open time of the channels controlled by receptors bound by two agonists will be intermediate between the values characteristic of each agonist, which we did not find. A more general discussion would have to take into account other possibilities—if the two binding sites on one receptor are not identical, then models compatible with our results are possible.

Proton NMR detection of acetylcholine status in synaptic vesicles

H. Stadler & H. H. Füldner

Max-Planck-Institut für biophysikalische Chemie, Postfach 968, D 3400 Göttingen 1, FRG

The storage granules of cholinergic nerve terminals, the synaptic vesicles, have a central role in the mechanism of cholinergic transmission, and direct evidence as to whether acetylcholine is stored in them in a free or partially immobilized form is therefore of interest. In some secretory systems it has become evident that low molecular weight secretion products are stored within the granules as complexes with proteins or proteoglycans[1]. The application of high resolution NMR spectroscopy to isolated granules[2–4] has recently elucidated the internal structure of secretory granules. We report here that proton NMR analysis of isolated cholinergic synaptic vesicles from *Torpedo marmorata* allows the identification of acetylcholine within the organelle. The spectrum shows that all the acetylcholine is dissolved in an essentially fluid phase within the core. Vesicular and uncompartmentalized acetylcholine can be distinguished from each other and in addition, any hydrolysis to choline and acetate can be monitored. The results open the possibility of studying dynamics of acetylcholine pools and their breakdown in cholinergic tissue by a direct and non-perturbing method.

After isolation[5], vesicles were pelleted, resuspended in a small volume, dialysed against isosmolar D_2O buffer and spectra recorded in a Bruker WH 270 FT spectrometer interfaced to a Nicolet B-NC 12 computer. Chemical shifts are given relative to the internal standard 3-(trimethylsilyl)-d_4-propionic acid, whose pH dependence has been observed where necessary[6]. Complete recording of integrals was assured by proper choice of the acquisition parameters. The temperature was kept at 5 °C.

Basically, three experiments were carried out. In the first experiment, the spectrum of intact vesicles was recorded (Fig. 1*a*). In the second, the acetylcholinesterase present as a contaminant[5] in the sample was blocked by diethyl-*p*-nitrophenyl phosphate (paraoxon). The vesicles were then lysed by several freeze–thaw cycles and the spectrum was taken (Fig. 1*b*). In the third experiment the esterase was left active, the vesicles were lysed and a spectrum with the resulting choline and acetate resonances was obtained (Fig. 1*c*).

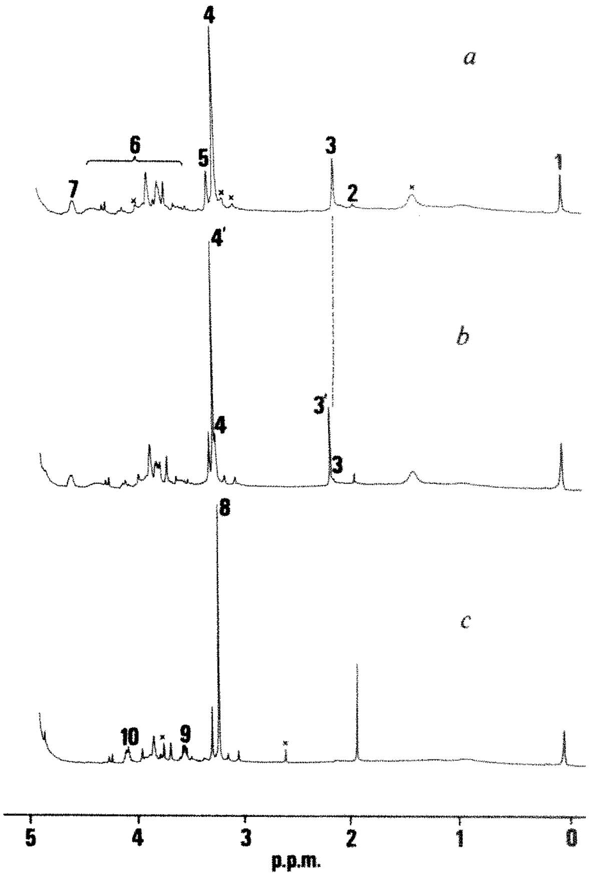

Fig. 1 Proton NMR spectra of isolated cholinergic synaptic vesicles from *Torpedo marmorata*. Vesicles were pelleted from the corresponding fraction from a sucrose density step gradient and suspended and dialysed against 0.4 M NaCl and 20 mM phosphate pD 7.4 made in D_2O and the spectrum recorded at 5 °C. *a*, Intact vesicles in the presence of 50 µM paraoxon (acetylcholine esterase blocker). *b*, The same preparation as *a*, but after lysis of vesicles and release of acetylcholine by repeated freezing and thawing. The dashed line indicates the chemical shift between resonances 3 and 3', the shift is present on all acetylcholine resonances (see text). *c*, Another vesicle preparation that has been lysed by freezing and thawing in the absence of an acetylcholine esterase blocker. The acetylcholine has been hydrolysed by the esterase present in the sample. Identified resonances: (1) 3-(trimethylsilyl)-propionic acid (internal standard, 1 mM); (2) free acetate; (3) and (3') $-CH_3$ protons of the acetyl residue of intact acetylcholine; (4) and (4') $-N-(CH_3)_3$ protons of acetylcholine; (5) trimethyloxamine; (6) resonances from residual sucrose and $-CH_2-$ protons from acetylcholine; (7) $-CH_2-$ protons of acetylcholine adjacent to the acetyl group; (8) $-N-(CH_3)_3$ protons of choline; (9) and (10) $-CH_2-$ protons of choline superimposed on sugar resonances; (×) unidentified resonances.

The simple spectrum of intact vesicles (Fig. 1*a*) contains the resonances of acetylcholine, trimethyloxamine (present in high concentrations in the body fluids of elasmobranchs[7]) and residual sucrose, together with a few minor unidentified resonances. Although ATP is present in vesicles in a 1:7 ratio relative to acetylcholine[5], its resonances could not be identified unambiguously. The membrane lipids gave only a very broad background.

Figure 2 shows the changes in the spectral region containing the $N(CH_3)_3$ and acetyl-CH_3 resonances when the vesicle preparation was subjected to several freeze–thaw cycles in the presence of the anticholinesterase. The progressive release of the intact acetylcholine as vesicles are broken is apparent.

0028–0836/80/290293–02$01.00

Three observations were noted: (1) The acetylcholine resonances of intact vesicles are shifted upfield relative to free acetylcholine as obtained after lysis or from a simple acetylcholine solution in our buffer (spectrum not shown). The shift ranges from about 0.02 p.p.m. to 0.04 p.p.m. for the various acetylcholine resonances (compare Fig. 1*a*, *b*). Although small, it is reproducibly above the resolution limit of 0.01 p.p.m. Possible explanations for this shift include susceptibility differences between the vesicle core and the external medium, differences in *p*H or ionic strength, and a weak interaction of acetylcholine with the negatively charged groups of a glycosaminoglycan found to be associated with the vesicles[8]. The effect of *p*H and ionic strength was insufficient to explain the observed shifts. (2) The integrals of corresponding resonances are identical before and after lysis. This means that all the vesicular acetylcholine is detected in the intact vesicles. (3) The stored form of acetylcholine shows only slightly bigger linewidths than the released one. Therefore, there is no doubt that the stored acetylcholine is dissolved; the differences in linewidths are presumably due to viscosity differences.

The result of the third experiment (several freeze–thaw cycles in the presence of active cholinesterase) is presented in Fig. 3. Here, vesicle breakdown and the immediate hydrolysis of the released acetylcholine are indicated by the disappearance of the acetyl-CH_3-resonance of intact acetylcholine and the concomitant appearance of the CH_3-resonance of free acetate. Correspondingly, all other acetylcholine resonances change over to those of choline (see Fig. 1*c*). This observation supports our deduction from the chemical shifts in the spectrum of acetylcholine that these were due to the difference between intra- and extravesicular acetylcholine. Another experiment of type 3 (omitting the freeze–thaw cycles) established that the half life of acetylcholine (~36 h) is long compared with the time of the experiments.

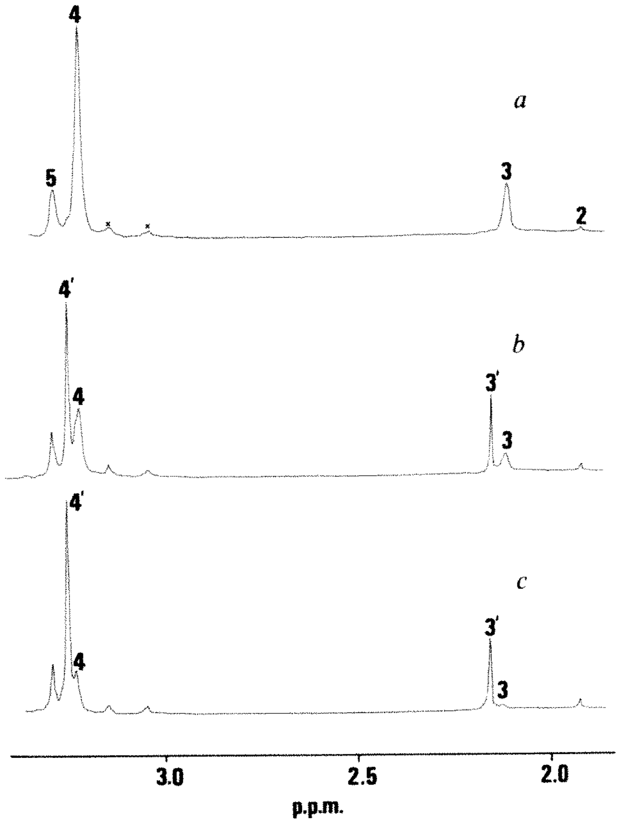

Fig. 2 Proton NMR spectra of cholinergic synaptic vesicles as a function of progressive release of acetylcholine from the vesicles by repeating freezing and thawing. Conditions and labelling as in Fig. 1*a*, *b*; a window of the resonances (2) to (5) is presented on an expanded scale. *a*, Intact vesicles before freezing and thawing; *b*, after 4 freeze–thaw cycles; *c*, after 12 freeze–thaw cycles.

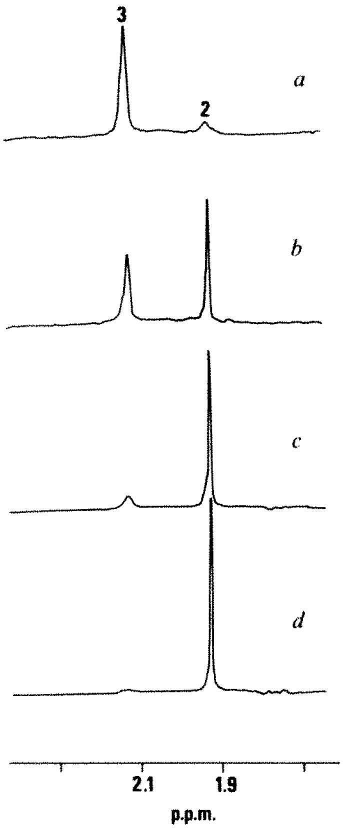

Fig. 3 Hydrolysis of acetylcholine progressively released from synaptic vesicles in the presence of unblocked acetylcholine esterase. Conditions as described in Fig. 1*c*, labelling as in Fig. 1. Part of the spectrum shown in Fig. 1*c* is presented. *a*–*d* Are spectra after 0, 2, 8 and 16 freeze–thaw cycles, respectively. Freezing and thawing of an acetylcholine solution in the same condition has no effect.

CALCUTTA

We accordingly conclude that the internal organization of acetylcholine in synaptic vesicles, in agreement with our recent findings that no soluble or easily releasable high molecular weight material is present in the core [5,13], constitutes a specialized version of a secretory organelle with fully dissolved storage product, thus fulfilling the need for quick acetylcholine release, which presumably occurs via exocytosis of vesicles during synaptic transmission. The result is consistent with density measurements suggesting that the vesicular acetylcholine is in an 'osmotically active' state [9,10].

As there is evidence that the dynamic structure of the internal content of an isolated secretory granule is identical with that of the granule in the intact organ[11], the shift differences mentioned might provide the basis for future NMR experiments using synaptosomes or intact (perfused) tissue to study the turnover and breakdown of acetylcholine pools, a matter of current interest[12].

Metallothionein mRNA induction in HeLa cells in response to zinc or dexamethasone is a primary induction response

Michael Karin, Robert D. Andersen, Emily Slater, Karen Smith & Harvey R. Herschman

Metallothioneins (MTs) are low molecular weight, heavy metal binding proteins unique in their high cysteine content and high affinity for Zn^{2+}, Cd^{2+}, Hg^{2+}, Ag^{2+} and Cu^{2+} (refs 1–3). The synthesis of MTs is induced by zinc or cadmium in the liver and kidney[4–8] and in cultured cells[9–12]. More recently MT induction by the steroid hormone dexamethasone (Dex) has been demonstrated in HeLa cells[13] and adrenalectomized rats[14]. Because glucocorticoid hormones lead to an intracellular accumulation of zinc[15–17], the question arises of whether the induction of MT gene expression by steroids is a 'primary induction response' (ref. 18), or due to elevated intracellular Zn^{2+}. The glucocorticoid-induced transport of Zn^{2+} is dependent on concurrent protein synthesis[10,19]. We now show that, in contrast to glucocorticoid-stimulated Zn^{2+} transport, the Zn^{2+} and Dex induction of translatable MT-mRNA is independent of concomitant protein synthesis but not RNA synthesis; that is, MT induction by either agent is a primary induction response[18].

We first compared the effects of Dex and Zn^{2+} on (1) the patterns of protein synthesis directed by total HeLa cytoplasmic RNA in a cell-free system, and (2) the patterns of soluble protein synthesis in the cells (Fig. 1). HeLa cells were grown as previously described[13]. To demonstrate an elevated MT-mRNA level in response to Zn^{2+} or Dex, confluent plates of HeLa cells were incubated for 6 h in control medium, 10^{-7} M Dex, or 3.7×10^{-5} M Zn^{2+}. At the end of this induction period the cells were collected by scraping, with a rubber policeman, into ice-cold phosphate-buffered saline. The cells were collected by centrifugation in a Beckman Microfuge B for 45 s. Total cytoplasmic RNA was extracted from the cells by the phenol–chloroform method of Anderson *et al.*[20]. Total cytoplasmic RNA extracted from HeLa cells was translated in the wheat-germ cell-free translation system described by Andersen and Weser[21] for translation of rat liver MT-mRNA. The incorporation of radioactivity into MT is a linear function of the amount of HeLa cell total cytoplasmic RNA added to the translation system up to 15 µg of total RNA per reaction mixture (data not shown). To examine the effects of Zn^{2+} and Dex on MT synthesis in the cells, additional plates were exposed to inducers for 6 h, shifted to cysteine-free medium and exposed for an additional hour to ^{35}S-cysteine (see Fig. 1 legend).

At the end of either the *in vitro* translation reaction or the radioactive labelling of the cultured cells, the fractions to be analysed were reduced and alkylated (ref. 21 and Fig. 1 legend) and subjected to electrophoresis on polyacrylamide gels. Due to its high cysteine content, reduced and carboxymethylated MT has a large net negative charge (carboxymethyl cysteine is negatively charged in the conditions used for electrophoresis). As a consequence, the carboxymethylated MT migrates abnormally rapidly on 20% polyacrylamide SDS gels (see ref. 21). In this gel system MTs migrate as a single band with an R_F of 0.72 relative to bromphenol blue, and are completely separated from all other proteins[21].

Lanes *a*, *c* and *e* of Fig. 1 are the reduced and carboxymethylated proteins synthesized in the cell-free system. The reduced and carboxymethylated soluble proteins extracted from ^{35}S-cysteine-labelled cells are in lanes *b*, *d* and *f*. The MT band (indicated by the arrows) is markedly increased by Dex (lanes *c*, *d*) and by Zn^{2+} (lanes *e*, *f*) in comparison with control cells (lanes *a*, *b*). Dex and Zn^{2+} clearly stimulate MT synthesis both in the cells and in the RNA-dependent *in vitro* translation system. Characterization, by both DEAE-Sephadex chromatography and electrophoresis on native polyacrylamide gels, of the Zn^{2+}- and Dex-induced MT from HeLa cells

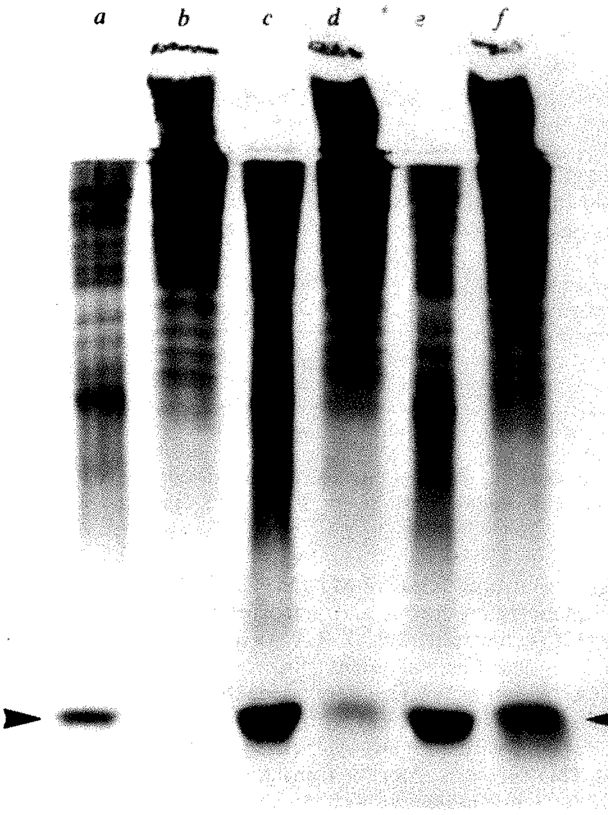

Fig. 1 Dexamethasone- and Zn^{2+}-induced stimulation of MT synthesis and MT-mRNA accumulation in HeLa cells cultured in serum-free medium. HeLa cells were incubated for 6 h with control medium (*a*, *b*), medium $+10^{-7}$ M Dex (*c*, *d*), or medium $+3.7 \times 10^{-5}$ M Zn^{2+} (*d*, *e*). At the end of the incubation period three culture plates for each point were collected and total cytoplasmic RNA was extracted. The cell-free translation was carried out as described by Andersen and Weser[21] in a total volume of 25 µl, optimal salt concentrations were 4.5 mM $MgCl_2$ and 65 nM KCl. Unlabelled cysteine was omitted from the amino acid mixture and replaced with 0.8 µM of ^{35}S-cysteine (translation grade, NEN 608 Ci mmol^{-1}). The reaction was initiated by adding exogenous RNA. All samples were assayed with both 10 µg (a subsaturating amount) and 15 µg (the peak of the concentration curve) of cellular RNA. At the end of the 2-h incubation at 25 °C the samples were carboxymethylated as previously described[21]. The remaining culture dishes were labelled from the 6th to the 7th hour with 30 µCi of ^{35}S-cysteine (NEN, 300–500 Ci mmol^{-1}). Radioactive labelling was carried out in cysteine-free medium containing the appropriate inducers. At the end of the 1-h pulse, the cells were collected and the soluble proteins extracted as described before[13]. Reduction and alkylation of proteins synthesized in the cells were done as follows. To 200 µl of the cell extract were added 20 µl of 1 M HCl and 20 µl of 0.25 M EDTA. After 20 min at room temperature, 300 µl of 8 M guanidine, 0.5 M Tris-Cl, 0.05 M EDTA, pH 8.5, containing 20 mM dithiothreitol were added. After 3 h incubation at 37 °C, 50 µl of 2 M neutralized iodoacetic acid were added and the mixture was incubated for another 90 min at 37 °C. The reaction was terminated by dialysing against H_2O for 24 h. All the samples were subjected to electrophoresis on 20% polyacrylamide, 0.1% SDS slab gels. Lane *a*, 76,000 c.p.m. of translation product from the cell-free protein synthesis reaction, synthesis directed by RNA from control cultures. Lane *b*, 151,000 c.p.m. of intracellular ^{35}S-cysteine-labelled soluble proteins from control cultures. Lane *c*, 81,000 c.p.m. of *in vitro* synthesized translation product directed by RNA from Dex-induced cultures. Lane *d*, 161,000 c.p.m. of intracellular labelled soluble proteins from Dex-induced cultures. Lane *e*, 77,000 c.p.m. of *in vitro* synthesized translation products directed by RNA from Zn^{2+} induced cultures. Lane *f*, 162,000 c.p.m. of intracellular labelled soluble proteins from Zn^{2+}-induced cultures. Electrophoresis and fluorography have been described previously[21–25]. The position of the MT band is indicated by the arrows.

Table 1 Dexamethasone stimulation of zinc uptake by HeLa cells

	Expt 1 (confluent cells)	Expt 2 (confluent cells)	Expt 3 (exponential cells)
Control (6 h)	37,734 ± 953	37,543 ± 3016	21,474 ± 3772
Dex (6 h)	43,899 ± 220	43,140 ± 1689	26,200 ± 2848
Cycloheximide (6 h)	—	31,144 ± 1288	19,040 ± 2206
Dex + cycloheximide (6 h)	—	26,729 ± 3858	18,938 ± 891
Control (24 h)	57,903 ± 2780	—	—
Dex (24 h)	97,647 ± 2475	—	—

HeLa cells were incubated for the times indicated in our serum-free medium[13] with 0.5 μCi of $^{65}Zn^{2+}$ per plate. Dexamethasone, where indicated, was 10^{-7} M; cycloheximide was 10^{-4} M. At the end of the incubation period the cells were washed twice with 5 ml of cold phosphate-buffered saline. Cells were dissolved in 1 M NaOH. $^{65}Zn^{2+}$ content was measured in a Beckman Biogamma counter. Expts 1 and 2 were with confluent cells; expt 3 was with cells at half-maximal density.

suggests that both forms of MT (MT_I and MT_{II}, refs 2, 12) are induced by heavy metals and glucocorticoid hormones (M.K. and H.R.H., in preparation). R.A. *et al.*[20] have demonstrated that the wheat-germ system preferentially translates small mRNAs *in vitro*. We also see a reduction in high molecular weight proteins synthesized in the cell-free system (lanes *a*, *c*, *e*) compared with proteins synthesized in intact cells (lanes *b*, *d*, *f*). This does not affect the translation of MT-mRNA, which codes for a low molecular weight (6,000) protein.

To determine whether or not the elevation of MT-mRNA in response to the two different inducers is dependent on *de novo* synthesis of RNA and protein, we used inhibitors of RNA and protein synthesis (actinomycin D and cycloheximide). HeLa cells were exposed for 6 h to 10^{-7} M Dex or 3.7×10^{-5} M Zn^{2+}, either in the absence or presence of inhibitors. At the end of the 6-h exposure period total cytoplasmic RNA was extracted and translated in the cell-free system, using ^{35}S-cysteine to label the proteins synthesized. The reduced and carboxymethylated proteins were subjected to electrophoresis and fluorograms were prepared (Fig. 2). Lanes *a*, *b* and *c* are, respectively, proteins from control, Dex-induced and Zn^{2+}-induced cells in the absence of inhibitors. Lanes *d*, *e* and *f* are, respectively, proteins from control, Dex-induced and Zn^{2+}-induced cells in the presence of 1 μg ml^{-1} of actinomycin D during the 6-h induction period. Lanes *g*, *h* and *i* are, respectively, control Dex-induced and Zn^{2+}-induced cells in the presence of 10^{-4} M cycloheximide during the induction period. Once again, Dex and Zn^{2+} exposure leads to an elevation in translatable MT-mRNA (lanes *a*–*c*). Both the hormone- and metal-elicited elevations in MT-mRNA are inhibited by 1 μg ml^{-1} of actinomycin D (lanes *d*–*f*) but not by 10^{-4} M cycloheximide (lanes *g*, *h*, *i*). This concentration of cycloheximide blocks more than 90% of protein synthesis in HeLa cells (results not shown).

To quantitate the amounts of MT synthesized, a fluorogram prepared from the experiment shown in Fig. 2 was scanned with a densitometer. The optical density (a direct function of radioactivity, data not shown) in the MT band was summed and normalized to the amount of total radioactivity applied to the gel. Figure 3 shows the quantitative results from a densitometric analysis of a fluorogram from the same experiment shown in Fig. 2. In this particular experiment MT-mRNA was elevated about five-fold by 10^{-7} M Dex and six-fold by 3.7×10^{-5} M Zn^{2+}. Inclusion of 1 μg ml^{-1} actinomycin D in the culture medium during the induction period not only prevented the elevation of MT-mRNA, but also lowered its level relative to control cultures by 50–60%. In contrast, inclusion of 10^{-4} M cycloheximide did not inhibit the induction of MT-mRNA; in fact, cycloheximide caused an elevation in the level of MT-mRNA in both control and treated cultures.

We considered it essential to examine the role of RNA and protein synthesis in MT induction by Zn^{2+} and Dex at similar levels of induction. The Dex concentration used (10^{-7} M) causes maximal MT synthesis in response to this inducer. In contrast, we used a concentration of Zn^{2+} (3.7×10^{-5} M) which, although it causes approximately the same level of induction as maximal dexamethasone, results in only 20% of the maximal MT response to the optimal Zn^{2+} concentration (10^{-4} M). Variable cycloheximide enhancement of MT synthesis (40–100%) in Zn^{2+}-treated cultures and control cultures was observed in two *in vitro* translation experiments and four *in vivo* experiments of the type described in Fig. 1 legend. In contrast, we observed only 0–30% cycloheximide enhancement with Dex-treated cells. The stimulatory effect of cycloheximide observed in control- and Zn^{2+}-induced, but not Dex-induced expression of MT-mRNA may be due to the fact that in one condition (with Dex) the system is operating at maximal potential for that physiological condition, whereas in the other cases (control, Zn^{2+}) the system is operating in sub-optimal conditions of expression. Alternatively, the glucocorticoid receptor may have a short half life: its decay in the presence of cycloheximide may counterbalance a true stimulating effect of the drug. Recently, Enger *et al.*[22] have also used *in vitro* translation of mRNA in a wheat-germ system to demonstrate that induction of MT in cultured CHO cells in response to cadmium occurs as a consequence of an elevation in translatable message.

Cox[19] reported that exposure of HeLa cells to Dex leads to an increased uptake of Zn^{2+}. We find that Dex exposure of HeLa cells grown in serum-free medium also leads to a twofold elevation in the uptake of $^{65}Zn^{2+}$ after 24 h (Table 1, expt 1). Cox also reported the Dex-induced Zn^{2+} uptake was,

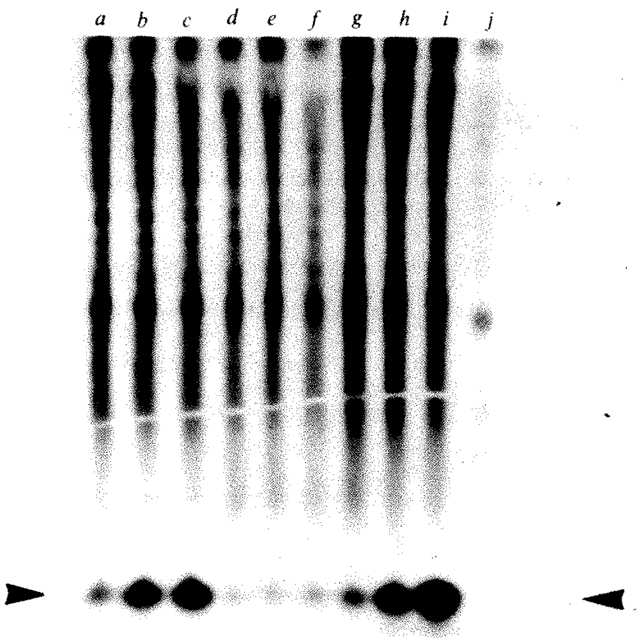

Fig. 2 *In vitro* translation of RNA preparations from control, Dex-treated and Zn^{2+}-treated HeLa cells and the effect of actinomycin D and cycloheximide on MT-mRNA accumulation. Confluent cultures of HeLa cells were incubated for 6 h in: *a*, control medium; *b*, medium containing 10^{-7} M Dex; (*c*, medium containing 3.7×10^{-5} M Zn^{2+}; *d*, control medium plus 1 μg/ml^{-1} actinomycin D; *e*, 10^{-7} M Dex plus 1 μg ml^{-1} actinomycin D; *f*, 3.7×10^{-5} M Zn^{2+} plus 1 μg ml^{-1} actinomycin D; *g*, control medium plus 10^{-4} M cycloheximide; *h*, 10^{-7} M Dex plus 10^{-4} M cycloheximide; *i*, 3.7×10^{-5} M Zn^{2+} plus 10^{-4} M cycloheximide; *j*, no exogenous RNA added to the translation system. At the end of the 6-h incubation period, total cytoplasmic RNA was extracted and translated in the cell-free system. The translation products were reduced and alkylated, dried down under vacuum in a desiccator and resolubilized in 50 μl of electrophoresis sample buffer. A 10-μl aliquot containing 40,000–60,000 c.p.m. was subjected to electrophoresis on 20% polyacrylamide, 0.1% SDS gels. The position of the MT band on the resulting fluorogram is indicated by the arrows.

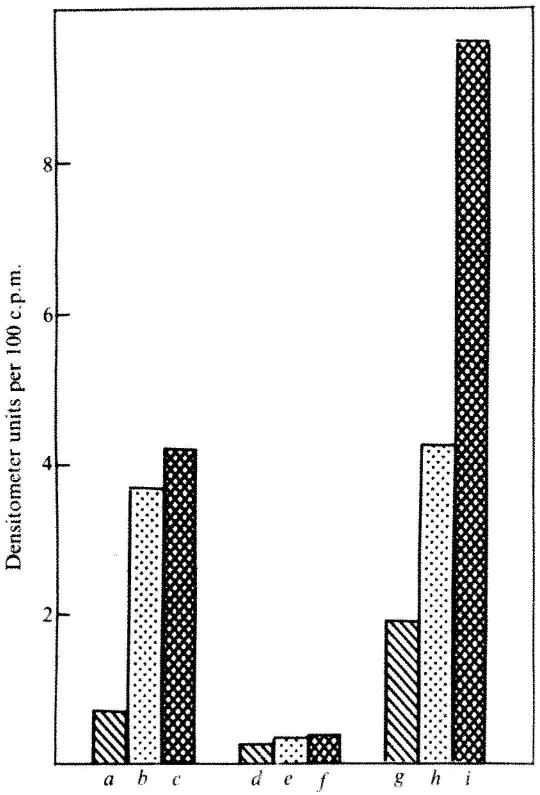

Fig. 3 Quantitation of the effects of RNA and protein synthesis inhibitors on elevation of MT-mRNA in response to Dex and Zn^{2+}. A fluorogram similar to that shown in Fig. 2, but in the linear response range, was scanned with an Optronics Photoscan model P-1000 digitalized densitometer, using a photometer window with a 200-μm raster. RNA at 10 μg per translation (a subsaturating concentration) was used. The density in the MT band was summed and normalized to the amount of radioactivity applied to each slot.

however, dependent on *de novo* RNA and protein synthesis[19]. We find that after 6 h of exposure to Dex there may already be a slight increase in $^{65}Zn^{2+}$ uptake. More importantly, in the presence of cycloheximide there is no Dex stimulation of $^{65}Zn^{2+}$ uptake over the 6-h induction period (Table 1, expts 2, 3). In contrast to Dex stimulation of Zn^{2+} transport, the induction of MT-mRNA is not blocked by cycloheximide (Figs 2, 3). In the HeLa system, glucocorticoid induction of MT is thus not a consequence of protein synthesis-dependent Zn^{2+} uptake into the cells, as suggested by Failla and Cousins[17] for primary rat hepatocytes.

Several of the currently studied steroid hormone induction systems are not primary induction responses. Hepatic induction of $\alpha 2\mu$-globulin mRNA by glucocorticoid hormones is inhibited by cycloheximide[23], in contrast to our results for glucocorticoid hormone induction of MT-mRNA. McKnight[24] has also reported that the induction in explants of chick oviduct of mRNA for both ovalbumin and conalbumin by oestrogen (or progesterone) is blocked by inhibition of protein synthesis. A primary induction system such as the Dex induction of MT synthesis in HeLa cells, in which no intervening protein synthesis need occur, should be much more amenable to cell-free analysis of transcription control by steroid hormones.

We conclude that (1) Dex and Zn^{2+} both lead to an elevation of the mRNA for MT in HeLa cells, (2) the elevation is dependent on *de novo* RNA synthesis (inhibition by actinomycin D), (3) the elevation is independent of *de novo* protein synthesis (insensitivity to cycloheximide), and (4) the elevation is not dependent on increased Zn^{2+} transport (Table 1). MT induction by both Dex and Zn^{2+} is a primary induction response[18], that is, it is not dependent on the induced synthesis of any protein intermediates. The MT induction system should provide an excellent experimental model both for the study of the physiological regulation by glucocorticoid hormones of Zn^{2+} metabolism and for the elucidation of the control mechanisms responsible for regulation of gene expression in eukaryotes by heavy metals and glucocorticoids.

Independent replication and expression of B-component RNA of cowpea mosaic virus

Rob Goldbach, Geertje Rezelman & Albert van Kammen

Department of Molecular Biology, Agricultural University, De Dreijen 11, 6703 BC Wageningen, The Netherlands

Cowpea mosaic virus (CPMV) is a plant virus with a split genome, composed of two single-stranded plus-type RNA molecules which are separately encapsidated in two (bottom and middle) nucleoprotein particles[1–3]. The protein capsids of the bottom (B) and middle (M) component are similar and consist of two proteins in equimolar amounts[4,5]. Both B and M components are necessary for virus multiplication, indicating that the genetic information is distributed between both (B and M) RNAs[6]. However, little is known about the location of genes on either RNA and the reason for a divided genome is unknown. Inoculation of cowpea protoplasts with complete virus (M + B components) results in the synthesis of at least seven virus-specific polypeptides, including the capsid proteins[7,8]. We show here that on inoculation of protoplasts with the separated components, the B component RNA is replicated and expressed independently, whereas the M component RNA is not. The results presented suit a model in which B RNA codes for early functions and M RNA for late functions during viral infection, supplying a possible explanation for the divided genome of CPMV.

The molecular weights (MWs) of M and B RNAs are 1.37×10^6 and 2.02×10^6, respectively[9]. Both RNAs possess a 3′-terminal poly(A) tail[10] and a protein covalently linked to their

0028-0836/80/290297-04$01.00

5′ termini[11,12]. Translation in a wheat-germ cell-free system and in extracts from rabbit reticulocytes results in the synthesis of large proteins which readily account for more than 80% of the coding capacity of both M and B RNA[13–15]. Pelham[15] has shown that in the reticulocyte system some processing of the large proteins occurs. However, no polypeptides corresponding to the viral coat proteins were observed. Mesophyll protoplasts can be isolated from the primary leaves of cowpea plants (*Vigna unguiculata* (L.)) and infected with CPMV[16]. We have analysed the proteins synthesized in this *in vivo* system after inoculation with separated B and M components.

Figure 1 shows the electrophoretic patterns of the proteins from mock-infected protoplasts and protoplasts inoculated with M, B or the mixture of M+B components. In agreement with earlier results[7,8], protoplasts infected with M+B components produce seven virus-specific polypeptides of MWs 170,000, 110,000, 87,000, 84,000, 37,000, 30,000 and 23,000. The polypeptide pattern obtained from protoplasts infected with M component alone is similar to that of the uninfected protoplasts. No virus-specific proteins were detected. In contrast, protoplasts infected with B component alone produce all virus-specific polypeptides with the exception of the (37,000 and 23,000 MW) capsid proteins. No immunoprecipitate with antiserum against virions was obtained from protoplasts infected with either M or B components, confirming the absence of coat proteins. The total of the MWs of the five B RNA-coded polypeptides greatly exceeds the coding capacity of the RNA. Peptide fingerprint experiments, using *Staphylococcus aureus* V8 protease, have shown, however, that the polypeptides of MWs 110,000, 87,000 and 84,000 are derived from the 170,000 MW polypeptide by post-translational cleavage (data not shown). The results shown in Fig. 1 raise the question of why B RNA alone can be expressed whereas M RNA cannot. Two possible explanations can be given. First, M RNA can only be translated when B RNA or B RNA-coded proteins are present in the cell. This explanation seems improbable as M RNA is readily translated *in vitro*. Second, B RNA codes for the viral replicase[17,18] and on infection of protoplasts with B component, B RNA is replicated to give a large quantity of RNA subsequently directing detectable translation. Translation of M RNA in protoplasts remains undetectable because multiplication of M RNA does not occur.

Table 1 Replicase activity in cowpea protoplasts inoculated with CPMV components

Protoplasts inoculated with	^{3}H-UTP incorporation per 13×10^6 protoplasts (c.p.m.)
	5,492
M	5,688
B	17,876
M+B	17,332

Portions of 13×10^6 protoplasts were inoculated with 3.5 μg M, 3.5 μg B or 7 μg (1:1 mixture) M+B components and incubated as described elsewhere[7]. The cells were collected 42 h after inoculation, resuspended in 1 ml of 50 mM Tris-HAc (*p*H 7.4), 10 mM KAc, 1 mM EDTA, 10 mM dithioerythritol (DTE) and 0.5 mM phenylmethylsulphonylfluoride (PMSF) and disrupted at 0 °C in a Thomas homogenizer with a Teflon pestle. Cell homogenates were centrifuged at 1,000*g* for 15 min. The supernatants were adjusted to 20% (v/v) glycerol and centrifuged at 31,000*g* for 30 min. The 31,000*g* pellets were resuspended in 0.4 ml 50 mM Tris-HAc (*p*H 8.2), 25% (v/v) glycerol, 50 mM KAc, 1 mM EDTA, 10 mM DTE and 0.5 mM PMSF. ^{3}H-UTP incorporation in the resuspended 31,000*g* pellets was measured in standard replicase assay conditions[18]. Although the ratio between the activities of uninfected and M+B-infected cells is only slightly more than 3, it was reproducible in other experiments. Moreover, in time course experiments (not shown) it was found that the extra activity in M+B-inoculated cells was induced at 15–30 h post-infection, that is, the period of maximal virus production[16].

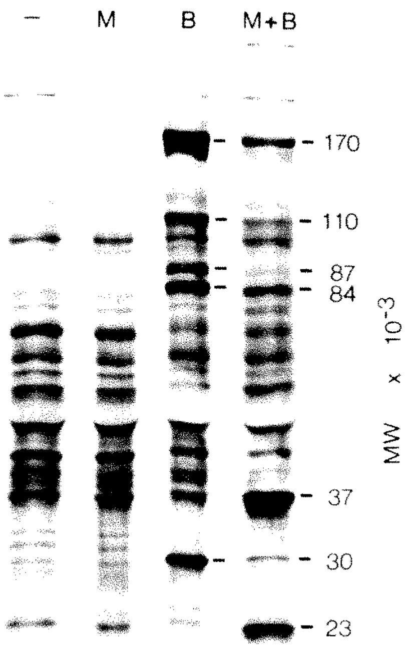

Fig. 1 Analysis on a 7–15% linear SDS-polyacrylamide gradient gel of ^{35}S-labelled proteins from uninfected protoplasts (–), protoplasts inoculated with purified M components (M), purified B component (B), and complete virus (M+B). CPMV was grown in *Vigna unguiculata* L. 'blackeye early ramshorn' and purified as previously described[27]. M and B components were separated by three cycles of centrifugation in a linear 15–30% zonal sucrose gradient (Beckman Ti 15 rotor, 16 h, 23,000 r.p.m. at 10 °C). By means of the local lesion infectivity assay[16] it was determined that M components were free of B and that B components contained less than 0.2% M. Portions of protoplasts (5 ml, 5×10^5 ml^{-1}) were mock-infected or inoculated with 7 μg M, 7 μg B or 14 μg (1:1 mixture) M+B virus components and labelled with 150 μCi ^{35}S-methionine 20–25 h after infection as described in detail elsewhere[7]. Neither actinomycin D nor any other inhibitor of host protein synthesis was added in this experiment. Soluble protein fractions (31,000*g* supernatants) were prepared and electrophoresed (using equal amounts of radioactivity) as previously described[7]. In the M+B slot the large (170,000–84,000 MW) virus-specific polypeptides are not as clearly visible as in the B slot, as most radioactivity is found in the capsid proteins (37,000 and 23,000 MW). MW markers used were: *Escherichia coli* RNA polymerase subunits (MWs 165,000 and 155,000), *E. coli* β-galactosidase (116,200), phosphorylase *a* (92,500), human transferrin (80,000), bovine serum albumin (68,000), catalase (57,500), γ-globulin (54,000 and 23,500), ovalbumin (46,000), lactate dehydrogenase (35,000) and tobacco mosaic virus coat protein (17,500).

To test the latter hypothesis, the RNA replicase activity was examined in infected and uninfected protoplasts using the assay conditions for CPMV replicase as described by Zabel *et al.*[17,18]. The results presented in Table 1 show that in protoplasts infected with a mixture of M+B the ^{3}H-UTP-incorporating activity increases three times over the activity measured in uninfected protoplasts. A similar increase in activity occurs in protoplasts infected with B component but not in those infected with M component. This finding strengthens the suggestion that B RNA contains information essential for viral RNA replication. This suggestion was substantiated by analysing the RNAs produced. Protoplasts inoculated with M, B or M+B components, or uninfected, were labelled by incubation with $^{32}PO_4$ 20–25 h after inoculation and then analysed for RNA. As shown in Fig. 2, protoplasts infected with a mixture of M+B components produce two RNAs which co-migrate with standard CPMV B RNA and M RNA. These RNAs are absent in uninfected protoplasts as well as in protoplasts infected with M component. However, protoplasts inoculated with B component efficiently produce ^{32}P-labelled B RNA. This finding verifies that B RNA replicates independently whereas M RNA does not.

The absence of M RNA (or fragments of M RNA) in protoplasts infected independently with M or B components was checked using cDNA made from B and M RNA. The results of the hybridization experiments presented in Table 2 show that M RNA is not synthesized in protoplasts inoculated with M component alone, whereas in protoplasts inoculated with the M+B mixture this RNA is readily detected. The results confirm that B RNA is made in protoplasts infected with B component alone. The amount of B RNA produced in these cells is comparable with the amount of this RNA in protoplasts infected with M+B, consistent with the independent expression of B as shown in Fig. 1. To a certain degree CPMV resembles another two-component virus, tobacco rattle virus (TRV). The large RNA of TRV is also able to replicate independently, whereas no coat protein is produced[19]. CPMV differs from TRV, however, in that inoculation of plants with B component does not result in infection detectable by local lesions.

The data obtained from the present experiments provide evidence that B RNA can be independently replicated, implying that this RNA codes for a protein involved in replication. Although in theory B RNA (but not M RNA) may code for a protein inducing the expression of a host gene, this possibility is very unlikely. A host gene must be proposed, which is 'sleeping' in normal (uninfected) conditions and acting harmfully during infection. It is plausible that B RNA codes for the viral replicase or a subunit of this enzyme. Zabel *et al.*[17,18] have isolated CPMV RNA replicase from virus-infected cowpea leaves and have shown that such replicase preparations contain a protein which binds CPMV RNA specifically and is absent in control preparations from healthy leaves. Together, these findings favour the hypothesis that CPMV RNA carries information for a protein required for viral RNA replication. They do not support the idea that plant viral RNA is replicated by a host enzyme, as has been suggested[20–22].

The results shown here suggest that M RNA codes for both capsid proteins, these being the only viral proteins absent in protoplasts infected with B component. A similar conclusion is reached from complementation studies using particles from different CPMV isolates[23,24]. The results are consistent with a model for the distribution of genes among the components of CPMV in which B RNA exclusively codes for early proteins (for example, the replicase or replicase subunit(s)) and M RNA for late proteins (for example, both capsid proteins). The usefulness of the split genome would therefore lie in its ability to regulate separately the expression of early and late genes.

Table 2 Hybridization of ^{32}P-labelled RNA from infected and uninfected protoplasts with cDNA made from B and M RNA

^{32}P-RNA from protoplasts inoculated with	Hybridization (c.p.m.) to M cDNA	B cDNA	Calf thymus DNA
—	165	122	93
M	173	147	130
B	290	2,966	161
M + B	1,665	2,342	152

Protoplasts were incubated with ^{32}P-orthophosphate 20–25 h after inoculation. For details see Fig. 2 legend. Portions of 100,000 c.p.m. ^{32}P-RNA were hybridized to 1 μg of filter-bound DNA for 18 h in 0.45 M NaCl and 0.045 M Na-citrate (*p*H 7.0) at 65 °C, essentially as described by R.G. *et al.*[25]. Complementary DNA from purified M and B RNA (M cDNA and B cDNA, respectively) was made as previously described[26].

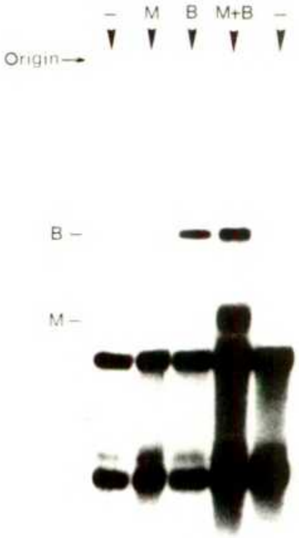

Fig. 2 Agarose gel electrophoresis of glyoxal-denatured RNAs from protoplasts infected with CPMV components. Portions of protoplasts (5 ml, 5×10^5 ml^{-1}) were inoculated with virus components as described in Fig. 1 legend. The cells were collected 20 h after inoculation, resuspended in phosphate-deficient medium[7] (10^6 cells ml^{-1}) and labelled for 5 h with ^{32}P-orthophosphate (1 mCi ml^{-1}) in the presence of actinomycin D (15 μg ml^{-1}). Total cell RNA was isolated by heating the cells for 5 min at 60 °C in a detergent mix (2% *p*-aminosalicylate, 1% Na-deoxycholate, 0.5% tri-isopropylnaphthalene sulphonate and 2% Sarkosyl in 50 mM Tris-HCl (*p*H 8.2) and 0.1 M NaCl) and centrifugation of the lysate on a 5.7 M CsCl cushion according to Glišin *et al.*[28]. Yields were: uninfected cells, 840 μg (7,900 c.p.m. per μg); M-inoculated cells, 780 μg (8,200 c.p.m. per μg); B-inoculated cells, 860 μg (10,200 c.p.m. per μg); M + B inoculated cells, 790 μg (9,400 c.p.m. per μg); c.p.m. were measured by scintillation counting. RNA samples (comprising 20,000 c.p.m.) from uninfected (–) protoplasts and those inoculated with M, B and M + B components were denatured with glyoxal and electrophoresed in a 1.5% agarose gel according to McMaster and Carmichael[29]. After the run the gel was dried and autoradiographed. B and M below the origin indicate the position of standard (unlabelled) virion B and M RNA in the gel. Recently, it has been reported[30] that the poly(A) tail of M RNA is heterogeneous in length (50–400 residues), whereas the length distribution of the poly(A) tail in B RNA shows a narrow distribution (50–150 residues). This heterogeneity is visible in the gel, where the band of B RNA is sharp but the band of M RNA rather diffuse.

We thank Drs J. Stanley and P. Zabel for helpful comments and Mr J. Verver for carrying out the RNA electrophoresis experiments. This work was supported by the Netherlands Foundation for Chemical Research (SON) with financial aid from the Netherlands Organization for the Advancement of Pure Research (ZWO).

Compressed microfibril models of the native collagen fibril

Benes L. Trus & Karl A. Piez

Laboratory of Biochemistry, National Institute of Dental Research, National Institutes of Health, Bethesda, Maryland 20205

A three-dimensional crystal model for packing of collagen molecules (type I) in the native fibril has recently been proposed by Hulmes and Miller[1]. It provides a straightforward explanation of the major features of the X-ray diffraction pattern, and is consistent with measurements of fibril density. However, there is independent evidence for a well defined microfibrillar substructure, which is absent from their model. This evidence, which is derived from electron microscopy[2-5] and studies of *in vitro* assembly[6,7], the pattern of covalent cross-links[8] and sequence analysis[9,10], is convincing. Therefore, we have searched for a means to reconcile this conflict. We now propose two models which contain five-stranded microfibrils compressed to place molecules (in cross-section) on a pseudo-hexagonal lattice. The unit cells are equivalent or related to the cell proposed by Hulmes and Miller[1]. In the simplest case, molecules, and thus microfibrils, are straight-tilted. However, it is not ruled out that molecules are supercoiled and microfibrils are straight. Noncrystallographic considerations[6,7,9,10] favour supercoiling.

The five-stranded microfibril in which D-staggered collagen molecules ($D = 67$ nm) form a 5_1 or 5_4 helix (Fig. 1*A*), originally proposed by Smith[11], has been the most widely accepted model for packing of collagen molecules. In the original interpretation by Miller and colleagues[12-14] of the X-ray diffraction pattern, the unit cell contained four 5-fold microfibrils in a tetragonal unit cell. A more recent study[15] suggests a sheared tetragonal cell. In the present study we retain the microfibril but compress it to place molecules on a pseudo-hexagonal lattice as illustrated in Fig. 1*B*. As proposed by Hulmes and Miller[1], we assume that the three strong X-ray diffraction reflections in the equatorial region with row-line spacings of 1/1.369, 1/1.328 and 1/1.264 nm^{-1} are the reciprocal distances between planes of molecules in the three sets that define the pseudo-hexagonal lattice. We suggest that a microfibril in isolation or in small bundles may have a symmetrical or loosely symmetrical 5-fold cross-section but that in large bundles (fibrils) the internal crystal energy is sufficient to distort the helix and force molecules onto a hexagonal lattice. Molecules may be straight or supercoiled, as discussed below. We envisage supercoiling as being accommodated by tilts of molecular segments, the angle varying about some average value. As a molecule coils about the microfibril axis it would appear at successive lattice points within the compressed microfibril cross-section. The trapezoidal cross-section, in general, would not rotate. The distortion required is consistent with NMR studies[16-18] which have shown that since collagen molecules in the native fibril are in rapid segmental motion in directions perpendicular to the fibril axis, intermolecular interactions must be fluid. In addition, systematic as well as random deviations from the lattice are possible as long as a large portion of the protein density is near the lattice planes. That is, the actual structure of the microfibril may be between the two extremes illustrated in Fig. 1*B*.

Table 1 Observed and calculated equatorial row-line spacings

Observed	Model 1	Model 2 Smaller cell	Model 2 Larger cell
3.800	3.777 (1, 0)	3.777 (1, 0)	3.777 (1, 1)
		3.837 (1, −1)	3.837 (2, 0)
2.651	2.582 (1, −1)	2.582 (1, −2)	2.621 (1, −2)
2.461	2.436 (0, 1)	2.436(0, 2)	2.436 (2, −2)
1.890	1.889 (2, 0)	1.889 (2, 0)	1.889 (2, 2)
1.748	1.748 (1, 1)	1.748 (1, 2)	1.748 (1, −3)
1.57	—	1.560 (2, 1)	1.560 (1, 3)
1.503	—	—	1.505 (5, −2)
1.369	1.369 (3, −1)	1.369 (3, −2)	1.369 (5, 1)
1.328	1.328 (1, −2)	1.328 (1, −4)	1.328 (6, −1)
1.264	1.264 (2, 1)	1.264 (2, 2)	1.264 (0, 4)

For convenience real spacings are given. Units are nanometres. Indices are shown in parentheses. Observed row-line spacings are from rat tail tendon[12-14]. For descriptions of models 1 and 2, see Figs 2 and 3, respectively.

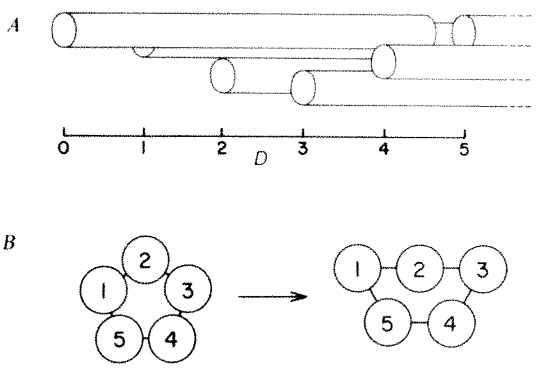

Fig. 1 Schematic representations of one end of a 5-fold microfibril of collagen molecules (*A*) and its conversion to a compressed microfibril where molecules in cross-section lie on a pseudo-hexagonal lattice (*B*). $D = 67$ nm. The numbers designate the D segment cut in the cross-section. Molecules may be straight as shown or supercoiled.

In model 1 the compressed microfibrils are arranged in a hexagonal pattern as shown in Fig. 2. Every point on the lattice of molecules is occupied and the unit cell contains a D segment of one microfibril. The unit cell is equivalent to that proposed by Hulmes and Miller[1], but the arrangement of molecules within the cell is different. Table 1 shows the agreement between observed and calculated row-line spacings. As can be seen in Fig. 2, the unit cell can be drawn in two equivalent ways, one of which was selected by Hulmes and Miller[1]. We have used the other because it is directly related to the unit cell of model 2.

The simplest way to explain the equatorial position of the 1/1.264-nm^{-1} reflection and the off-equatorial positions of the 1/1.328- and 1/1.369-nm^{-1} reflections is to straight-tilt molecules in the direction of the 1.264-nm plane so the tilting vector is 0° normal to that plane but about 4° normal to the other two planes. Here also, the unit cell of our model 1 is equivalent to the Hulmes and Miller[1] cell and thus provides as satisfactory an explanation of the X-ray diffraction pattern insofar as the analysis has been developed. However, we do not rule out the possibility that molecules are supercoiled about the microfibril axis rather than straight-tilted. The strong reflections near 1/1.3 nm^{-1} would then be explained by sampling of the transform of the supercoiled molecules. Because distorted helices are involved, this more complex

0028-0836/80/290300-02$01.00

situation requires a more complex analysis, which we have not attempted.

The advantage of supercoiled molecules is that the microfibrils are better defined and thus provide a better explanation of evidence for a microfibrillar substructure, already quoted. For example, *in vitro* studies[6,7] have shown that assembly of native fibrils from collagen monomer is a stepwise process involving thin filaments as intermediates. Lateral association of supercoiled microfibrils is consistent with these data whereas assembly of straight-tilted molecules implies a three-dimensional crystallization. Also, regularities in the amino acid sequence can be explained by supercoiling of molecules in a microfibril[9,10].

In model 2 we assume that the asymmetric unit contains *D* segments of two compressed microfibrils related by a noncrystallographic 2-fold axis. We have examined all possible arrangements and find one (Fig. 3*A*) in which the unit cell (Fig. 3*B*, smaller cell) accurately predicts the observed reflections in the near-equatorial region of the X-ray diffraction pattern (Table 1). The unit cell contains one asymmetric unit and its dimensions, not surprisingly in retrospect, are the same as those of the unit cell in model 1 except that one dimension is doubled. The advantage of model 2 is that it predicts one of two observed weak reflections not predicted by model 1, and it predicts a second reflection near the critical reflection at 1/3.8 nm^{-1} (Table 1). Both predicted reflections near 1/3.8 nm^{-1} arise from important structural features of the model (Fig. 3*B*) and thus both could be present but unresolved.

If the unit cell in model 2 is doubled (Fig. 3*B*), the second of the two reflections not predicted by model 1 is present and the fit to the observed reflection at 1/2.651 nm^{-1} is markedly improved (Table 1, larger cell). That is, the true unit cell may contain four compressed microfibrils. If so, they must in some sense be non-equivalent. The situation may be analogous to the earlier interpretation[12–14] of the X-ray diffraction data in which the unit cell contained four 5-fold microfibrils related by a 4-fold screw axis. Therefore, some of the arguments based on that model may still be valid. For example, the larger unit cell is consistent with recent electron microscopic evidence[5] for an 8-nm unit in collagen fibrils. Regularities in the amino acid sequence have also been interpreted in terms of a 4-fold screw axis[9,10], results which are not inconsistent with the distortion required for hexagonal packing of supercoiled molecules.

As in model 1, molecules in model 2 may be straight-tilted or supercoiled. The same arguments hold. A somewhat stronger case may be made for supercoiling in model 2 as the tilting vectors arising from the supercoil will be largely parallel to the long axes of the compressed microfibril cross-sections, which lie in the 1.264-nm planes. As already noted, this spacing gives rise to an equatorial reflection whereas the 1.369- and 1.328-nm planes give rise to reflections that are off-equatorial. However, a detailed analysis has not been done.

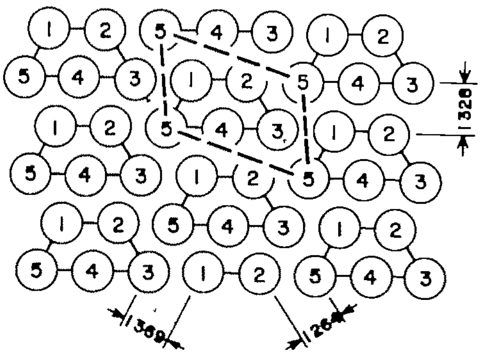

Fig. 2 Model 1. One possible arrangement of molecules in a native collagen fibril. The lines join sets of five molecules constituting a microfibril (Fig. 1). The lattice spacings are given in nanometres. The unit cell (dashed lines) has dimensions *a* = 2.668 nm, *b* = 4.136 nm and γ = 114.04° and contains one microfibril.

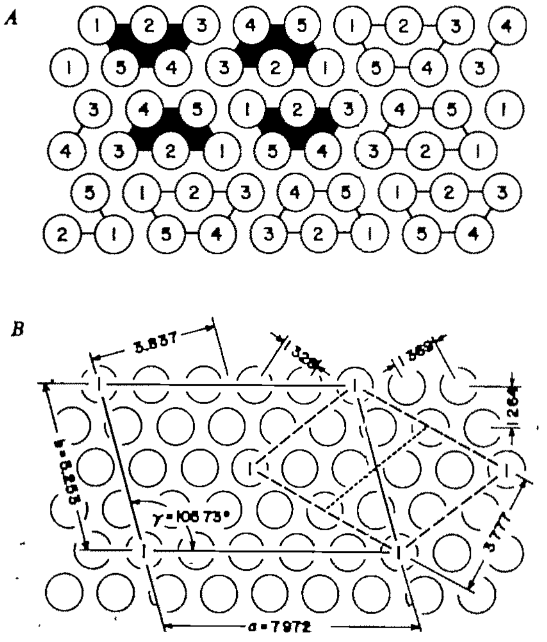

Fig. 3 Model 2. *A*, A second possible arrangement of molecules in a native collagen fibril. The lines join sets of five molecules constituting a microfibril (Fig. 1). The shading designates a group of four microfibrils which in the larger unit cell constitute the true repeating unit. *B*, The same arrangement showing the larger (solid lines) and smaller (dashed lines) unit cells, some of the major spacings and the dimensions of the larger unit cell. Distances are given in nanometres. The dimensions of the smaller unit cell are *a* = 5.335 nm, *b* = 4.136 nm and γ = 114.04°. The dotted line halves the smaller cell and defines a pseudo-cell identical to the unit cell of model 1.

Of course, the unit cell in model 1 can be doubled or quadrupled and microfibrils made non-equivalent; the unit cells of models 1 and 2 become identical. Therefore, evidence for a large unit cell does not favour one model over the other. It is also possible that different arrangements of microfibrils with varying degrees of order exist within a group of fibrils.

Further analysis and perhaps independent evidence will be needed to provide a definitive answer. What we have shown is that hexagonal packing of molecules is not inconsistent with some type of ordered microfibrillar substructure.

We thank Drs Hulmes and Miller for a copy of their manuscript[1] before its publication.

Note added in proof: We have recently learned that Katz and Li[19] in 1973 proposed the general idea that microfibrillar structures (5- and 7-stranded) could be contained within a hexagonal lattice of collagen molecules.

The bacterial cytochromes c' (ref. 1) occur in various photosynthetic and denitrifying bacteria, where they are presumed to function in electron transport[2]. Most cytochromes c' are isolated as dimeric molecules composed of two identical subunits of ~14,000 molecular weight (MW), with each polypeptide chain incorporating a protohaem IX prosthetic group covalently bound through thioether linkages formed by condensation of two cysteine side chains with the haem vinyl groups[3]. Although a similar mode of covalent haem attachment is found in members of the well studied mitochondrial cytochrome c family[4], the cytochromes c' are, in contrast, high-spin haem proteins (hence the prime designation) which bind neutral ligands[5], characteristic properties generally associated with members of the oxygen-binding globin family[6]. Here we present a preliminary structural description of the cytochrome c' derived from the photosynthetic, purple non-sulphur bacterium *Rhodospirillum molischianum*, and show that it bears little structural resemblance to members of either the cytochrome c or globin structural families. The cytochrome c' monomer structure is, instead, principally organized as a left-twisted, 4-α-helical bundle, a structural motif previously observed in several other sequentially and functionally unrelated proteins[7-13].

R. molischianum cytochrome c' crystallizes in the orthorhombic space group $P2_12_12_1$ ($a=56.5$ Å, $b=71.8$ Å, $c=75.6$ Å) with a dimeric molecule (MW ~ 29,000) in the crystallographic asymmetric unit[14]. Native and heavy atom (K_2PtCl_6 and K_2HgI_4) intensity data were collected from three crystals on the multiwire area detector developed by Xuong and co-workers at the University of California at San Diego[15,16]. Heavy atom sites for the singly substituted platinum and doubly substituted mercury derivatives were determined by deconvolution of the respective heavy atom difference Patterson maps and referred to a common origin by calculating a difference Fourier map for each derivative based on phases derived from the other. Anomalous dispersion effects arising from the platinum and mercury derivatives were incorporated into the final phase refinement cycles (Table 1) as described by Matthews[17], giving an overall figure of merit of 0.72 for the 10,667 independent reflections phased to 2.5 Å resolution. The resulting map was contoured to allow construction of a 2 cm Å^{-1} Kendrew model of the dimer, which was built according to the established amino acid sequence of the molecule[18]. Preliminary atomic coordinates were measured from the model using an electro-mechanical optical superpositioning device[19]. Figure 1 shows a representative view of the electron density of the 2.5 Å resolution map, whose overall quality was sufficient to trace unambiguously the backbone chain and establish the majority of the side-chain conformations.

Table 1 Data collection and phase refinement for *R. molischianum* cytochrome c'

Crystal	Native	K_2PtCl_6*	K_2HgI_4†
No. of intensities measured (observations/unique reflections)	81,380/18,513	71,072/10,881	67,994/14,082
Scaling R	0.062	0.074	0.068
No. of reflections used in phase refinement	10,667	10,372	10,540
R_C	—	0.55	0.54
R_K	—	0.084	0.095
E/F_H	—	0.37	0.48
E''/E	—	0.23	0.25

The overall figure of merit, m, to 2.5 Å resolution is 0.72. E, E'' = r.m.s. differences between observed and calculated heavy atom and anomalous dispersion contributions, respectively. F_H = mean heavy atom contribution.

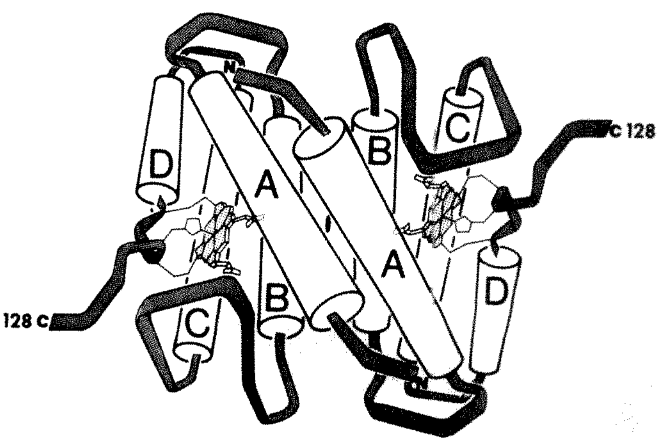
Fig. 2 Schematic representation of the *R. molischianum* cytochrome *c′* dimer viewed down the molecular diad axis. The cytochrome *c′* monomers are principally composed of four, roughly parallel α-helices shown here as sequentially labelled cylinders. The left-twisted 4-α-helical arrangement of the monomers is qualitatively repeated at the subunit interface, due to the pairwise interaction of two helices from each subunit. The haem groups, situated at one end of the helical bundle, are orientated roughly parallel to each other and to the subunit interface, with their propionate side chains pointed towards the molecular surface. Regions of essentially extended polypeptide chain (shaded) connect and terminate the helices in each monomer. Approximately one-half of the residues in the molecule exist in an α-helical conformation.



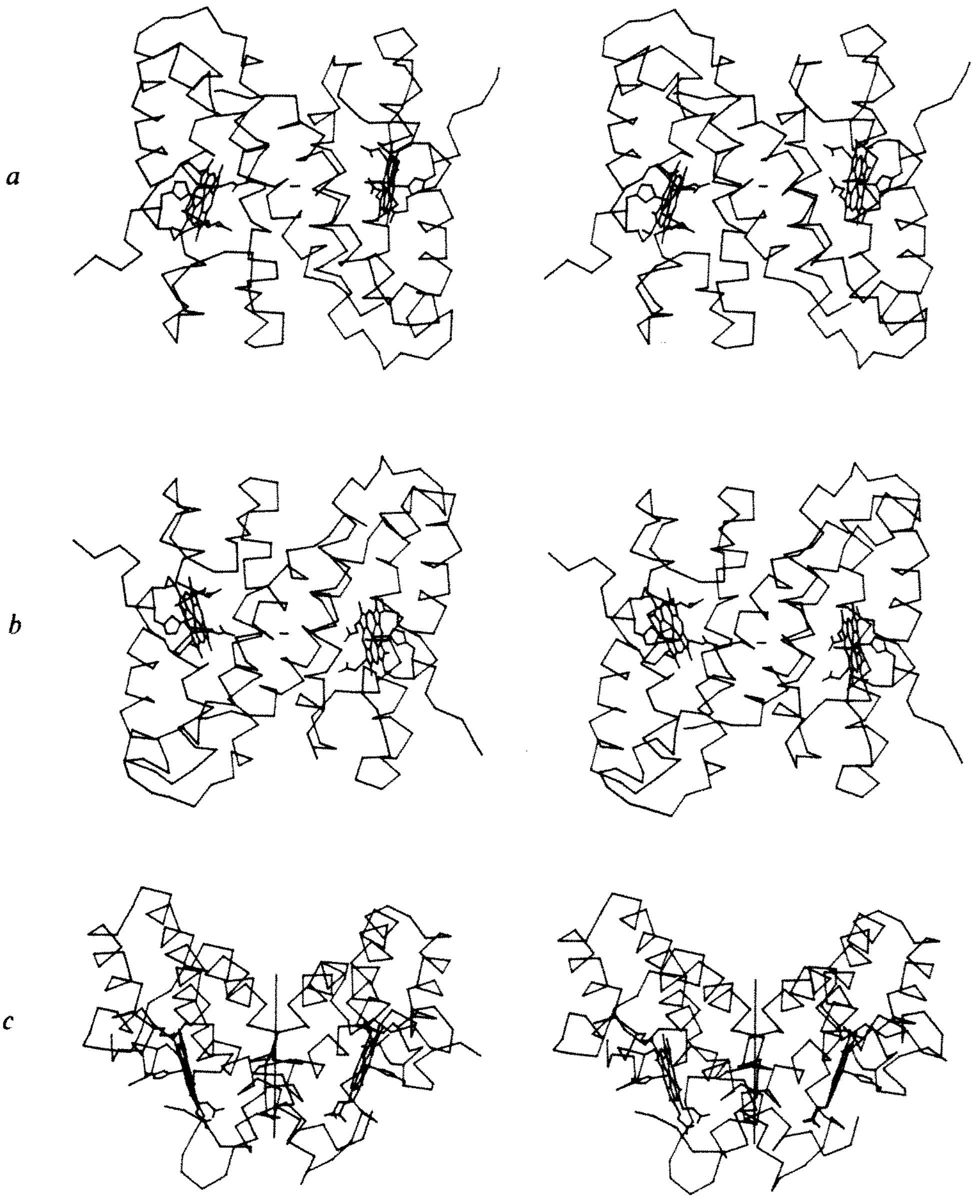


Fig. 3 Stereoscopic α-carbon drawings of *R. molischianum* cytochrome *c′*. *a* Shows the structure from the same aspect as Fig. 2, looking down the molecular diad axis at the molecular surface which has greatest haem exposure. The haem prosthetic groups, covalently bound near the carboxy termini, are separated in space by the two A helices, one from each subunit, which form the closest inter-helical interaction in the entire structure. The regions of extended polypeptide between helices are orientated towards this 'haem side' of the dimer. In contrast, the opposite side shown in *b* is primarily composed of α-helices. The ~110° crossing angle between subunits gives the dimer a V-shaded appearance when viewed normal to the diad axis as in *c*.

Figures 2 and 3 show schematic and α-carbon stereo representations of the cytochrome *c′* dimer. Each subunit is composed of a 128-amino acid polypeptide chain incorporating a covalently bound protohaem IX prosthetic group. Structurally, each monomer is composed of four, roughly parallel α-helices (sequentially labelled A–D) connected by more or less extended loops which join adjacent helix ends. Additional regions of essentially extended polypeptide chain occur at both the amino and carboxy termini of the molecule, the latter providing the covalent attachment points for the haem prosthetic group. The α-helices of the monomer pack with an overall left-handed twist along the direction of the helix axes. However, the helices of the bundle distinctly diverge at one end to accommodate the haem prosthetic group.

The cytochrome *c′* monomers pack about a non-crystallographic diad axis at an angle between bundle axes of approximately 110°, giving the dimer a V-shaped appearance when viewed normal to the diad symmetry axis (Fig. 3*c*). The subunit interaction is mediated by the pairwise interaction of the A and B helices of each monomer, to give a 4-α-helical, left-twisted AA′–BB′ bundle at the dimer interface whose geometry is qualitatively similar to the arrangement of the helices within each monomer. The fact that the subunit interface interactions are similar to those within each monomer, both with respect to the hydrophobic nature of the amino acid residues involved and the overall similarity in extent and geometry of the α-helical interactions, provides an explanation for the observation that some homologous species of cytochrome *c′* can only be dissociated in conditions which lead to protein denaturation[20].

The protohaem IX prosthetic group in cytochrome *c′* forms three covalent attachments with the polypeptide chain, all of which are derived from the pentapeptide sequence Cys-X-X-Cys-His at residues 118–122. Two of these are the haem thioether linkages which serve to orientate the haem so that its propionate-substituted edge lies roughly parallel to each monomer bundle axis, and roughly perpendicular to the dimer diad axis. The third haem–polypeptide interaction is formed by the fifth position axial ligation of the ferric haem iron with $N^{\varepsilon 2}$ of His 122. The sixth ligand ferric iron coordination site is either unoccupied or ligated by a solvent molecule, consistent with the high-spin character of the haem iron[21,22]. Space-filling representations of the molecular structure show the haem environment to be highly asymmetric, with the imidazole side chain of the fifth haem iron ligand and two-thirds of the corresponding haem surface being exposed to the solvent. In contrast, the distal haem surface, which faces towards the dimer interface, is surrounded by aromatic or otherwise hydrophobic amino acid residues. Many of these packing interactions are provided by residues of the A helix, which are orientated so as to restrict access of exogenous ligands to the sixth haem iron coordination site through the most direct route to the molecular surface.

Because of the geometry of the monomer–monomer packing interaction, both haem groups of the molecule are situated on the same face of the dimer in nearly parallel orientation. Although this structural arrangement suggests that the haems of cytochrome *c′* may be situated so as to allow their simultaneous interaction with some physiological oxidoreductase, it is equally possible that this arrangement provides the basis for inter-haem communication in the molecule. Of relevance to the latter possibility is the fact that the 24 Å iron–iron vector is nearly coincident with the A–A′ inter-helix contact normal vector, which at 6.0 Å is the shortest inter-helical interaction in the entire molecule. As described above, it is residues of the A helix which principally provide the packing interactions about the unliganded, distal haem surface. Thus, it seems possible that any local structural alterations accompanying haem ligation or oxidoreduction could be communicated between the haems due to the intimacy of the A–A′ helix packing interaction.

The principal similarity between the cytochromes *c′* and the mitochondrial cytochromes *c* is the common presence of a Cys-X-X-Cys-His sequence which provides the covalent attachment points and fifth axial ligand for the haem prosthetic group. Otherwise, the molecules are distinctly different with respect to overall chain folding, sequential location of the haem-binding peptide, spin state and extent of haem exposure to the solvent. Similarly, almost the only major feature shared by the cytochromes *c′* and the globins is their high-spin haem character, the general nature of the haem environments being otherwise quite different in the two molecules. Nevertheless, the fact that the cytochromes *c′* and globins are both high-spin haem proteins which can bind exogenous ligands and occur in both monomeric and higher aggregate forms[2,6], suggests interesting parallels between these molecules which require further investigation.

This work and facilities were supported by NIH grants GM18528-11 to M.D.K., RCDAK04EY0013 to M.A.C., GM20102, RR00757, to N.H.X., and GM21534, GM25664 to F.R.S. and NSF grants GB36019X to M.D.K., PCM7804349 to M.A.C. and PCM7722495 to N.H.X. Structure determination was done in partial fulfilment of the requirements for a PhD at the University of Arizona by P.C.W. who was a Carl S. Marvel Fellow. F.R.S. received a Dreyfus Teacher-Scholar Award and the University of Arizona Computer Center also provided support.

Molecular dynamics of ferrocytochrome *c*

Scott H. Northrup, Michael R. Pear & J. Andrew McCammon*

Department of Chemistry, University of Houston, Houston, Texas 77004

Martin Karplus

Department of Chemistry, Harvard University, Cambridge, Massachusetts 02138

The cytochromes *c* function as single-electron carriers in the mitochondrial electron transport chain[1,2]. The native structures of the proteins from different species are quite similar[1,2], as are the structures of the reduced and oxidized forms[3,4]. The 103-residue polypeptide chain of tuna cytochrome *c* contains 5 α-helical segments (residues 2–13, 50–54, 61–69, 71–74, 89–100); the haem group is almost completely buried in a hydrophobic pocket and is covalently bonded to the polypeptide chain by thioether linkages involving Cys 14 and Cys 17 and by linkages to the iron involving His 18 and Met 80 (refs 1–3). NMR[5,6] and hydrogen exchange[7,8] studies indicate significant internal mobility in cytochrome *c*. In spite of the apparent similarity of the time-average structures of the reduced and oxidized proteins, the structural fluctuations are significantly larger in the latter form[2,7,8]. It has been suggested that the internal motions have a role in the electron transfer mechanism[2,9]. A 16-ps computer simulation[10–14] of the atomic motions in reduced tuna cytochrome *c* has now been completed; this reveals various correlations between the magnitudes of the atomic position fluctuations and the structural features of the protein.

The dynamical simulation method used here is similar to that used in earlier studies of the pancreatic trypsin inhibitor[10]. The protein potential energy function consists of a sum of terms associated with bonds, bond angles, dihedral angles, hydrogen bonds and nonbonded (van der Waals and electrostatic) interactions. The partial charges of the atoms have been reduced according to the distances of the atoms from the protein centre to approximate dielectric screening effects due to surrounding water[15]. To begin the simulation, the protein was dynamically equilibrated as follows. The X-ray structure[16,17] was first subjected to 100 cycles of steepest descent energy minimization[18] to relax any sizeable local stresses. The atoms were then assigned random maxwellian velocities corresponding to a temperature of 50 K and the classical equations of motion were solved for a 2-ps period using the fifth order Gear algorithm[10]. Repeated velocity assignments corresponding to increasing temperatures followed by 2-ps periods of dynamical relaxation were used to bring the protein to a final average temperature of 297 K; the total period of temperature adjustment was 12 ps. To equilibrate the protein further, the dynamics was continued for 20 ps; the average temperature remained at 297 K. The actual simulation was obtained by continuing the run for an additional 16 ps.

---

*To whom reprint requests should be addressed.

The time-average structure from the simulation is quite similar to the 2.0-Å resolution X-ray structure[16], except that several exposed, flexible sidechains have folded down on to the protein surface. The average r.m.s. deviation of C^α positions is 1.58 Å, while that for all heavy atoms is 1.90 Å. There is some correlation between the residues with the largest deviations and those which have somewhat different positions in different crystal structures[3]. The largest deviations occur at the protein surface, particularly in the exposed sidechains of Lys 25, 27, 39, 72, 73 and 87 and Arg 38, where some atoms moved nearly 9 Å. Concomitant with these sidechain shifts, the accessible contact surface area of the protein as determined by Richards' method[19] with a probe of 1.4-Å radius decreased from 1,751 Å^2 for the X-ray structure to 1,440 Å^2 for the dynamical average structure.

The fluctuations of the atoms about their average positions are sizeable and show interesting correlations with the time-average structure. The average r.m.s. fluctuation of the C^α positions is 0.70 Å and that of all heavy atoms is 0.85 Å. To compare interior and exterior fluctuations, averages were calculated for atoms in spherical shells of 3-Å thickness centred at the protein centre of mass. Shells with outer radii greater than 12 Å contain exterior atoms, because the average atomic density decreases rapidly with increasing radius for such shells. In the interior, the fluctuations are relatively small and increase slowly with shell size; the average r.m.s. fluctuations are 0.66, 0.70 and 0.73 Å for shells with outer radii of 6, 9 and 12 Å, respectively. In the exterior, the corresponding results are 0.98, 1.05 and 1.64 Å for shells with outer radii of 15, 18 and 21 Å, respectively. The average r.m.s. fluctuations for individual residues are correlated with their relative surface exposures in the time-average structure, with more exposed residues exhibiting larger fluctuations (Fig. 1*a*,*c*).

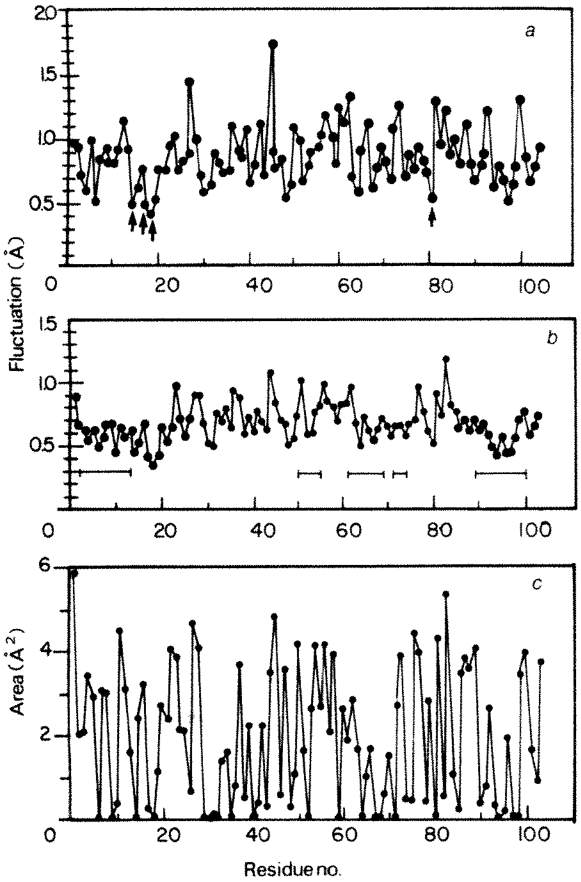

Fig. 1 *a*, Average r.m.s. atomic position fluctuation for each residue. Arrows indicate the residues (14, 17, 18 and 80) that are covalently bonded to the haem group. *b*, r.m.s. position fluctuations of the C^α atoms. Bars are drawn to indicate the α-helical segments. *c*, Exposed surface area of each residue in the dynamical average structure, divided by the number of heavy atoms in the residue. The exposed surface area is the accessible contact surface area as calculated by Richards's method[19] using a probe of 1.4-Å radius.

The haem group is expected to be relatively rigid due to the extensive pi electron delocalization in its ring system. The average r.m.s. fluctuation of the haem atom positions is 0.51 Å, which is significantly smaller than that of the other atoms in the protein interior. To assess the effect of the haem group on the mobility of nearby polypeptide atoms, a haem neighbourhood was defined by two cylindrical disks of 6-Å radius and 6-Å thickness lying on either side of the haem and coaxial with the iron. The average r.m.s. fluctuation of the 56 heavy atoms in this neighbourhood is 0.64 Å, compared with 0.72 Å for the other 411 heavy atoms of the protein interior. The average r.m.s. fluctuations are larger in the disk on the Met 80 side (0.71 Å) than in the disk on the His 18 side (0.56 Å).

The position fluctuations of the backbone atoms show a correlation with secondary structure (Fig. 1*b*). The average r.m.s. fluctuation of C^α positions in the α helices is 0.65 Å, while that of the other C^α atoms is 0.72 Å. Within the α helices, residues which have the smallest surface exposures tend to have the smallest fluctuations (for example, residues 6, 9, 10, 52, 64, 67, 71 and 74 in Fig. 1*a*,*c*).

The correlations of atomic mobility with structural features in cytochrome c are in general accord with the results of theoretical[10–14] and experimental[20,21] studies of other proteins. Relatively small fluctuations of interior atoms and of backbone atoms in regions of secondary structure were found in simulation studies of the pancreatic trypsin inhibitor[11–14] and in analyses of the X-ray temperature factors for myoglobin[20] and lysozyme[21]. The myoglobin study[20] also revealed an asymmetrical reduction in the fluctuations of protein atoms on the two sides of the haem group.

The dynamical simulation described here is being repeated with more rigorous equilibration. The magnitudes of the fluctuations will apparently be somewhat smaller, but the structural correlations will be unchanged. Detailed accounts of this simulation and of a planned simulation of the oxidized form will be presented in the future.

MATTERS ARISING

Cometary evidence against the solar companion

WILKINS[1] has concluded, from his computation of the perturbation of cometary orbits, that the Sun cannot have a fast moving neutron star as a companion. His results exclude all objects other than a massive black hole ($350 M_\odot$) with velocity $\gtrsim 10^2\,\mathrm{km\,s^{-1}}$ as candidates for the solar companion whose existence was proposed by Harrison[2]. In a previous paper[3] I performed a closely similar calculation and concluded that an object of solar mass cannot be ruled out as a solar companion on the basis of cometary evidence, provided that its speed exceeds $20\,\mathrm{km\,s^{-1}}$. Our results are thus in conflict by several orders of magnitude.

In equation (8) of Wilkins' paper, the perturbation of a comet's energy is given, to an order of magnitude, by the difference in the potential exerted by the companion at the end points of the comet's orbit, that is

$$\Delta E \sim \frac{Gm_c}{D} \cdot \frac{r_{\odot i} \cos\theta}{D}.$$

If m_c and D are now increased, such that the ratio m_c/D^2 remains constant, the resulting perturbation is unchanged. This means that the perturbation as calculated by Wilkins would still exist if the Sun and comet were freely falling in a uniform gravitational field; the calculation must therefore be in error.

A correct evluation of the perturbation of the cometary orbit uses the gradient of the disturbing function due to the companion[4], as in equation (9) of ref. 3. In this case the perturbation

$$\Delta\left(\frac{1}{a}\right) \propto Gm_c/D^2 v$$

goes to zero as D becomes large, since the velocity v scales with D.

4. Smart, W. M. *Celestial Mechanics*, 9 (Longmans, London, 1953).

WILKINS REPLIES—The black hole was mentioned as only one example satisfying the luminosity criteria of Pineault[1]. But its supposed distance (15,000 AU) and mass may need to be increased severalfold.

Note that Kirk uses a different reference frame to calculate ε, the specific energy (per unit mass) of the comet (K). Kirk finds ε_I relative to the instantaneous rest frame of the Sun (S), which is accelerated by the companion (C). I, however, determine ε_F relative to a fixed inertial frame, that of the Sun at apparition. These energies increase (Δ) as follows:

$$\Delta\varepsilon_I = \int (\mathbf{f}_{CK} - \mathbf{f}_{CS}) \cdot (\mathbf{v}_K - \mathbf{v}_S)\,dt \qquad (1)$$

$$\Delta\varepsilon_F = \int \mathbf{f}_{CK} \cdot \mathbf{v}_K\,dt - \int \mathbf{f}_{KS} \cdot \mathbf{v}_S\,dt \qquad (2)$$

(In general ε_I is the total energy of the binary system K–S referred to its centre of mass, divided by its reduced mass.) Here $\mathbf{f}_{ij}$ is the force (per unit comet mass) of body i on j. Equation (1) is the integral form of Kirk's equation (9), divested of esoteric notation. Integration by parts of equation (2) yields $\Delta\varepsilon_F = \Delta[\varepsilon_I + \mathbf{v}_S \cdot (\mathbf{v}_K - \mathbf{v}_S) + \mathbf{v}_S^2/\mathbf{2}]$, which also follows from the definitions of $\varepsilon_{F,I}$. Because the cross-term vanishes for a parabolic comet and because the last term $\simeq (Gm_c/Rv_C)^2$, where $R = r_{CS}$ at apparition, is small, $\Delta\varepsilon_F \simeq \Delta\varepsilon_I$.

The discrepancy between my results and those of Kirk arose from my too-crude approximation for the first integral of equation (2), and the second integral should have been three times larger than in my equation (6). Thus I did not realize that the two integrals would cancel almost completely, leaving a difference smaller than either by about r_i/R (defined after equation (3)).

A head-on approach of C towards S, at high speed v_C = constant, can be calculated analytically. Introducing the semi-major axis a through $1/a = -2\varepsilon_I/Gm_S$, one finds

$$(1/a) = -0.22(3\cos^2\psi - 1) \times (m_C/m_S)[(r_i/R)^2 + 0(r_i^3/R^3)]R^{-1} \qquad (3)$$

ψ is the polar angle from axis CS about S, of the comet's zero-energy radial infall to the Sun; the comet's distance from the Sun at a time $2R/v_C$ before apparition is denoted by $r_i = (9Gm_S/2)^{\frac{1}{3}}(2R/v_C)^{\frac{2}{3}}$. Averaging over the isotropic flux of comets, one finds that the mean value of $1/a$ is unchanged, but its r.m.s. spread due to C, equals $\sigma_C = 0.2 \times (m_C/m_S)(r_i/R)^2 R^{-1}$. Demanding that $\sigma_C < 2 \times 10^{-5}\,\mathrm{AU}^{-1}$ (as for comets without non-gravitational forces[2]) and setting $g_C = Gm_C/R^2$ yields the constraint

$$(g_C/10^{-6}\,\mathrm{cm}^{-2})^{\frac{3}{2}}(R/10^3\,\mathrm{AU})^{\frac{1}{2}} \times (30\,\mathrm{km\,s^{-1}}/v_C)^2 < 0.86 \qquad (4)$$

If, for example, the first two factors are each unity, this gives $v_C > 32\,\mathrm{km\,s^{-1}}$, exceeding Kirk's estimate. Actually, the lower limit should be still larger because an off-side collision prolongs the epoch of closest approach and unless v_C were augmented, σ_C would increase.

The smallness of Neptune's perturbations, however, forbids a close encounter unless the companion has speeds well above $10^2\,\mathrm{km\,s^{-1}}$. Let $T = 2R/v_C$ be the effective transit time (10^2 yr for $R = 10^3$ AU, $v_C = 10^2\,\mathrm{km\,s^{-1}}$). Neptune's known perturbations roughly limit

$$(Gm_C/R^3) \times \begin{cases} & ,\ T > 170\,\mathrm{yr} \quad (a) \\ (T/170\,\mathrm{yr})^2, & T < 170\,\mathrm{yr} \quad (b) \end{cases} \qquad (5)$$

to less[3] than $1.2 \times 10^{-24}\,\mathrm{s}^{-2}$. Case (a) yields

$$R > 5.3 \times 10^4\,\mathrm{AU}\,(g_C/10^{-6}\,\mathrm{cm\,s^{-2}}) \qquad (6)$$

This excludes a close approach lasting more than 170 yr. Only a briefer encounter, case (b), permits $R \sim 10^3$ AU, if the speed is high enough:

$$v_C > 440\,\mathrm{km\,s^{-1}}(R/10^3\,\mathrm{AU}) \times (g_C/10^{-6}\,\mathrm{cm\,s^{-2}})^{\frac{1}{2}} \qquad (7)$$

This easily predominates over the cometary limit above.

My article gave a limit on R three times smaller than in equation (6) because I had adopted the allowed tidal gradient[4] for a companion in circular orbit at $r_{CS} \leqq 75$ AU, which turns out unexpectedly to be three times larger than the value[3] for $r_{CS} = 150-600$ AU. Equations (5), (6) use the latter value, assuming that it has already stabilized at its large-distance limit.

Note added in proof: In work to be published I confirm that the right side of equation (4) never exceeds 0.86 for any fast encounter.

Redshifts and distances

In the recent review by Burbidge[1] I had expected to find a wide ranging discussion of all the important evidence both for and against cosmological origin of quasar redshifts. However, no mention is made of how the continuity of properties between galaxies and QSOs and amongst QSOs themselves supports the cosmological interpretation of all QSO redshifts, or how the number/redshift distribution of bright QSOs is found to be incompatible with non-cosmological redshifts[2]. Even within his rather restricted brief (dealing only with QSO/galaxy associations) Burbidge has failed to include results which do not favour his conclusions. He cites the existence of five 3C QSOs near bright galaxies as evidence for non-cosmological redshifts[3]. However, he does not mention several subsequent investigations[4–6] of much larger samples of QSOs which failed to detect a statistically significant excess of close pairs compared with that expected by chance for a random distribution of quasars and galaxies.

Burbidge ignores published criticism of at least one of the arguments he uses. His Fig. 1 shows a correlation between galaxy redshift and separation of the galaxy from the associated QSO, and this is taken as good evidence for the galaxies and the QSOs being physically associated. Nevertheless, it has been pointed out by Noerdlinger[7] and Browne and Cohen[5] that when pairs selected from heterogeneous samples are used, strong selection effects inevitably give rise to a redshift–separation correlation roughly of the form presented by Burbidge. Note that not only is the legend to Fig. 1 confusing because it refers to a symbol not present in the diagram, but also the line shown is certainly not the best fit to all the points.

Finally, to establish the reality of non-cosmological redshifts systematic investigations of well defined samples must be undertaken. Then, at least, it will be unnecessary to resort to estimating Arp's allocation of telescope time as a way of assessing the statistical significance of the results.

BURBIDGE REPLIES—Browne is clearly strongly biased in favour of the cosmological redshift hypothesis, because none of his criticisms considers that I omitted discussion of the many problems associated with that hypothesis. His remarks imply that I have omitted only work critical of the evidence for non-cosmological redshifts. In fact I attempted to demonstrate that there is good evidence for the existence of both cosmological and non-cosmological redshifts. I spent more time discussing the Arp evidence to attempt to redress the balance as the normal practice is to quote Stockton and ignore Arp.

In a previous review article[1], which was far more wide-ranging, I did discuss all of the earlier evidence for association between galaxies and QSOs. In my later article I only quoted the 3C survey evidence for historical reasons, as I was concerned with an account of the more recent work. I had overlooked the paper of Browne and Cohen[2] which should certainly be taken into account in evaluating my Fig. 1.

The results of Green and Schmidt[3] lay outside my restricted brief. Had I discussed their results I would also have had to discuss other evidence, such as the existence of peaks and periodicities in the redshift distribution, the Compton problem, the Hubble diagram for QSOs, and the existence of so-called superlight velocities, all of which have to be discussed and evaluated before a balanced picture can be obtained.

The Lizard complex as an ophiolite

KIRBY[1] has stated "Of prime importance to the proposed ophiolitic nature of the complex is the relationship between peridotite and gabbro... Green's lithological map and the author's field observations show that the gabbro is further restricted to the primary-type peridotite and does not occur in the recrystallized varieties except as isolated and deformed scraps".

This is an oversimplification: Green[2] refers to the mineralogical assemblage within the primary peridotite and not to a completely unrecrystallized condition. He wrote that the "coarse anhedral texture with curving grain boundaries" was igneous but concluded that "the primary peridotite assemblage has a...texture compatible with deep seated igneous crystallization or at least of crystallization in a hydrostatic or near hydrostatic stress environment. Although the banding and incipient augen foliation are ascribed to crystalline flow of the body at a very early stage, this flow has occurred at a rate accommodated in the rock without cataclasis or creation of granulitic or schistose fabrics".

All the evidence of Flett[3], Green[4] and Rothstein[5,6] taken together suggests that the rocks within the mass of primary peridotite south of Coverack have undergone a near solid-state deformation, although within this primary assemblage peridotite, in the lherzolites and harzburgites containing little or no troctolite, there are relics of primary textures and structures resembling crescumulates rather than settled gravity stratified cumulates. The deformation of the primary assemblage structures in this area is part of the continuity which exists between the two major areas of peridotite with respect to the trends of the near vertical foliation and banding, the primary mineralogy (to be reported elsewhere), and the rare earth content[7]. It would seem reasonable, therefore, to regard the peridotite as originally one body (albeit the eastern part not quite so heavily deformed as the western part). This being so the continuity extends between the two parts of the peridotite and the hornblende schists, and is broken, one way or the other, by the cross-cutting field relationships of the gabbro. This implies a contrary view to that expressed by Kirby[1] "that the association of peridotite and gabbro existed before their juxtapositioning with the surrounding hornblende schists (the event in which some of the peridotite was recrystallized)". This does not preclude the possibility of a deformed and recrystallized eastern part of the peridotite undergoing some partial melting.

KIRBY REPLIES—The interrelationships between the foliations in the primary peridotite and those in the secondary peridotites and schists are not well

0028–0836/80/290307–02$01.00

exposed anywhere. However, on the south-east coast of the Lizard peninsular the foliation and banding in the primary peridotite, although mostly poorly defined, dips at moderate angles. The foliation in the underlying hornblende schists is subhorizontal. Green[1] described an increase in the metamorphic grade of the schists in approaching the overlying peridotite, demonstrating that the peridotite was the local heat source. The non-parallelism of the foliations implies that there is not a continuum in deformations as proposed by Rothstein. It shows that the development of foliations in the schists is a later event. In the absence of a continuum of deformation, the cross-cutting relationships of gabbro in primary peridotite do not imply that the gabbro was intruded after the development of the hornblende schists and secondary peridotites. Gabbro is very rare in the secondary peridotites and where it does occur it is invariably highly deformed. I have seen no gabbro intrusive into hornblende schists. These admittedly simplified observations suggest that the gabbro was intruded into the primary peridotite before the deformational event which led to the formation of the hornblende schists and secondary peridotites, and further that it was preferentially intruded into parts of the primary peridotite that generally escaped later deformation. These relationships are typical of ophiolite complexes in which gabbro intrudes peridotite with mantle-tectonite fabrics towards the top of the complex whereas at the base, this peridotite contains little or no gabbro and is overprinted by a later deformation associated with the formation of hornblende schists, as summarized recently by Nicholas *et al.*[3].

Evolution of bacterial cytochromes c_2

IN an attempt to uncover the phylogeny of cytochromes c_2, Ambler *et al.*[1] recently compared 13 cytochrome c_2 primary structures. The molecules they compared were from purple photosynthetic bacteria and could be classified on the basis of the length of their interhelical loops as belonging to three different cytochrome c_2 subclasses[2] (so-called short, medium and long cytochromes c_2). The molecular phylogeny reported by Ambler *et al.* is at apparent variance with a morphological one[3] and we should like to comment on this challenging fact.

Fig. 1 Phylogenetic trees[7] of bacterial cytochromes c_2. For abbreviations see Table 1. *a*, Tree constructed using the similarity matrix of the unstructured segments. *b*, Tree constructed using the similarity matrix of the secondary structure segments. Numbers give branch lengths in arbitrary units.

The phylogeny of Ambler *et al.* is based on a per cent similarity matrix of the whole primary structures (a matrix element represents % of identical amino acid residues found in a pair of primary structures aligned to maximize homology). It has been shown previously[4,5] that different segments of the primary structure which correspond to individual secondary structure elements (helices, pleated sheets, turns) evolve at a different rate (that is, they display different percentages of similarity) according to the different functional constraints imposed on them. We have therefore constructed two similarity matrices of the 13 cytochrome c_2 structures: the first contains per cent similarities of those primary structure segments which are involved in the secondary structures, the second consists of per cent similarities displayed by unstructured segments. (Assignment of the segments to the secondary structure

Numbers represent per cent identical amino acid residues in a pair of the primary structure segments compared. Above the diagonal (upper right): numbers obtained for segments with secondary structure; below the diagonal (lower left): numbers obtained for unstructured segments. Abbreviations *Rs.*, *Rhodospirillum*; *Rp.*, *Rhodopseudomonas*; *Rm.*, *Rhodomicrobium*.

0028-0836/80/290308-02$01.00

elements—four α-helices, two 3_{10} helices and three turns—is based on the three-dimensional structure of *Rhodospirillum rubrum* cytochrome c_2 (ref. 6) deposited with the Brookhaven Protein Data Bank.) The two matrices computed in this way clearly differ from one another (see Table 1). When phylogenetic trees[7] are constructed of them (Fig. 1), these also differ.

There are 135 amino acid positions in the cytochromes c_2, half of which (69) form helices and turns, the other half (66) being involved in unstructured loops. There is therefore no bias in favour of any of the two groups considered. They do differ evolutionarily, however, in that the secondary structure segments predominantly evolved by amino acid replacements whereas the unstructured loops harbour two-thirds of the deletions responsible for a distinction of the short, medium and long cytochromes c_2.

Thus, the following important points emerge as far as evolution of cytochromes c_2 is concerned. (1) Different phylogenies can be proposed for different segments of homologous primary structures, the phylogeny of the whole structure being a weighted average of the partial ones. (2) Because the differences can be correlated with typical features of the secondary structure, they seem to result from structural, rather then genetic causes.

Bacterial phylogeny is a notoriously difficult subject. Dickerson[8] and Woese *et al*[9]. have already tried to reconcile the cytochrome c_2 dilemma; this note, far from attempting to solve all the existing questions, aims at delineating a new approach to them.

We thank Dr Edgar Haber for discussions and for facilities used in the preparation of this manuscript.

Methotrexate binding to dihydrofolate reductase

RECENTLY, in discussing dihydrofolate reductase, Gready[1] described, with the emphasis on our paper[2], the finding that the inhibitor, methotrexate, binds to the enzyme with its pteridine ring 'upside down' with respect to the substrates dihydrofolate and folate. It is essential to point out that the most important observations leading to this conclusion were made by others.

In their report of the crystal structure of the enzyme–methotrexate–NADPH complex, Matthews *et al.*[3] discussed the implications for the stereochemistry of the reaction and specifically recognized the possibility that the substrates might bind the other way up. Shortly thereafter, Fontecilla-Camps *et al.*[4] determined the absolute configuration of 5,10-methenyl-tetrahydrofolate (which can be related to that of tetrahydrofolate itself; see ref. 2). This revealed the stereochemistry of reduction of dihydrofolate at C6, and by comparison with the results of Matthews *et al.*, showed that dihydrofolate does bind the other way up from methotrexate. This was pointed out by Hitchings[5]. Our NMR experiments extended this to folate, showing that both substrates have the same orientation on the enzyme, which, from the crystallographic work, differs from that adopted by methotrexate.

The interesting finding that substrates and structurally analogous inhibitors bind to dihydrofolate reductase in quite different orientations thus arises from a comparison of a number of separate observations.

Effects of the Earth's rotation rate on climate

HUNT'S[1] investigation of the meteorological effects of a faster rotating Earth has application to palaeoclimatology, but his findings cannot explain the occurrence or character of the several late Precambrian glaciations.

Hunt's[1] article does not distinguish between middle and late Precambrian. Late Precambrian glaciation occurred $0.95–0.60\times10^9$ yr ago[3–5], whereas glaciation is unknown during the middle Precambrian $\sim1.5\times10^9$ yr ago[3]. Pannella's[2] curve of length of year suggests a 19–20-h day during the late Precambrian. Using Hunt's[1] Fig. 4, an Equator-to-Pole temperature difference of ~41 K and poles ~4 K colder than at present accordingly are indicated for late Precambrian glacial time; these estimations assume an obliquity of the ecliptic near that of today, which geological[3–7] and geophysical[3,5,8] data suggest may be invalid.

In the Precambrian conditions predicted by Hunt's[1] model—an increased Equator-to-Pole temperature gradient, with equatorial regions warmer and polar regions colder than those of today—glaciation would be confined to high palaeolatitudes, while low palaeolatitudes remained ice-free. Available palaeomagnetic data[3,5,8] reveal, however, a dominant picture of low palaeolatitude (~0–40°) glaciation in late Precambrian time; although some of the daata are difficult to interpret[9], circumpolar models of glaciation can be ruled out. Furthermore, Hunt's[1] findings cannot explain the marked episodicity of the seven or more glaciations since the middle Precambrian[3,4].

The major application of Hunt's[1] model lies in testing explanations of low-palaeolatitude glaciation in the late Precambrian. The concept of global glaciation[3,8] as a cause of preferred low-palaeolatitude glaciation is difficult to reconcile with an Earth possessing a warmer Equator and an Equator-to-Pole temperature gradient greater than at present. The alternative hypothesis of an increased obliquity of the ecliptic ($\gtrsim 54°$) in late Precambrian time[3–8] to reduce equatorial insolation and thereby confine glaciation to relatively low palaeolatitudes explains the data better.

HUNT REPLIES—Current knowledge regarding climatic conditions during the Precambrian is fragmentary and subject to differing interpretations. However, there is considerably more information available than I was aware of, mainly in the geological literature, and I thank Dr Williams for providing very interesting data. Frakes[1] suggests that glacial conditions prevailed 2,300 Myr ago, followed by a warm period extending to 950 Myr when an interval of episodic ice ages commenced, terminating at about 600 Myr (ref. 2). If, as I suggested[3], 1,500 Myr ago the Earth was rotating 2–2.5 times faster than now with a somewhat smaller obliquity, climatic conditions should have been most conducive to an ice age. Thus the warm period which apparently then existed implies some very marked difference between the model and the actual atmosphere. What this difference was remains a mystery! With regard to the late Precambrian (600–1,000 Myr ago) when the Earth's rotation was closer to its present rate, Williams[2] suggests that glaciation was confined to low and middle latitudes, attributable to the Earth's obliquity then exceeding 54°. Clearly any such obliquity variations would create climatic conditions completely different from those of my model regardless of rotation rate effects.

The concept of climatic changes induced by obliquity variations has considerable attractions, but also unresolved problems. Williams[2] has suggested an obliquity cycle with a period of over 1,000 Myr and a total amplitude exceeding 54°. Wolfe[4], from Tertiary palaeobotanical data, has deduced obliquity variations of up to 25° in ~25 Myr. No mechanism is advanced to account for these obliquity changes. The absence of an identifiable mechanism, however, should not preclude them from consideration; rather it should stimulate a search for the cause. If such obliquity changes did occur this implies that current understanding of the Earth–Moon dynamical interaction over the ages as presented by MacDonald[5], for example, is deficient. The rotational period and obliquity variations with time shown in my Fig. 1 (ref. 3) were taken from MacDonald's[5] calculations, and had the great attraction of being dynamically based and mutually consistent.

One positive way to investigate the hypothesis of obliquity-induced climatic variations is to resort to numerical modelling; as noted by Williams this approach has considerable potential. In 1980 I intend to run the same model as used in my study[3], with an obliquity of 0° and a value near 60° as an initial contribution to this fascinating area of science. It is hoped this will throw light on the combined climatic effects of an increased rotation rate and extreme values of obliquity.

Analysis of host specificity of temperate and tropical animals

IN the contingency-table analysis of the host specificity of temperate and tropical ambrosia beetles, Beaver[1] erred in using the percentages of species showing various grades of host specificity rather than the actual frequencies[2]. Depending on the sample size and the distribution of frequencies among cells, this procedure may either inflate or deflate the values of χ^2 and thus invalidate a test of independence of rows and columns. Also, Beaver[1] implied that a test of host specificity for xylomycetophagous beetles was carried out with a 2×4 table but no xylomycetophagous species was restricted to a single species of host plant. Thus, the data for this group should have been tested in a 2×3 design.

Corrected values of χ^2 for Beaver's[1] data are given in Table 1. Considering all species of both families of beetle, the evidence for increasing specialization with increasing latitude is considerably stronger than Beaver's analysis indicated. For phloeophagous species, the evidence is weaker than Beaver suggested but, for the most part, his hypothesis is strongly supported by data from this group of species. However, the data for the xylomycetophagous species are equivocal (4/6 country pairs show independence of rows and columns) and thus provide no evidence in support of Beaver's hypothesis. It is not clear whether this failure results from the small sample sizes for this group or from a fundamentally different pattern of resource utilization.

Table 1 Comparison* of the degree of specialization of feeding habits of Scolytidae and Platypodidae

	Countries compared					
Species group	Fr/Ca	Fr/Ma	Fr/Fi	Ca/Ma	Ca/Fi	Ma/Fi
All	15.085	165.121	70.169	245.781	100.747	20.505
Phloeophagous	13.058	37.753	40.718	55.899	40.905	12.110
Xylomycetophagous	1.640	19.339	2.148	9.583	4.161	5.126

*The null hypothesis states that there is no relationship between the degree of specialization and latitude. Data were tested in 2×4 (all species and phloeophagous species) or 2×3 (xylomycetophagous species) contingency tables. For 2×4 tables, critical values are 7.815, 11.345 and 16.266 for $\alpha = 0.05$, 0.01 and 0.001, respectively; corresponding critical values for 2×3 tables are 5.991, 9.210 and 13.816. The values of χ^2 comparisons among all pairs of countries are given. Ca, California; Fi, Fiji; Fr, France; Ma, West Malaysia.

BEAVER REPLIES—The point concerning the use of percentages in χ^2 tables is accepted. I had not intended to suggest that the xylomycetophagous species followed the pattern of the phloeophagous species and were less host specific in the tropics. As I noted[1], they show "a similar low specificity in both temperate and tropical regions". I think it probable that this difference from the phloeophagous species is related to the different methods of resource utilization. If the ambrosia fungi can grow in the dying or dead wood of a high proportion of the tree species present in a tropical forest, this forest may not appear more heterogeneous to an ambrosia beetle than a temperate forest.

BOOK REVIEWS

Peripatetic physicist

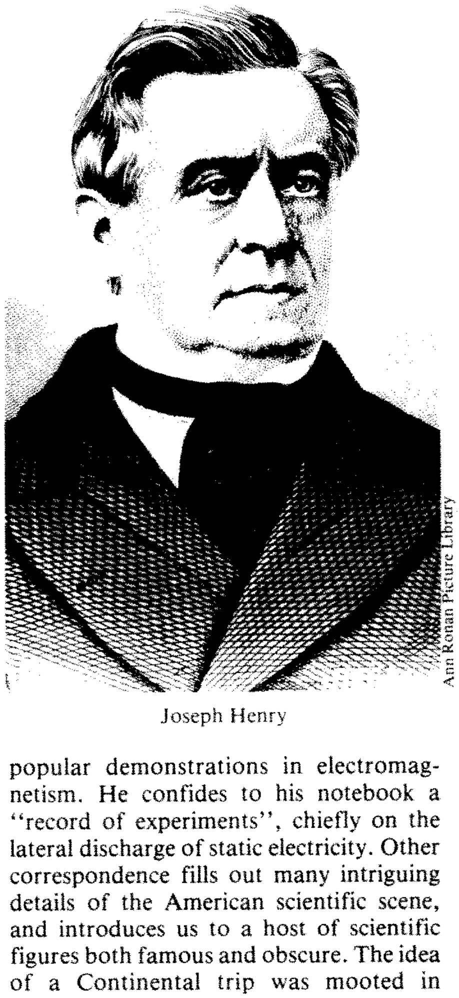
C.A. Russell

The Papers of Joseph Henry. Vol. 3: *January 1836–December 1837, The Princeton Years*. Edited by N. Reingold. Pp. 585. (Smithsonian Institution Press: Washington D.C., 1979.) $30.

THE PHYSICIST Joseph Henry (1797–1878) achieved lasting fame for his work on electromagnetism and, in particular, his anticipation (1830) of Faraday's discovery of electromagnetic induction. He became, in 1832, Professor of Natural Philosophy at Princeton, and in 1846 the first Director of the Smithsonian Institution in Washington. In his later years he was active in establishing the American Association for the Advancement of Science and the National Academy of Sciences. Today, his name is perpetuated in two main ways: by the unit of electrical inductance, the henry, and by the splendid collection of his personal papers in the archives of the Smithsonian Institution. It is this deposit which forms the nucleus of *The Papers of Joseph Henry*, currently in course of publication. Two volumes have already appeared dealing with, respectively, his years at Albany, New York, until 1832, and the first part of his Princeton period. The present book covers the years 1836–1837, subsequent volumes being planned for the remainder of his life.

For a book of this size merely to span two years may seem an excessively generous use of space, but as the editor rightly observes "the period covered was extraordinarily eventful". In the study of electricity the outlines of a coherent view of electromagnetism were beginning to emerge. Developments in optics, metallurgy and engineering were bearing fruit in lighthouse construction, instrumentation, shipbuilding and the new steam railways. Thanks partly to geological progress, searching questions were being asked about the nature of science and its relation to revealed religion. And Henry's own university was struggling to equip its laboratories in a manner fitting for the new challenges, even though its efforts coincided with the great economic depression of 1837. For Henry himself an even more significant event took place at this time: a scientific tour of Europe. In his own extensive reporting of this unforgettable experience lies the greatest interest of this remarkable collection of documents.

In the first part of the book we see Henry writing to his brother James on family matters, to his wife while away on a visit to Albany and to Benjamin Silliman on popular demonstrations in electromagnetism. He confides to his notebook a "record of experiments", chiefly on the lateral discharge of static electricity. Other correspondence fills out many intriguing details of the American scientific scene, and introduces us to a host of scientific figures both famous and obscure. The idea of a Continental trip was mooted in mid-1836 as a means of procuring the required scientific equipment. It was but one of many such journeys undertaken by Americans to post-Napoleonic Europe. Thereafter, foreign travel figures frequently in the correspondence until February 22 when he set sail for Europe. An increasing apprehension about the potential hazards of his voyage is evident in his letters. It would hardly have been dispelled by the request of a scientific colleague that he convey to Europe for distribution numerous copies of his latest paper, "On the gales and hurricanes of the Western Atlantic".



Ann Ronan Picture Library

Joseph Henry

The account of Henry's European tour is supplemented by one from his friend and counterpart in Philadelphia, A. D. Bache, who left for Europe a few months before Henry. Their two diaries illuminate the great sensitivity of Americans at that time to their reputation overseas. Nowhere is this more evident than in Henry's experiment in King's College, London, when he tried to obtain a spark from thermoelectricity; the successful outcome, which had eluded Faraday, gained in significance with each retelling of the tale and Henry became a folk-hero in his own country. During his London stay he frequently enjoyed the hospitality of Daniell's laboratory at King's College, and quickly became acquainted with most of the leading metropolitan scientists. His lodgings were chosen so as to be a few steps from the Royal Institution. Visits to Greenwich, Woolwich and an unnamed gasworks still further enlarged his circle of acquaintances, and he did not hesitate to characterize many of those he met. Sturgeon was reckoned to be "a very good experimenter but an indifferent lecturer"; Wheatstone was the most "talented" person he had encountered; but Faraday (who welcomed him into his own family circle and home) was "the greatest man".

From England Henry went to France where his diaries and letters reveal interesting details of transport, social life and an American's impressions of Paris. But scientifically it was less successful. Equipment ordered in France failed to be delivered, and he found considerable difficulty in meeting the great figures of French science. Partly this was due to a language problem, but also, as the editor admits, "many of Henry's opinions of France would provide ammunition for recent historiography arguing the decline of French science in the nineteenth century". Several times Henry wished he had spent less time in France and more in Britain.

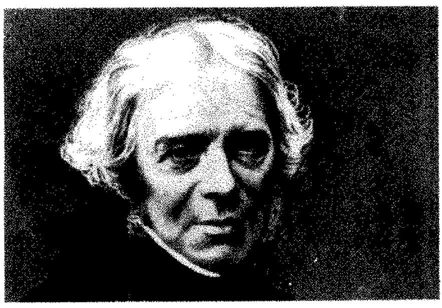
The final part of his tour took him to Scotland where he gives graphic accounts of life in Edinburgh, trips to Scottish lighthouses and (especially) the Edinburgh

Observatory. Then, after attending the British Association meeting in Liverpool, and a brief visit to Cambridge, he set sail from Portsmouth on 22 October 1837 for his homeward journey.

It is impossible to do justice to the richness of material in these papers. A great number of Henry's contemporaries flit in and out of his pages: obscure instrument-makers, technicians, engineers and others on the periphery of science; relations, students, friends and casual acquaintances; politicians and royalty (though not much, for Henry was a staunch republican); poets and philosophers; and above all men and women active in science. We are treated to his views on race and slavery, on the status of women, on the cost of war, on the politics of science — and even on the philosophy of tea-making.

Popperfoto

Charles Wheatstone — the most "talented" person . . .



Popperfoto

Michael Faraday — "the greatest man".

The task of the editor and his assistants has included the provision of very full notes with (where possible) full identifications of individuals, places and incidents referred to in the papers. The massive index is a testimony to their thoroughness and care. Naturally, a few blemishes have been detected; there is now some doubt about the authenticity of "Newton's" telescope at the Royal Society (p. 189); the spectrum studied by Brewster was most certainly not that of "nitrous acid" (p. 482); the Brunel referred to on p. 225 as the engineer of the Great Western Railway was not Marc but his more famous son Isambard; and there are a few uncorrected colloquialisms in the notes and a small number of misprints. But these cannot detract from the great merits of a work that will be invaluable to social historians as well as historians of science working on that period. There are eight pages of portraits (though, curiously, not one of Henry himself) and several other illustrations in the text and endpapers. For a work of this size and complexity it is excellent value for money. Subsequent volumes will be awaited with keen interest.

C. A. Russell is Reader in History of Science at The Open University, Milton Keynes, UK.

Anecdotal astrophysics

G. T. Bath

Introduction to Advanced Astrophysics. By V. Kourganoff. Pp. 479. (Reidel: Dordrecht, The Netherlands, Boston and London, 1979.) Hardback Dfl. 135, $71.05; paperback Dfl. 55, $28.45.

WHEN Martin Schwarzchild wrote *Structure and Evolution of the Stars* (Princeton University Press) in 1958 (rightly referred to as "a remarkable treatise" in this book), the revolution in astrophysics which we have witnessed in recent years had already begun. For the first time computers provided a tool which led, using considerable intellectual ingenuity, to the solution of previously intractable equations describing the structure of stars and other cosmic objects. Radioastronomy had broken down barriers that restricted our view of the Universe to the optical region of the electromagnetic spectrum. New optical instrumental techniques were continuously developing and were a continuing source of unpredictable discovery.

Since then astronomy and its associated research fields have matured into a fully fledged science — one which in the UK currently receives 20% of the Science Research Council budget. The bulk of the electromagnetic spectrum is now visible through satellite or ground-based telescopes.

The new astronomies based on γ-ray, X-ray, ultraviolet and microwave observations have added a vast body of data ranging from the galactic binary X-ray sources to the cosmic microwave background. Nonetheless optical and radio wavelengths have retained their central position. In 1964 quasars were discovered, and the subject of active galaxies and galactic evolution was opened up by the mysterious optical spectra of the Cambridge 3C radio survey sources, 3C48 and 3C273. Even more startling was the way in which the persistent detective work of Bell-Burnell, Hewish and colleagues tracked down the neutron star using techniques developed to study interstellar scintillation. The Cambridge group quickly convinced the world of the reality of pulsars in 1968 (in a piece of teamwork which it does service to no one today to break down into isolated individual contributions as attempted in this book).

All this is well known. Less widely appreciated are the developments in optical instrumentation that have produced a rich source of surprises — solar oscillations, polarization and pulsations in white dwarfs, confirmation of accretion disks in stellar binary systems, complex quasar spectra reflecting structure around the quasar powerhouse and within the intergalactic medium, velocity dispersion studies providing a wealth of information on the morphology and evolution of galaxies — to mention but a few.

There is clearly a place, though competitors already exist, for a lucid, approachable and up-to-date introduction to the subject at postgraduate level: a book which reflects the past excitement, together with the logic and physics underlying models which account for these cosmic discoveries; something akin to *Structure and Evolution of the Stars.* Unfortunately, *Introduction to Advanced Astrophysics* does not provide this, at least in the way I would have hoped for.

The *Concise Oxford Dictionary of Current English* gives one definition of the word 'idiosyncrasy' as "mode of expression peculiar to an author". This book is a rich source of idiosyncrasy — of content, style, science and even English usage. In my view the author and publisher have not been successful in producing a well-balanced introduction to the study of astrophysics at the postgraduate level, which is their stated aim.

The book covers radiative transfer, stellar structure, white dwarfs, neutron stars and pulsars, binary systems and galactic X-ray sources, simple cosmological models, and, very briefly, extragalactic astronomy. The style is the lecture-note format elaborated to contain a multitude of *caveats* to simple introductory statements. These confuse the intelligent, inquiring reader, and distract from the main thrust of the subject. Most of the topics treated can hardly be described as advanced, and the treatment is muddled with anecdotes and asides.

Kepler's laws occupy 40 pages, the physics of X-ray binaries two, in a section totalling 70 pages, and the two pages on the physics are confused and misleading. Perhaps there is a place for an exhaustive discussion of the solution of binary orbital elements in a section devoted to X-ray sources, but not at the expense of a thorough discussion of the basic physical processes that power them, and make them what they are — amongst the powerful stellar energy sources in the Universe. It is a Sunday magazine supplement howler to state that in mass exchanging binaries "the very strong *gravitational field in the neighbourhood* of the compact object obliges the surrounding gas to flow over to the object" from the companion (my italics).

The English is eccentric and frequently grammatically incorrect. I am full of sympathy for the problems facing scientists whose mother tongue is not English. In the preface Professor Kourganoff, in his defence, quotes Zel'dovich: "Specific broken English (not Shakespearian or slang) plays the role played by Latin in the time of Copernicus". Broken English presents no difficulty, and can even have unsuspected advantages, when reporting original research. But textbooks are a different matter. The author has a responsibility to capture the reader's attention, to further his appreciation of the excitement of the subject, to have faith in the content and to help him use his intelligence. And that demands as much attention to style as to content. In this case I feel the author is not wholly at fault. The editor and publisher must also take some responsibility. ☐

G. T. Bath is a Research Fellow at Wolfson College and a Research Officer at the Department of Astrophysics, University of Oxford, UK.

Hormones from start to . . .

George Fink

Hormones and Evolution. Edited by E.J.W. Barrington. 2 vols, pp.989. (Academic: London and New York, 1979.) Each volume £30, $69.

Hormones and Evolution is an important treatise which tests the hypotheses that underlie the oft-quoted aphorisms of Peter Medawar — "Endocrine evolution is not an evolution of hormones but an evolution of the uses to which they are put" — and J.B.S. Haldane — "The evolution of vertebrate hormones was nearly complete in Silurian times". Medawar's hypothesis is proved correct for the steroids which, as shown in the interesting first chapter by Sandor and Mehdi, have been found in most species of animal and many species of plant (including prokaryotes). Sandor and Mehdi argue that the steroid nucleus (cyclopentanoperhydrophenanthrene) could have been synthesized abiotically, and because steroids interact with DNA (including the DNA of bacteriophages) they could be considered to be universal biomolecules which were among the first transmitters of chemical information. Medawar's hypothesis may also hold for the monoamines and the thyroid hormones the structure, but not function, of which remains unchanged among the vertebrates.

Common to the vertebrates and many invertebrates is the fact that the nervous and endocrine systems are linked by neuroendocrine cells, the transmitter most often being a peptide. Peptide hormones have recently attracted much interest, but even so the information obtained thus far, especially about their structure in lower vertebrates and invertebrates, is too meagre to enable us to determine for most compounds whether there has been a significant evolution of peptide structure as well as function. However, in agreement with Medawar's hypothesis, the mammalian thyrotropin releasing hormone (TRH), a tripeptide, is present in the brains of amphibians, reptiles and fish, but does not appear to release thyrotropin in these animals. Jackson suggests that TRH is a central neurotransmitter which, during evolution, acquires a role in the hypothalamic-pituitary system, first as a releasing factor for prolactin and then for thyrotropin. By contrast, the peptides of the neurohypophysis and the gut do appear to have undergone an evolution of structure as well as function. Thus, in mammals, gastrin and cholecystokinin are distinct, whereas in amphibians, fish and cyclostomes there appears to be only one gastrin/cholecystokinin molecule. In their review of the evolution of responses to the neurohypophysial principles, Sawyer and Pang point out the need in mammals for separate regulation of urine flow and milk ejection. This might explain why arginine vasopressin is the predominant pressor-antidiuretic peptide in the mammal, while arginine vasotocin predominates in non-mammalian vertebrates. Arginine vasotocin is about half as potent as oxytocin (the milk-ejection principle in mammals) in stimulating milk ejection and only half as potent as arginine vasopressin (which has little milk-ejection activity) in blocking diuresis. Thus, the switch from vasotocin to vasopressin, which only involves the substitution of phenylalanine for isoleucine (one base change in the codon), would confer a considerable advantage to the mammal. Further studies will be required to determine whether there are any common precursors for the invertebrate and vertebrate peptide hormones. Is there, for example, any relationship between the hyperglycemic hormone of the crustaceans and the gut and pancreatic hormones of the vertebrates?

As a treatise on comparative endocrinology, biologists will find this a most valuable handbook which they will wish to keep close to hand in the laboratory. Professor Barrington has chosen the topics and the authors carefully. Most vertebrate hormones and endocrine

systems are reviewed in detail, and one chapter each is devoted to the annelids, molluscs, crustaceans, insects and echinoderms. The chapters are mostly well written and illustrated, and reflect excellent scholarship. The authors, however, show a disappointing readiness to fit their data to prevailing views on evolution and the origin of life rather than looking for clues that might spark revolutionary ideas. There is one surprising omission — no chapter on the pineal gland which continues to tantalize the endocrinologist and evolutionist. Perhaps in man the pineal is *only* the seat of the soul (although recent studies suggest that it may also moderate gonadal function); but what an elevation in function from a mere phototransducer! □

Cookery book for immunologists

A.J. Munro

Selected Methods in Cellular Immunology. Edited by Barbara B. Mishell and Stanley M. Shiigi. Pp. 486. (W.H. Freeman: San Francisco and Oxford, 1980.) $29.95, £17.70.

THIS BOOK contains most of the principal methods used by cellular immunologists working with cells from mice. It started as a manual for teaching students and research workers in the Department of Microbiology and Immunology at the University of California, Berkeley, but has been expanded to include chapters from workers in other laboratories, although the majority of the 40 or more contributors are from the same department. The editing and the production of the book has ensured that the style of each contribution is very similar. Each chapter starts with a brief introduction, explaining the principle behind the method to be discussed. For example, there is a clear and precise description of limiting dilution analysis before details of how to measure the frequency of precursors of B-cells, helper T-cells and cytolytic T-cells.

About half of the procedures considered are only applicable to experiments using murine cells, but the rest are of general value and make the book of interest to all immunologists. The purification of immunoglobulins and their fragments and different assay procedures for detecting the reactions of immunoglobulins are described in useful detail. There is a section devoted to the method developed by Köhler and Milstein for the production of monoclonal antibodies from hybrid cell lines which will be particularly valuable to researchers trying this procedure for the first time.

Although most of the contributions contain a list of comments, often describing particular snags in the procedure or why particular reagents have been used, this is not always the case. One feels that, as with recipes, descriptions of methods should include some indication of which steps are essential, or which reagents were used because they happened to be conveniently at hand at that moment. A further criticism concerns the expense of some of the approaches suggested — by simple modification some of the procedures could be carried out at one-tenth of the cost.

The editors have not tried to make this collection of methods comprehensive, but nevertheless they have brought together most of the important techniques for studying cellular immunology and all immunologists will find valuable procedures clearly laid out. I have had considerable difficulty in reviewing this book, since whenever I brought it into the laboratory it vanished. And, like all good cookery books, it is rapidly accumulating stains on the more used pages. □

A.J. Munro works in the Division of Immunology, Department of Pathology, University of Cambridge, UK.

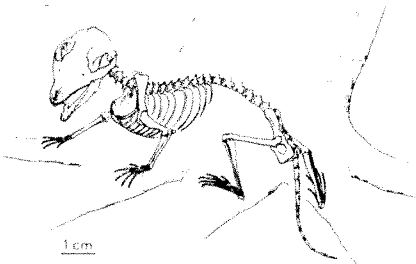
Mammals through the mists of time

Barry Cox

Mesozoic Mammals: The First Two-Thirds of Mammalian History. Edited by J.A. Lillegraven, Z. Kielan-Jaworowska and W.A. Clemens. Pp.321. (University of California Press: Berkeley and London, 1980.) Hardback $30, £18; paperback $8.75, £5.25.

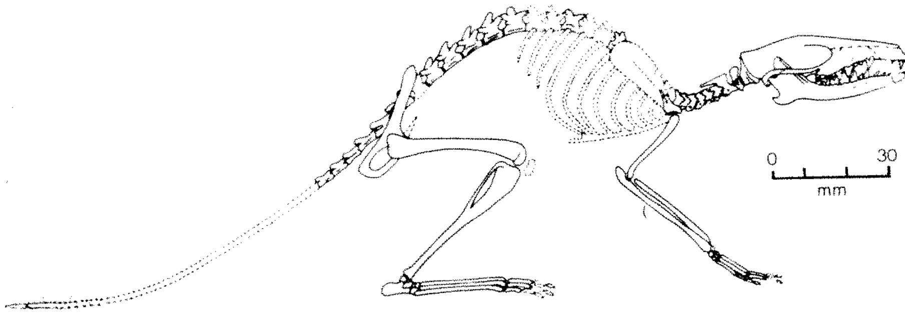
THE EARLY days of mammalian evolution were perhaps the Dark Ages in more than one sense — because not only were the little early mammals probably nocturnal, but also their tiny remains are fragmentary and uncommon. It is not so long ago that it was said that all their known remains could have been put in a shoe-box and, though the volume of their known fossils has considerably increased, it is still true that the overwhelming majority are isolated teeth or tooth-bearing fragments of skull. Study of their evolution is therefore still largely a matter of comparative odontology, as is reflected by the names of their orders: Triconodonta, Symmetrodonta, Multituberculata etc. These Dark Ages are particularly frustrating, for they separate the period of reasonably well-known Permo-Triassic mammal-like reptile evolution, which culminated in the very mammal-like cynodonts, from the Cenozoic period of well-documented, diverse, fully-evolved marsupials and eutherians ('placentals').



Jenkins and Parrington

Skeletal reconstruction of a Triassic triconodont

This book is therefore an extremely valuable synthesis of our current knowledge of Mesozoic mammals. It includes an introduction and 14 other chapters, by a total of 12 authors — mostly from the USA, but also including Dr Zofia Kielan-Jaworowska from Poland. After the Introduction, Chapter 2 provides a summary, on a world-wide basis, of the state of the record of Mesozoic mammals, giving faunal lists for each locality or group of localities, brief discussions (where necessary) of geological age assignments and information as to what parts of the mammals are actually known from those localities. Seven of the chapters are devoted to the morphology and systematics of the different orders of Mesozoic mammal. For each of these, one table



Z. Kielan-Jaworowska

Skeletal reconstruction of *Zalambdalestes lechei*

provides a complete listing of the taxonomic hierarchy from order to species, giving their authors, and another table shows the known distribution of the genera in space and time. The tables are followed by sections devoted to the anatomy, systematics, phylogeny and ecology of the order. There is also a brief chapter evaluating current opinion on the relationship between the monotremes and the Mesozoic groups.

The taxonomy of Mesozoic mammals used in the book is based on that of Simpson and Romer, and the editors have wisely decided that this was neither the place nor the time to embark on novel ventures in this field. Indeed, they have been extremely cautious, to the extent of refraining from formal use of the terms Prototheria and Theria in view of increasing scepticism about the theory that there was a corresponding fundamental dichotomy in early mammalian evolution. The book can therefore be used without needing to translate one's memory of well-established usage into some new-fangled (and perhaps transient) system of taxonomic/phyletic interpretation, which is a considerable relief.

Three evolutionary topics have been selected for treatment in particular detail. Crompton and Jenkins discuss the origin of mammals from mammal-like reptiles. The gap between the two groups has been gradually reduced, and little change would be needed in the braincase, jaw-joint and dentition of the small chiniquodont cynodonts known from the Middle Triassic to turn them into the tiny, insectivorous morganucodont mammals of the late Triassic. Crompton and Jenkins believe that, although there are some differences between the structure of the braincase in the therian and non-therian mammals, these are not great, and certainly not so great as to suggest that these two groups originated from the mammal-like reptiles separately.

Bown and Kraus give a clear, well-illustrated account of the origin of the tribosphenic molar, describing how it evolved from the three surfaces of the late Triassic symmetrodonts to the six surfaces of the early eutherians by the gradual proliferation of shearing surfaces. The proliferation was one aspect of the change in tooth shape that exploited the new masticatory process based on transverse shear rather than on simple puncture-crushing.

In the last of these three chapters, Lillegraven discusses reproduction in Mesozoic mammals. He provides a strong case for believing that it was the evolution of a trophoblast that could suppress maternal immunological rejection of the fetus that provided the eutherians with a decisive advantage over the marsupials. He also suggests that the pair-bonding or social structure, that in eutherians may have facilitated rapid genetic change and evolution, was impossible in marsupials because of the greater likelihood of maternal rejection of subsequent inseminations by the same, or a closely related, male.

At the end of the book Lillegraven, Kraus and Bown summarize the palaeogeographical changes that took place in the Mesozoic world. As they point out, it is in the late Cretaceous that the mammalian fossil record becomes most complete, and therefore the possibility of accurate biogeographical interpretation becomes greatest. But, even here, a good record is known from only two land areas, and only a few fragments are known from three others; in the remaining nine areas the fossil record is silent. Their concluding phrase — "We have much to learn" — may be taken as a suitable keynote, not only for this chapter, but for the book as a whole.

The book has an attractive format, most of the figures are clear and the editors are to be congratulated on an almost fault-free text. Though it would have been improved by the addition of an index, the organization of the book makes it easy to find topics and make cross-references. *Mesozoic Mammals* is an extremely valuable statement and synthesis of this field, both for those whose research lies in or near to it and also for those who have to try to explain it in the course of their teaching. ☐

Barry Cox is Professor of Zoology at King's College, University of London, UK.

Direct methods and the phase problem

C. J. Gilmore

Theory and Practice of Direct Methods in Crystallography. Edited by M. F. C. Ladd and R. A. Palmer. Pp.421. (Plenum: New York and London, 1980.) $35, £22.05.

DURING THE past 20 years, three developments have revolutionized X-ray crystallography. Two of them are well known even to the non-specialist. The automatic diffractometer has removed the drudgery of measuring the complicated diffraction pattern that results from the interaction of X-rays and crystals while, at the same time, increasing the speed and accuracy of the process. Similarly, processing this raw data to produce a crystal structure at an atomic level was also once an even more laborious business that has now been almost completely taken over by computers. As a result of these two advances over 2000 new crystal structures are reported each year; 20 years ago the figure was nearer 200.

One stumbling block still remains. The step between the diffraction experiment and obtaining the crystal structure is not trivial, since the relative phases of the diffracted X-ray beams need to be determined and they cannot be measured experimentally. This is the crystallographic phase problem and it is here that there has been a third major development that is less well known.

It is called 'direct methods' and is a technique by which phase angle information is obtained directly from the diffraction pattern by mathematical means. The subject started modestly enough 30 years ago as a mathematical curiosity and has grown to become the principal method by which the phase problem is now solved. It has allowed crystallographers to study a whole range of molecules that were previously inaccessible, and it has revolutionized our knowledge of structural chemistry.

It is by no means a static field and there has been a large influx of new ideas in the last decade, but strangely there have been very few books on the subject. Pioneering monographs by Hauptman and Karle (American Crystallographic Association: New York, 1953) and later Woolfson (Oxford University Press: Oxford, 1961) are now outdated or unavailable, and more recent books have either been conference proceedings or have restricted themselves to specialized aspects of the technique. Consequently, there is a need among crystallographers for a book that covers both theoretical and practical features of direct methods in an integrated and up-to-date way.

This book does not quite achieve this. It contains ten chapters that discuss various aspects of direct methods, each chapter having a separate author. The editorial hand could have been firmer. Apart from the inevitable problems of duplication and overlap, each contributor has been allowed to use his own nomenclature which is consequently different in every section. This will confuse the non-expert and so limit the overall usefulness of the book. The index, too, is rather poor.

There are, however, some excellent individual contributions. Rogers has written a thorough chapter on origin and enantiomorph definition, looking at what can be a difficult subject in a fresh and interesting way. Hauptman, who was one of the pioneers of direct methods, has contributed a clear and elegant summary of some recent theoretical developments including potentially important work on seminvariant theory. Another pioneer, Sayre, gives an account of phase expansion and refinement methods in his typically concise and illuminating style. There is also an interesting chapter by Argos and Rossmann on the molecular replacement method although its inclusion somewhat extends the customary boundaries of direct methods.

Whether these chapters justify buying the whole volume is of course a personal decision. In any case, the price is not unreasonable for a book of this length. However, the field is still open for a definitive book on direct methods in X-ray crystallography.

C. J. Gilmore is a Lecturer in Chemistry at the University of Glasgow, UK.

A wealth of virus lore

D.H. Watson

Introduction to Virology. By K. M. Smith and D. A. Ritchie. Pp.212. (Chapman and Hall: London and New York, 1980.) Hardback £12, $29.95; paperback £5.95, $14.95.

THE STRENGTH of this book lies in its wide-ranging selection of examples from the world of plant and invertebrate as well as of vertebrate and bacterial viruses. Fungal, protozoal, mycoplasma and spiroplasma viruses are also mentioned. The reader will also benefit from K. M. Smith's wide knowledge of the natural history of plant and insect viruses in particular, as well as from the beautiful electron micrographs (more profuse than is usual in a book of this size) which reach the excellent standard one would expect from this author. Many of these micrographs are of viruses not often represented in illustrations of more comprehensive texts.

The order of presentation is a little unconventional and in some respects illogical; an elementary introduction to the general characteristics of viruses and a survey of the morphology of some representative viruses are followed by chapters on purification, classification and nomenclature, virus diseases of a wide-ranging selection of organisms, spread of viruses and latency, satellite viruses and viroids.

At this stage are interpolated two basic chapters by Professor D.A. Ritchie on virus replication and virus genetics. The chapter on replication in particular is a masterly summary of replication of the various groups of viruses. However, many teachers of virology would, I think, agree that this core topic should have been brought forward since an understanding of the basic principles of replication is a necessary preliminary to the study of many of the topics discussed in earlier chapters, for example latency.

There follows a rather dated discussion of tumour viruses which only mentions virus isolation and electron microscopy as methods for establishing virus aetiology. Late in the book come tissue and cell culture of viruses and virus assay which are surely basic to much of the earlier chapters.

The book concludes with a chapter on control of virus disease. This is sketchy in the extreme and also somewhat dated. The student reading the paragraphs on interferon will surely contrast the low-key treatment of interferon with what he picks up from the media. The selection of thiosemicarbazone as the only chemotherapeutic agent discussed for animal viruses is also likely to give a somewhat distorted view.

The student requiring an introduction to the subject, either from the standpoint of another discipline or as background reading for an elementary course, would perhaps be better served by one of the other paperback volumes — say Primrose's *Introduction to Modern Virology* (Blackwell Scientific: Oxford) now appearing in a second edition, although Ritchie's chapter on replication would be very usefully read by him. Paradoxically, the book should perhaps be read by more advanced students because of the wealth of lore on viruses often perfunctorily treated in the more standard texts, and also for the wide selection of micrographs.

D. H. Watson is Professor of General Microbiology and Head of the Department of Microbiology in the University of Leeds, UK.

Mathematical plasma physics

R.J. Bickerton

Plasma Physics for Nuclear Fusion. By K. Miyamoto. Pp.610. (MIT Press: Cambridge, Massachusetts, 1979.) $50, £31.

PROFESSOR Miyamoto's book is aimed at postgraduate or advanced undergraduate students but it will be equally useful as a reference volume for research physicists in the field. The book was first published in Japanese in 1976 and has now just appeared in English. It appears to date effectively from about 1974 and is consequently dated in the more rapidly moving parts of the subject.

The book opens with arguments in favour of nuclear fusion based on apparently unsubstantiated figures for future energy requirements and for reserves of fossil fuels and uranium. There are then four sections in the book covering fundamentals, magnetohydrodynamics, kinetic description and finally heating diagnostics and confinement. Under fundamentals we have particle orbits, field configurations, Coulomb collisions and the Vlasov equation. The magnetohydrodynamic section includes toroidal equilibria of various kinds, plasma diffusion and a full range of instabilities. Topics considered under kinetic description are waves in cold and hot plasma, Landau damping and microinstabilities due to inhomogeneities in real or velocity space. The final section covers heating by a variety of methods, plasma diagnostic techniques and a survey of confinement experiments.

Professor Miyamoto's view of the world is clearly mathematical rather than physical. The treatment is comprehensive but monochrome with no attempt made to highlight important concepts and no concessions are made or detail sacrified in the interests of clarity. In many cases the mathematical working is fully displayed so that derivations can be followed step by step. One result is that the book is a heavy read and less than gripping. The main body of the book is very weak and largely silent on the extent to which the theory being presented has been tested by experiment. Although it can be justified by the title it is nevertheless sad that that reader is given no impression of the relevance of the main body of plasma physics to non-fusion fields, in particular to astrophysics.

The chief merit of the book is its completeness and in the detail of the presentation. As such it will be a useful reference book, although somewhat marred by a crop of misprints.

R.J. Bickerton is Associate Director (Science) at the JET Joint Undertaking, Abingdon, UK.

nature

24 July 1980

Should academics make money outside?

When, and under what circumstances, is it proper that academics should be involved with commercial enterprises? This question — always teasing — has been made more urgent by developments in the past few months which have involved academic scientists in attempts commercially to exploit the new techniques of genetic manipulation. Those concerned are likely to be by this stage keenly aware that many of their academic colleagues are deeply resentful of some of the most publicized developments. Harsh things are said over normally genteel coffee tables. There is a danger that the atmosphere of academic research will be soured, the reputations of academic institutions damaged and, perhaps worse still, the progress of research in this important field impeded. What is to be done?

The events which have made this question an important issue are memorable enough. It is now more than a year since a group of molecular biologists at the University of California, linked both by their common scientific interests and by their membership of a company called Genetech, announced that they were in a position to develop the manufacture of insulin (and some other peptide hormones) by means of genetically manipulated strains of *E. coli*. The announcement, widely acclaimed as an important development, also prompted complaints that those concerned had fallen into unacademic habits of not talking as freely to their academic colleagues as would normally have been the case. Since then, the number of prominent academic molecular biologists caught up in extramural commercial activities has increased substantially, as has the volume of somewhat embittered complaint at what is going on. The activities of the company known as Biogen, based in Switzerland and organized principally by Professor Charles Weissmann of the University of Zurich, usually excite most comment, partly because of the distinction of the academic scientists linked with it, partly because of the company's willingness to talk about itself and partly because of the somewhat breathless press conference on the prospects of manufacturing interferon with genetically altered *E. coli* held improbably at the Waldorf–Astoria Hotel in Manhattan earlier this year. Colleagues of those involved have now taken to complaining that such events are likely to undermine the integrity of academic life, to cloud the supposed single-mindedness of academic researchers in the pursuit of what might be called the truth and to create restraints on the normally free flow of information within the academic community.

Everybody will agree that the issues raised by these developments are complicated and are unlikely to be resolved quickly. Several sets of conflicting considerations intereact. Perhaps the most serious impediment to a proper resolution of these difficulties is that, so far at least, too little has been done, by commercially inclined academics or by their critics, to define the issues which perplex them. No list of these could at this stage be complete, although a few bones of contention prominently stand out. It goes without saying that the issues, whatever they are, are most difficult when academics rather than, say, public employees are concerned, but this is not to say that important conflicts of interest do not arise when, for example, employees of the National Institutes of Health in the United States, or of the research councils in the United Kingdom, find themselves inclined to cash in on their expertise.

Universities are the chief testing grounds for the underlying principles because universities are proud to call themselves self-governing communities of scholars. Even if, in practice, many universities fall short of this ideal, seeming to be uneasy alliances of warring factions (departments) or grudgingly subject to the inclinations of their administrators, it is a mark of grace that the ideal is so often held to be desirable. Does it necessarily follow that extramural commercial interests by some members of such a community are incompatible with the ideals they and their colleagues hold? The answer is complicated by the way in which, especially in recent years, many governments have urged that universities should contribute more directly to the economies which ultimately support them, and by the way in which universities themselves, for the best of educational reasons, have sought to attract teachers with practical and even continuing experience of industry. It is also important that the problem is by no means a creation of the past few years. In what sense, if any, does a molecular biologist with an interest in the success of some commercial genetic manipulation enterprise differ from, say, an academic who happens to be a successful novelist or textbook author, or from one who spends a substantial part of his time consulting for an engineering company or a drug house?

The simplest conclusion, a necessary but not sufficient condition of propriety, is that an academic should carry out the duties required of him by his contract of employment. The difficulty here is that while it is relatively easy for heads of departments to assess a person's diligence (though not his flair) in teaching, the standard requirement that he or she should also be active in research is much harder to evaluate. This, no doubt, is why many universities now require that academics should spend no more than one day a week on outside work. It is a rule of thumb which does at least ensure that an academic with outside interests has some time in which to pursue research. (In the United States, the growing zeal of those responsible for the public audit of research grant expenditure may turn out to be a tighter restriction.) Such requirements, of course, cannot ensure either the quality or the single-mindedness of a person's research, but it is a fair guess that those most able to contribute to the success of commercial enterprises outside their universities are likely also to be among the most valuable teachers and the most creative researchers. In the present wave of grumbling about the activities of molecular biologists, allegations of the neglect of simple academic duties are conspicuous by their absence.

A much more serious charge is that external commercial interests create intolerable conflicts of interest within academic laboratories. For how, if academic A is linked with some company, can academic B talk freely, over coffee or at some departmental seminar, of his own work in a related field? The difficulty is real, and those who have complained at recent developments are entirely right to say that too much of this could easily endanger not merely the social climate but the creativity of university laboratories. It is partly for this reason that many universities (but, shamefully, not all) require that academics should declare their outside interests to the heads of their departments. That is the very least that they should ask. For one thing, even though the head of a department may be apprised of his colleagues' outside interests, other researchers appear often to be unaware of what their colleagues are about. In these democratic days, is there not at least a case for asking that the disclosure of people's outside interests should be common knowledge within each closely-knit group of colleagues? And would it not be seemly and also important that heads of departments should themselves be required to spill the beans to those who work for them? That disclosure on this limited scale might be embarrassing to the academics concerned, or that

0028-0836/80/300319-02$01.00

students might make trouble if they knew what their teachers were up to on the side, is unfortunate but unavoidable. Yet this, too, is merely a necessary but not a sufficient condition of seemliness.

The third and perhaps the most intractable cause of present discontent is, bluntly, that many academics are resentful of the money their colleagues stand to make from outside involvement. Even if, as seems probable, biotechnology turns out to be less like a gold mine than some people have been supposing, great disparities of income have arisen in the past and will no doubt arise in the years ahead. The problem is to decide what is seemly. If an academic should write a successful novel, his colleagues may envy him but they have no more right to complain than if he were to win a fortune in some lottery. If, on the other hand, his extramural rewards are dependent on some special knowledge derived from his position within the group of academics to which he belongs, his colleagues are rightly resentful. If his profit should in part derive from the use of university facilities, laboratories or computers for example, wider issues arise. In such circumstances, indeed, it is only equitable that a person's profit should be shared with the institution to which he belongs. A neat way of doing this emerges from the constitution of the French company *Transgène* (see *Nature*, 10 July) where the University of Strasbourg and the Pasteur Institute will each hold a small percentage of the shares.

There are many, no doubt, who will argue that even these three conditions — diligence, open disclosure and profit-sharing where special knowledge is involved — are insufficient. Others will be attracted by more ambitious if more cumbersome ways of enabling academics to contribute to industrial development — companies or corporations set up by universities, for example. Universities differ sufficiently among themselves for the outcome of full-blooded debate on these issues to vary from place to place. There would be no harm in that. The danger lies in the virtual absence of debate. Academics grumble among themselves, but have done very little to ensure that their grumbles are openly discussed. While that reticence persists, the capacity of universities to contribute to industrial development will be impaired, while their reputation as self-governing communities of scholars will be tarnished.

Reviving (in the US) an old British recipe

The United States Congress seems bent on an exercise that resembles the re-invention of the wheel. Last week (see *Nature*, 17 July) it became known that the Department of Commerce is working on plans for the setting up of a number of "generic technology" centres and that both the Senate and the House of Representatives are ready to approve whatever scheme comes forward. Generic technology is the ugly name for what appears to be basic research related to some branch of industrial technology. Both the Department of Commerce and the Congress have it in mind that public funds should be used to launch a number of these centres, but that the industries most likely to benefit should provide an increasing proportion of the budgets of the centres, allowing the federal budget to be used for other purposes after the five years or so. Opinions, it is reported, are divided on the question whether universities should be given an important role in the management of the new centres. The antecedents of this proposal are as respectable as anybody could — the report of the level-headed Advisory Panel on Research and Development that contributed to last year's grand review of federal policy.

In reality, the new proposal in the United States is a neat amalgam of two kinds of institutions already tried in Britain. Is it too much to ask that Congress might profit from a study of the mixed success of the British experiments? The two kinds of enterprises concerned are the industrial research associations, originally recommended in the United Kingdom while the First World War was under way, and which have been over a switchback of ups and downs since their creation, and the ecology centres set up by Mr Anthony Wedgwood Benn (nor Mr Tony Benn) during his spell in the then Ministry of Technology in the late 1960s. The research associations resemble the American centres now proposed in that they were originally financed in partnership between central government and the group of industrial companies most likely to benefit. The more recently created technology centres were intended to be concerned with rather more specific problems than those which provided bread and butter for the research associations, but it was intended from the start that they would be based in universities. Again (for this is the way that governments think) the intention was that industry should take over financial responsibility for these centres in the course of time.

How well have these parallel devices worked? Most probably it is unfair to judge their success from successive British governments' opinions of them, but the research associations have lived through a succession of unpleasant ups and downs. When the wind was blowing in their direction, in the late 1950s and early 1960s, public policy stemmed from the conviction that some of the ills of British industry might be cured if only there were a mechanism for making sure that basic research germane to important sectors of manufacturing industry was effectively undertaken. During this period, public funds were used on a modest but impressive scale and new research associations were from time to time created. They fell from favour for a variety of reasons. Some of them turned out to be second-rate. Some of them turned out to be more interested in the provision of market research than basic research. Others were undermined by the unwillingness of successful industrial subscribers with their own programmes of research and development to allow research associations more than a peripheral role. Central government, having agreed in the 1950s that the research associations should be a continuing charge on public funds, eventually changed its mind — and then found the process of making the research associations stand on their own feet more painful than it had imagined. The end result, however, is that some thirty substantial and apparently valuable research associations have survived from this half-century of initiative.

The British government's attempts to set up technology centres in universities have, by comparison, left hardly any trace. To be fair, the plan was hardly given a fair trial. Mr Anthony Wedgwood Benn (as he then was) swept into the Ministry of Technology in 1966 with a sheaf of plans for stimulating industrial research. To begin with, half a dozen centres of tribology (lubrication etc.) were set up, but plans to create a number of more broadly based centres were frustrated by the defeat of the Labour government in 1970. For what it is worth, some of these centres survive, making their way in the world with the help of funds from the University Grants Committee, the Department of Industry and fees for contract research. As such, they do not greatly differ from the industrially orientated centres for research and development that universities and polytechniques have set up on their own initiative.

What lessons should the United States Congress and the Department of Commerce draw from this experience? The first need is that they should know that it exists. Most probably, they should also reconcile themselves to providing support of some kind for the centres they plan to set up for rather longer than is now apparently foreseen. Industrial companies will pay up only when they know from experience that a new centre is doing a useful job. The successful research associations in Britain are those which have served industries (such as the water industry) where the potential members have little tradition of basic research. British experience throws little light on the usefulness of links with universities, but Congress might push in that direction.

British biotechnology boat comes home

The plan to set up a British biotechnology company, much talked of recently (*Nature*, 5 June) came into the open this week. A company has been set up with an initial capital of £12 million, between 40 and 50 per cent of which will be provided by the National Enterprise Board. It is hoped that it can be registered as Celltech, but the formalities had not been completed on Monday.

The managing director will be Mr Gerard Fairtlough, until two years ago joint managing director of Shell UK Limited with responsibility for the £300 million turnover of the petrochemical part of the enterprise, and who has since then been a division head at the NEB.

Mr Fairtlough said this week that the NEB had been looking at the opportunities in biotechnology since the early autumn of last year, when it commissioned a study of the opportunities, apparently from Professor J D Watson, director of the Cold Spring Harbor Laboratory in the United States. At that stage the NEB had not known that Sir Alf Spinks was working on a report on biotechnology for the Advisory Council on Applied Research and Development (ACARD).

The new company will be jointly owned by the NEB (the largest shareholder) and four commercial partners — the Prudential Assurance Company Limited, the Midland Bank Limited, Finance for Industry and British and Commonwealth Shipping Limited. It is intended that roughly a third of the board of the company should be molecular biologists.

The new company plans to recruit between 50 and 75 people over the next two years. It will not build a laboratory of its own but will use existing premises. The location has not been finally decided, but may well be in Cambridge.

The company has taken trouble to come to good terms with the Medical Research Council, and claims that it has a "framework for collaboration" that will allow it to place contracts with MRC laboratories and to have access to MRC "ideas". The embryo company has also been talking to two other institutions, not openly identified but probably including the Imperial Cancer Research Fund.

Mr Fairtlough says that particular trouble has been taken to study the ways in which molecular biologists might be involved with the new company. Appreciating that some may wish to make money out of their skill, and that others are offended by the notion, it is planned that the company will make commercial arrangements only with the institutions to which people belong, leaving them to decide how individuals should be paid.

At the outset, the new company will make and sell monoclonal antibodies, but will also explore longer-term projects. It is laid down that the company should make money out of something within two or three years. The phrase "lean and hungry" is much used. The first opportunities will, it is said, be in the field of diagnostic tests.

At the same time, the NEB is anxious that the company should be financially strong enough to tackle "big things". The company will not always seek to market its own products to their ultimate users, but will be content with selling licences for manufacture by others where that seems the best course to follow.

The board of the NEB itself is said to be pleased at having launched its first "constructive project" — since the previous board resigned *en bloc* last November, the board has been primarily concerned with housekeeping. The fact that the NEB rather than the National Research Development Corporation has become the chief public sponsor of the new biotechnology company is not only a sign of its skill but a mark of the disfavour in which the NRDC finds itself with academic scientists in general and those working for the Medical Research Council in particular.

On the question why the present British government may have sanctioned this modest investment, Mr Fairtlough said that the involvement of private capital had been a necessary condition, given "the way our guidelines have been evolving". He said that the new company would succeed if it could show that it had a "distinctive competence" and if it combined a hard-headed appraisal of the market with a capacity to make better use of people's talents. He considers that Celltech will be able to establish better relations with academic scientists than companies such as Genetech and Biogen.

Supreme Court stirs up more fear

Washington

Recombinant DNA research is moving from the frying pan to the fire. Last month's decision by the US Supreme Court to permit the patenting of live micro-organisms has started a new round of public debate about the conditions under which recombinant DNA research should be carried out.

When the National Institutes of Health formulated safety guidelines in 1976, the main concern was the potential health hazard. Attention is now concentrated on the rights of ownership and control over natural processes.

The Supreme Court ruling has crystallized various areas of concern. Several scientists, for example, have expressed their fears that the decision to allow a patent on a strain of *Pseudomonas* bacterium, developed by research workers with the General Electric Company by inserting foreign plasmids, could create barriers to the free flow of research ideas. Others disagree, claiming that the requirement to publish details of a patent ensures that the information will be publicly available. And the American Society for Microbiology is sponsoring a meeting in Washington this week to explore such areas of disagreement.

The ASM meeting will debate "the proper role of the patent laws in genetic research and development". Questions to be discussed include that of whether the law should be modified to preclude exclusivity or monopoly over a microorganism; and,more generally, whether the decision is consistent with the objectives of the microbiological and biomedical scientific communities.

Professor Emilio Schaechter, chairman of the committee organizing the ASM meeting, highlights one particular area needing attention, that of how research using recombinant DNA techniques should be regulated in the private sector. Although NIH operate a system of voluntary compliance with their safety guidelines, they have no desire to act as a full-blown regulatory agency. NIH are considering delegating most safety decisions to local biohazard committees, and there is concern that the regulatory apparatus may be inadequate.

The Department of Labor's Occupational Safety and Health Administration is already taking steps to define its own role, including setting up a committee to outline voluntary control of the exposure of workers to processes involving recombinant DNA techniques.

Both the closeness of the Supreme Court decision — a five to four majority — and the justices' opinions on both sides provide an open invitation to Congress to look more closely at the patenting question. The four minority justices wrote "it is the role of Congress, not of the court, to broaden or narrow the reach of the patent laws". For the majority, Chief Justice Warren Burger admitted that the court's decision had been reached on a narrow interpretation of present patent law and added that Congress was free to amend the law to exclude from patent protection organisms produced by genetic engineering, or to "craft a statute specifically designed for such living things".

Pope John Paul II warned in an address to Unesco that genetic manipulation might be applied to "ends contradictory to those of humanity". Four days after the Supreme Court's decision was announced, religious groups representing Protestant, Catholic and Jewish viewpoints issued a statement which said that the questions raised by genetic engineering — who should control it, who would benefit and

0028-0836/80/300321-02$01.00

who might bear adverse consequences — dealt with "the fundamental nature of human life".

Finally, the whole issue may come under review by the newly established President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioural Research. Following an approach from the National Council of Churches, the commission is exploring whether any major reviews of the ethical implications of genetic manipulation are already in progress. If not, the subject might be selected for study by the commission when it meets in September.

David Dickson

Biotechnology

European setback

Brussels

THE European Commission's programme of research in biotechnology was seriously set back last week, when a meeting of CREST failed to endorse the programme or even to agree on a compromise. Over the past four years, the commission has developed a plan for spending £28 million over the next five years (half of it to be supplied by national governments) on a number of projects.

France was the chief stumbling block at last week's meeting of CREST, the committee which advises the European Community on research and development policy. French representatives argued for an alternative programme of fellowships to help train potential genetic engineers. The meeting of CREST was the last at which the biotechnology programme will be considered — a decision on what to do now rests with the Council of Ministers of the European Community, on which France will be able to exercise its veto.

According to reliable national sources, the council will have to choose between the commission's original plan, the French proposal and a compromise between the two supported by the United Kingdom. That would entail spending a total of £18 million over only four years and the elimination of some of the research projects proposed by the commission.

The CREST decision has caused much ill-feeling among European states. West German delegates at the meeting last week supported the French position, but more flexibly. One angry Dutch observer said last week that the smaller European states would feel misled by the larger states. An Italian offical said that France had opposed the commission's plan because it wished to keep all projects with "pace" to itself.

The difficulty now is that the Council of Ministers, when considering the biotechnology programme, will be advised by an *ad hoc* scientific subcommittee of COREPER — the committee of community ambassadors in Brussels, which is well used to taking political considerations into account. It could, for example, think of trading an agreement on the biotechnology programme for an agreement on sheepmeat.

There is nevertheless a chance that a compromise proposal may be adopted, if Germany can be persuaded to agree. The compromise would involve restricting the research projects to:

- the development of new reactors involving immobilized multi-enzyme systems;
- the transfer of genes to *Escherichia coli, Saccharomyces cerevisiae,* and other organisms;
- gene transfer in microorganisms and plants important important to agriculture;
- safety studies.

The compromise also emphasizes mobility of manpower, in line with the French proposals, by devoting 30 per cent of the budget to training of foreign nationals in national laboratories, training of industrial scientists in university laboratories, and short courses in biohazards and safety measures. However, the French proposal does not mention safety questions, which must be satisfactorily answered if public confidence in the emerging technology is to be maintained.

In Britain, the possible demise of the European initiative is seen more as a danger signal than as an unmitigated disaster. Dr Duncan Davies, Chief Scientist at the Department of Industry, and chairman of the Cabinet Official Committee on Biotechnology which has just produced a draft White Paper on biotechnology in Britain, told the House of Lords recently that the commission programme — as it would affect the UK — would amount to only 10 per cent of the probable British effort over the next five years.

At Imperial Chemical Industries Limited, which probably has the most advanced industrial biotechnical team in Britain, the loss of the European programme is seen as less sad for ICI than for "UK Limited". Things could be done on the European scale, said Dr Bernard Langley of ICI's Policy Group last week, "which would help everyone". Coordinating safety standards and experimentation and developing new host-vector systems were examples.

In academic circles, where the UK Spinks report on biotechnology recommended an immediate injection of 20 new posts, and cash, the loss of commission money is taken more seriously. "Unless we have more posts soon, we are in deep trouble" said one leading biotechnologist last week. "And I see no sign at all of the Department of Education and Science taking an intelligent interest in the issue." The loss of the European programme could be the end.

The draft version of the White Paper currently in circulation also may be little consolation to Britain's biotechnologists. According to one comment, "it offers everything short of real help".

Robert Walgate

Yugoslav academics

No liberalization

At least for academics and scientists in Yugoslavia, there seems to be little sign of the liberalization expected to follow Tito's death.

Ivan Supek, a leading Yugoslav nuclear physicist and an active participant in the Pugwash movement, has just published in Britain a defence of his view that scientific research must be based on ethical principals, and of his resolute opposition to nuclear weapons. His views, he claims, have been consistently misrepresented by the official Communist press, which treats him, at best, as some kind of Don Quixote.

Supek, who is now head of the Institute of the History and Philosophy of Science in Zagreb, was formerly in charge of the Rudjer Boscovic Institute of Theoretical Physics in Zagreb. While working there, he watched with increasing alarm the development of a nuclear institute on the outskirts of Belgrade where, he suspected, preparations were being made for the development of nuclear weapons.

His own anti-nuclear campaign of the 1960s was, he says, only one aspect of a growing discontent among intellectuals and scientists, who felt their status had been devalued by the Party in the name of the working class. The University of Zagreb's 300th anniversary in 1969 was seized on by the academics as a unique opportunity to redress the balance.

The appearance of Supek's apologia coincides with an appeal to the world academic community by seven professors from the University of Belgrade for support in their campaign against the latest revision of the Serbian law on universities.

These lecturers were closely associated with the philosophical journal *Praxis*, founded in the mid-1960s as the organ of the Croatian Society for Philosophy. Originally in the hands of Zagreb academics who took a generally social democratic line, it gradually became associated with the more liberal-marxist Belgrade philosophers. Finally, it was closed in 1975, and eight lecturers were suspended. They were not allowed to teach, lecture or publish; they did, however, draw a reduced salary and could benefit from the free health service.

Their status will however be radically changed by the revision of Serbian law on universities, passed on 5 June. Under the previous law, (introduced in 1974) lecturers could be suspended if they "damaged social interests". Under the new law, they can be sacked after two years' suspension. Persons already suspended for more than two years will be sacked in six months' time. The seven lecturers still under suspension (one has since found another post) maintain that this law has been brought in specifically to deal with their case. They further state that it is unconstitutional, being against the

Yugoslav Federal Labour code in which the specified grounds for dismissal do not include the nebulous charge of "damaging social interests", and because it specifically excludes any right of appeal. Most seriously, they see it as a violation of the Universal Declaration of Human Rights and the Helsinki Final Act, both of which have been ratified by Yugoslavia. They conclude that such "arbitrary interference and discrimination constitutes not only an act of harassment but an act of imperilling the very conditions of existence of a scholar".

Vera Rich

Scientists' pay

UK rumpus

A decade of discontent among scientists in the British Civil Service will come to a head on 5 August, when the dispute about salaries for 1980 will go to arbitration. The most immediate issue to be settled is whether the Civil Service will accept the latest pay offer by the Civil Service Department (CSD). Underlying the dispute, in which the Institution of Professional Civil Servants has taken most of the weight, is whether existing methods for settling Civil Service pay should apply to scientists.

The chief humiliation in this year's pay offer is that some grades of the scientific Civil Service are to be offered no increase of salary. After a period in which the general level of salary increases in the United Kingdom has been running at something like 20 per cent, it is not surprising that passions have been roused.

Thus the salaries of those at the top of the Senior Principal Scientific Officer grade will, if the CSD proposal is unchanged by the arbitration award, remain unchanged between 1979 and 1980.

Mr William McCall, general secretary of the IPCS, has said in a circular to his members that the offer of 1980 salaries is "disgraceful". The offer, if it is upheld by arbitration, may have repercussions outside the Civil Service, and among the staffs of research councils in particular.

The pay of scientists in the British Civil Service has been a contentious issue since the early 1970s, but the professionals within the service appear to be divided in how they would like to see the present arrangements changed. The ICPS bases its complaints chiefly on the use of what is called "pay research" to determine public servants' salaries.

This procedure entails the search for groups of scientists carrying out comparable work in the private sector of British industry. Quite independently, the use of pay research for determining civil servants' pay has recently been criticized in the United Kingdom on the grounds that the comparisons are flattering to the Civil Service and in any case take no account of the value of index-linked pensions to which retired public servants are entitled.

The IPCS objects to pay research because of the element of circularity which, it says, is likely to be introduced into the comparison because the Civil Service is the largest employer of scientists on research and development in the United Kingdom. But it also says that for some categories of senior people, suitable comparisons with private industry do not exist.

Other members of the scientific Civil Service are, on the other hand, anxious that there should be a more radical revision of the arrangements for regulating both pay and career prospects for scientists in the Civil Service. One body of opinion holds that the pay of scientists in the Civil Service compares well with that of scientists in,

Long-standing pay dispute continues

The dispute between the Civil Service Department of the British government and the Institution of Professional Civil Servants, the principal union representative of government scientists, has been rumbling on for two years. Since the early 1970s, the institution has reluctantly agreed that the pay of some categories of scientists should be determined on the recommendations of the Pay Research Unit Board, which is responsible for comparing civil servants' salaries with those of comparable groups outside.

The institution's misgivings about "pay research" for fixing the salaries of scientists stems from its belief that the Civil Service, which is the "largest single employer" of scientists working in research and development, is also a major influence on outside salaries. It also holds that pay research does not provide for the practice within the Civil Service of allowing for the promotion of individuals on the grounds of merit and says that career patterns outside are, in any case, quite different from those within the service.

The notion that civil servants should be fairly treated compared with people doing comparable civil work has been a cornerstone of Civil Service salary determinations since the Priestley Commission reported in 1956. More recently, however, the Fulton Commission on the organization of the Civil Service in 1968 advocated two further principles — the barriers between the scientific and the administrative branches of the Civil Service should be broken down and salaries in the two branches should be linked. From 1968 until recently, the salary scales of Principal Scientific Officers and of Principals (in the administrative branch) have thus been identical.

The first breach in this principle came last year, when Principal Professional and Technical Officers (including engineers) in the Civil Service were awarded a salary increase which, although three per cent above the general increase, gave them salaries which were £729 less than those of Administrative Principals.

This year, scientists within the Civil Service come off even worse. The offer from the Civil Service Department on 26 June, based on the work of the Pay Research Unit, would have increased the salaries of all but the more senior scientists in the Civil Service by between 14.0 per cent and 25.3 per cent. Senior Principal Scientific Officers, of whom there are more than 700, were however offered no increase of salary, while it was proposed that four points should be added at the bottom of the salary scale to be occupied by future entrants.

Senior Scientific Officers and Principal Scientific Officers also fare badly, with increases at the top of the pay scales concerned of 9.1 per cent and 6.2 per cent respectively. More significantly, to many civil servants, the link with the salaries of Administrative Principals has been broken — under the terms of the new offer from the Civil Service Department, the salaries of Principal Scientific Officers would in future be nearly £2,000 less than those of Administrative Principals.

The basis for the offer apparently rests, at least where the PSO grade is concerned, on the observation by the Pay Research Unit that in many industrial companies scientists are paid less than engineers. This has been held to justify the differential between the salaries of the Principal grades for scientists and engineers.

One of the issues in dispute between the Institution of Professional Civil Servants and the Civil Service Department is that of whether pay research can apply to the salaries of the small numbers of people in the grades of Senior Principal Scientific Officer and above. The CSD is insisting that comparisons with outside industry are possible at least for the SPSO grade.

There is also a dispute about the applicability of the agreed arbitration procedure.

Maximum salaries offered for 1980

Grade	No. in service (1979)	Salary offer	Percentage increase
Senior Principal SO*	728	£15,748	Nil
Principal SO	2,458	£12,050	6.2
Senior SO	3,830	£9,500	9.1
Higher SO	4,194	£7,900	17.3
SO	2,982	£6,400	16.7
Assistant SO	3,120*	£4,925	22.2

*SO = Scientific Officer.

0028-0836/80/300323-02$01.00

say, academic life, but that it would be in the long-term interest of those working as professional people within the Civil Service that something should be done to remove the barriers between the professional and administrative career tracks.

Although the Fulton Commission in 1968, in the course of its attack on the generalist as senior Civil Servant, advocated more administrative responsibility for professional civil servants, many scientists in the service are bitterly disappointed that so little has been done to implement these recommendations.

US science budget

Stability ahead?

Washington

Locked once again into the annual congressional switchback over research funds, science policy administrators in Washington have eagerly endorsed plans to place key aspects of the congressional budget review process on a multi-year basis. On 21 July, the House of Representatives passed a bill submitted by its Science and Technology Committee that would require the Administration to provide two-year (or longer) estimates of major research and development expenditures as part of its annual budget request to Congress.

The objective is that any authorization committee should then be able, if it so chose, to approve research programmes for two or more years. At present, most research spending has to be authorized annually (except for the National Institutes of Health, for which new authorizing legislation is now under consideration (*Nature*, 22 May)).

Multi-year authorizations would affect only part of the budget process. Decisions on appropriations (authority to spend) are usually more significant and these would continue to be decided annually. Even so, supporters of the new legislation hope that, if a companion bill can be coaxed from the Senate, the result will be a first step towards greater stability and continuity for research finding. Some even see it as a "pilot endeavour" for multi-year funding of federal programmes in general.

The idea appeals equally to Congress, to the Administration and to leaders of the research community. In the first place, it would cut down considerably on the amount of time and effort now required of all parties.

But as Dr Frank Press, director of the Office of Science and Technology Policy (OSTP), told a recent hearing on the bill, "by its nature, most research and development has to be carried out over a lengthy time-frame".

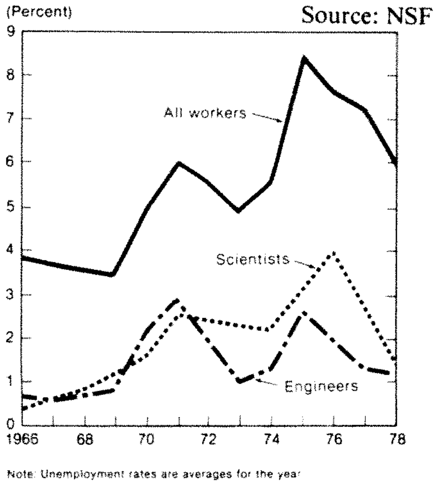
Some hope that the reduced commitment would provide more time for more detailed examination of specific policy proposals, and that multi-year authorization would help to improve the climate for long-range planning of research, a goal that frequently conflicts with the need to respond to fluctuating political demands. The result should be, according to the bill's supporters, that research and development expenditure is less vulnerable to short-term changes in the fiscal climate. As things are, research and development suffers because, although it is a relatively small proportion of the overall federal budget, it represents almost a quarter of that which is not predetermined by specific laws, those concerned with social security for example. Extending the timescale of federal planning for research happens also to accord with "the budgetary philosophy of this Administration", according to Mr Bowman Cutter, executive associate director of the Office of Management and Budget (OMB).

In practice, however, multi-year planning will be difficult; the Office of Technology Assessment has told the committee that simple and flexible methods will be needed for treating inflation for example. Inflation affects research and development differently from other part of the federal budget; Dr Press has told the committee that many areas of science suffer from the "natural" built-in inflation that comes about because research becomes more sophisticated and the equipment and technical support required correspondingly more costly.

The House committee has taken Press's point. The legislation now passed by the House would require OSTP to assist and advise OMB on the evaluation of the effects of inflation factors on research and development and to suggest how they should be allowed for.

Most of this is relatively uncontroversial. Less so are proposed changes in the reporting requirements which existing legislation imposes on the OSTP and the National Science Foundation (NSF) to keep Congress up to date with the direction and intentions of official research and development policy. In particular, the new bill would dispense with OSTP's annual report to Congress on the nation's research and development. Instead, the NSF would be required to produce a broad outlook every four years with revisions every two years. OSTP officials make little secret of their scepticism about the usefulness of such reports, hitherto required by the Presidential Science and Technology Advisory Organization Act of 1976, and the House Science Committee now appears to agree.

US unemployment



Note: Unemployment rates are averages for the year
SOURCES: Bureau of Labor Statistics and National Science Foundation

Some members of Congress, however, feel strongly that OSTP should be making public policy statements about the general health of research and development and the directions that it should be taking. They are thus unhappy about OSTP's apparent abdication of responsibility for long-range planning which, they claim, is explicitly required by its legislative mandate. Mr George Brown, a member of the House committee, in a minority report on the new bill, says OSTP has brought upon itself the difficulties it has encountered in preparing the reports required by law. There is reason to believe that the General Accounting Office is about to issue a report that is severely critical of OSTP on the same grounds.

India in space

One up so far

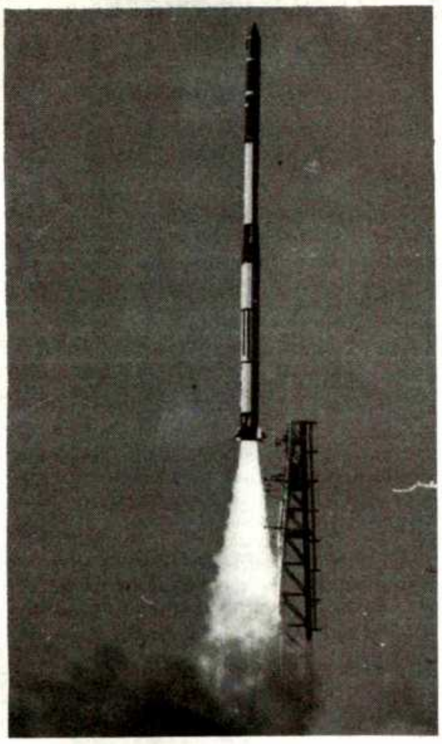
India has taken another step into the space age. Last week, the second test flight of the 17-tonne SLV-3 launcher successfully placed a small satellite into near-Earth orbit, making India one of a select group of countries with independent satellite launch facilities. SLV-3's first test flight last year ended in disaster when the rocket fell into the Indian Ocean 15 minutes after lift-off from the Sriharikota launch pad off India's east coast.

Mrs Gandhi's announcement that the second test flight was a success came during a debate in the Indian lower house (Lok Sabha) on defence ministry grants, leading some observers to speculate that the main impetus behind the rocket's development is military. India has never denied that its expertise in space technology could be used to launch reconnaissance satellites or develop intercontinental ballistic missiles, but it has always stressed that its space programme is intended to be peaceful and geared towards national development.

Space applications, such as remote sensing and telecommunications, form the major part of India's space programme. India has cooperated for several years with other countries such as the Soviet Union, France and the United States on remote sensing and telecommunications, one notable example being the SITE experiment with the US to bring educational television programmes to rural areas.

Rohini 1, the 40-kg satellite launched last week to record the flight characteristics of SLV-3 is the third Indian satellite to go into orbit. The Soviet Union launched the two others: Arybhata, a scientific satellite, in 1975 and Bhaskara, for Earth observation,

0028-0836/80/300324-02$01.00



India: where next?

in 1979. Plans for further satellites include two more in the Rohini series. These will be larger than Rohini 1 and geared to specific scientific or applications tasks. India is also planning to launch an experimental telecommunications satellite, APPLE, on the third test flight of Ariane, the European launcher, next year.

The present SLV-3 rocket, based on NASA's Scout launcher, is too small, however, to launch some of the large satellites planned. Large liquid rocket motors are already being developed at the Vikram Sarabhai Space Centre on India's west coast for incorporation into future rockets capable of putting up to 800 kg into geosynchronous orbit.

The current launcher programme, which began in 1973, grew out of earlier experience gained in building sounding rockets at the Thumba equatorial rocket launching station.

Nuclear explosions

No alarm

Washington

When can a cloud of dust particles resemble a nuclear explosion? When it is detected by a nuclear monitoring satellite, according to a report published last week by the US Office of Science and Technology Policy.

Spurred by speculation over the nature of a mysterious explosion apparently observed by a military Vela satellite over the lower Atlantic ocean last September, OSTP set up a panel of inquiry chaired by Dr Jack Ruina of the Massachusetts Institute of Technology.

The panel was at first inclined to agree with defence officials who claimed that the satellite had detected a clandestine nuclear explosion carried out by the South African Navy either on its own initiative or in collaboration with Israel.

After intense scrutiny of the data from the satellite, however, the panel now says that the flash of light seen by the satellite was "probably not" a nuclear explosion. Its alternative hypothesis is that the satellite was hit by a small meteroid, possibly as small as a speck of dust, and that this dislodged paint chips or other particles from the satellite's surface, which subsequently reflected sunlight into its detectors.

In support of this hypothesis, the scientists cite discrepancies in the data from the satellite's two sensors, indicating that the source may have been considerably closer to one sensor than the other.

In addition, there was a lack of any other evidence detected by stations on the ground — such as increased radiation or seismic activity — which would have corroborated the explosion hypothesis. Nor were there intelligence reports that a nuclear test had been carried out by either country. The Defense Intelligence Agency is not convinced. Before the OSTP report was released, the DIA leaked to the press its own conviction that a nuclear explosion had indeed been detected by the satellite, and that it had been carried out under weather conditions chosen to make detection difficult.

The White House, however, has adopted as its official position the OSTP panel's conclusion that there is insufficient evidence to prove a clandestine weapons test. According to State Department officials, this is the view that will prevail when a report on the incident is made to the Nuclear Non-Proliferation Treaty review meeting in Geneva next month.

Nuclear power

Ore running out?

The year just past was "another year of lost opportunities" according to the Nuclear Energy Agency (NEA), the OECD's own organization for the promotion of civil nuclear power. In its most recent annual report (the Eighth Activity Report covering 1979), the agency says that the growth of nuclear energy production in 1979 was a disappointing 2.2 per cent, compared with the average growth rate of 27.5 per cent a year during the period 1968-78. The pace of growth has paradoxically declined since the oil price rises of 1973.

On the face of things, however, the figures are not too bad. According to the report, there were 232 civil nuclear plants in operation at the end of 1979, and a further 229 under construction or on order, only seven more than in the previous year. New orders were almost offset by cancellation in West Germany, Spain and the United States.

Whatever happens to new orders, the output of nuclear electricity in the OECD area in 1990 is now almost certain to be between 33 per cent and 40 per cent of the energy equivalent of oil imports in that year, according to figures quoted in the report. The hiatus in the projected growth of the nuclear industry in 1979 is attributed to the international concern with nuclear proliferation, the Three Mile Island accident, uncertainty about waste disposal and "the related problems of public understanding".

On the consequences of the Three Mile Island accident, the NEA follows a judicious line. Its report says that the accident showed that nuclear power is not accident-free, that defence in depth can work in practice but also that the accident "has revealed a number of deficiencies in the way that reactor safety has been approached up to now". It urges that more attention should be paid to the malfunctioning of other than major items of equipment, and promises to do what it can to help.

One consequence of last year's hesitation about nuclear power is, according to NEA, that the uranium mining industry has become overcautious, thus threatening future growth.

World uranium reserves at costs up to $80/kg of uranium metal (the present economic limit on production) have increased by some 200,000 tonnes in the past two years, and now total 1.85 million tonnes. The increase came mainly from discoveries in Brazil and Canada and "improved knowledge" of deposits in Namibia, South Africa, Spain and the United States. NEA estimates that these reserves match the needs of Western nuclear power programmes between now and 2000-2005 but also considers that a significant portion of ore now identified will not be recovered "for technical or political reasons". So, the argument goes, there is an "urgent need" for the discovery of additional resources, reinforced by the wide range of the projections for nuclear power in 2025. The cumulative uranium requirements by that date range from 3.4 to 12 million tonnes, depending on nuclear power growth, the extent of reprocessing and the degree of development of fast breeders.

The NEA also looks forward to the exploitation of leaner ores, capable of yielding uranium at a cost of $\$130/\mathrm{kg}^{-1}$. Its upper estimate of the quantity of uranium in reserves now identified, not all of them explored, is put at 5.04 million tonnes, a quantity comparable with the estimated need of the nuclear industry by the second decade of the next century unless breeder technology is applied rapidly. Thus, the report concludes, the viability of the industry at the turn of the century will depend on the success of exploration in the coming ten years.

CORRESPONDENCE

Geothermal electricity

SIR,— Richardson and White[1] have raised the interesting possibility that electricity generation from geothermal aquifers in the UK might be an economic proposition. It is unfortunate, however, that they have supported their proposal with spurious comparisons; for example, comparing the performance of purpose-built (and as yet undeveloped) organic Rankine cycle generating plant with conventional unadapted district heating systems.

They state that district heating "... has dominated official thinking for several years. . ." and cite[2] Energy Paper No 9. I would not in general wish to defend that development, which is now outdated, but it actually says (p.51): ". . .it seems that district heating would be economic only if higher temperatures or higher housing density were to become available".

Current thinking is that the major market for heat from geothermal aquifers in the UK (as in France) will indeed be for space heating, but at the group rather than district level. Heating of only a few large buildings from each pair of wells (doublet) is envisaged, which would be located as close to the buildings as possible. Few aquifers in the UK seem likely to yield temperatures in excess of 80°C, so it will be necessary to instal heating equipment capable of (1) operating at temperatures lower than those used in conventional systems and (2) extracting as much heat as possible from the geothermal fluid. These conditions have already been met in France, and suitable equipment is available. In particular, rejection temperatures can be nearer 25°C than the 60°C envisaged in ref. 1.

In the operation of a resource with a high capital cost and a low running cost resource such as geothermal energy, there is a powerful incentive to maximize the load factor. In the French installation a conventional boiler plant is used in parallel with the primary geothermal circuit, allowing geothermal to meet the "base" heating load while peak demands are met by fossil fuel. In this way, a geothermal doublet designed to meet 40% of the peak demand can typically supply 70% of the buildings' annual energy needs while achieving a load factor of 60% or more[3]. The relative capacities of geothermal and conventional plant will be determined by local conditions — including cost of conventional fuel at the site; analysis of the heat demand curve for similar buildings in the UK[4] suggests that comparable figures for a UK geothermal scheme would be about 50%, 89%, and 74% respectively.

In comparing the two modes of use, we recognize that in the UK, calculations must be based on estimates and will be of value only in assessing relative rather than absolute performance. For consistency, the approach adopted by Richardson and White[1] has been used to calculate the relative performance of electricity generation and group heating for a range of probable UK aquifer temperatures and attainable flow rates. The capital cost of the doublet (£1m) and the pumping power required (250 kWe) have been assumed constant for all cases. For group heating, the geothermal system is assumed to meet 50% of the buildings' needs with the remainder supplied by conventional boilers. The size of the heat load ("equivalent dwellings" at a density in excess of 100/hectare for a mixture of commercial and residential property) is allowed to vary according to the output of the geothermal well. Capital costs for distribution mains, building internals and boiler plant are calculated according to refs 1 and 5. The rejection temperature is taken as 30°C, distribution and heat exchange losses as 10°C, the load factor as 70%, and the heat is assumed to be sold at £2.0 per GJ. For electricity generation, the conditions given in ref. 1 have been used, while the capital cost of turbogenerator plant is assumed to be proportional to (gross output)$^{1/2}$ with the £748,000 for a 1 MWe plant of ref. 1 used as a baseline.

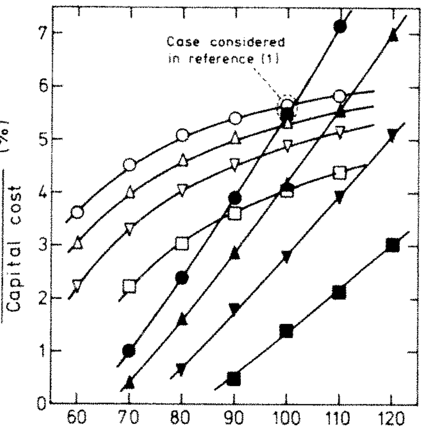

Fig.1 The effect of temperature and flow rate on the relative merits of group heating and electricity generation from geothermal aquifer sources in the UK.

Solid symbols, electricity generation; open symbols, group heating. Flow rates: ■ □, 20; ▼ ▽, 10; ▲ △, 40; ● ○, 50 kg s^{-1}.

The results are given in the figure. As might be expected, electricity generation becomes more attractive as temperature and flow rate increases but the return on capital is very sensitive to both parameters. Group heating is apparently less sensitive but this may be due to the method used for calculating capital costs. Comparing the data with those from French installations, capital costs derived from ref.5 seem very high, particularly for the larger schemes. Note also that the selling price of gas, in practice, varies from £2.03 per GJ (domestic user) to £2.47 per GJ (large industrial user). The cost of useful heat, even from gas, is thus nearer £2.90 per GJ than the £1.95 per GJ quoted in ref. 1, and the cost of heat from oil would be almost double. By contrast, the selling price of electricity is fixed (at 2.2 p/kWh); this calculation might then underestimate the relative advantage of direct heat uses over power generation.

Hence the advantages of electricity generation from low-enthalpy geothermal sources are not as clear-cut as Richardson and White[1] suggest. Until a borehole is drilled at any particular site, uncertainties will exist — particularly as regards flow rate.

However, such demand for heat will occur only in the larger towns, while many of the deep aquifers in the UK underlie rural areas where group heating would not be an option. If electricity production can be shown to be an economic proposition, then the contribution of geothermal sources to UK energy supply would be greatly increased.

Banking DNA sequences

SIR, — We were glad to see your article "Banking DNA Sequences" (8 May) 1980, in which you make a persuasive case that there should be such a computerized data bank. We fully agree. In fact, we already have compiled such a computerized DNA sequence bank, which now considerably exceeds the 100-kilobase figure mentioned in your article. Our DNA data bank is a natural adjunct to our Protein Sequence Reference Data Collection[1] that has been supported for the past 15 years mainly by the Institute for General Medical Sciences of the US National Institutes of Health and by the National Aeronautics and Space Administration.

Many people are aware of our facilities and we do various searches and computer studies each week for people all over the world. Our computer system includes a large number of programs especially designed for analysing such collections of data. The most frequently used capability is a search of the amino acid and nucleotide sequences for segments that match a given segment. Sequences can be retrieved quickly and compared, and statistical assessments of similarity can also be made.

Our DNA Reference Data Bank is growing continually, despite the fact that the collection of these data is aggravated by the nonavailability of material in computer-readable form (as are, for instance, the protein crystallography data). The sequences are not even in clearly readable form in some journals. We would be happy to receive sequence data in computer-readable form to add to the collection when this information is published in journals. The sequence in this additional format would then be available to others.

You also entertain the notion that it matters little by whom or where a bank is started and that a successful operation could be a depository run by a keyboard operator who sent out tapes. Based on our years of experience, we must emphatically disagree. There have been many attempts to start data collections but few have continued in operation, mainly due to greatly underestimating the amount of effort and training required for such an undertaking. Will the users be satisfied to say, in their papers, "I looked over a few sequences and reached the conclusion that . . ." or would they prefer to say, with confidence, "I looked over all of the sequences so far elucidated . . ."? Who will find corrections that have been made to the old data? Will the users want the corrected sequence in the collection? Will they want other information, such as which portions of the nucleic acid sequence code for proteins? Also, who will solicit the new material? It doesn't just drift into a depository. If the users have questions about the collection, do they want to be able to communicate with someone and expect answers? Do the users want the data center to be delicately attuned to their needs?

We feel that making the data base intellectually accessible requires a considerable amount of effort and that such an effort is warranted by the central importance of nucleic acid sequence data to many fields, including medicine, genetics, and biochemistry.

NEWS AND VIEWS

Just so stories and cautionary tales

from Robert M. May and Miranda Robertson

SPECULATION about the evolution of social behaviour had its historical beginning in Darwin's perplexity about (and tentative explanation for) sterile castes among the social insects. The recent upsurge of interest in such questions derives largely from Hamilton's papers in 1964 (*J. theor. Biol.* **7**, 1 & 17), and their popularization in Wilson's *Sociobiology: The Modern Synthesis* (Harvard University Press, 1975). A fascinating glimpse into the sociology of science is provided by Paul Harvey's and Jon Seger's recent analysis of the citation of Hamilton's seminal papers; in the span 1964–1975, *Science Citation Index* records no more than 2-3 citations in any one year; after the appearance of Wilson's book in 1975, the citation rate explodes faster than exponentially. But Wilson's citation contains an error ("the genetical theory of social behaviour", replacing the original "the genetical evolution of social behaviour"), and this mutant form had risen to constitute 80% of all citations by 1978. Possibly as a result of the Harvey and Seger study, the mutation has not gone to fixation, and has decreased to 60% of all citations in the most recent SCI.

For a quantitative discussion of the general phenomenon of altruism, Hamilton introduced the notion of an individual's "inclusive fitness" (see *Nature* **260**, 390; 1976; **260**, 9; 1976). Suppose the performance of an altruistic act (such as uttering an alarm call upon noticing a predator, or, in the extreme, remaining sterile and helping raise relative's offspring) diminishes the fitness of the altruist by a factor $(1-c)$ relative to a non-altruist, but increases the fitness of the beneficiary by a factor $(1+b)$. Such altruism will be favoured by natural selection provided the cost c accrueing to the performer is less than the fitness benefit b conferred upon the recipient, discounted by the degree of relatedness, r, between them;

$$r > c/b \qquad (1)$$

In a diploid population with no inbreeding, sisters have $r=1/2$, and the altruistic extreme of sterile castes ($c=1$) will evolve only if $b > 2$. But in a simple haplo-diploid system, sisters have $r=3/4$, and the critical degree of benefit is the weaker $b > 4/3$. This observation is one of the crucial points of Hamilton's paper.

But these ideas about inclusive fitness are based on the phenotype (altruist and non-altruist), and do not deal with the underlying genotypes and genetic mechanisms. So when ethologists, geneticists and theoreticians met recently in Berlin to talk about the evolution of social behaviour*, much discussion centred on the extent to which quick and dirty conclusions obtained from inclusive fitness arguments can be trusted. Several authors (Cavalli-Sforza & Feldman *Theor. Pop. Biol.* **14**, 268; 1978; Charlesworth, Uyenoyama & Feldman, this Conference) have recently analyzed the population genetics of altruistic traits governed by one locus with two alleles. These formal, genetic studies reveal at least three shortcomings in the phenotypic inclusive fitness approach. First, the assumption that relatedness-discounted benefits and costs can be added in a simple linear fashion does not always hold; often, it will be more appropriate to compound the effects in multiplicative fashion. However, as long as both costs and benefits are relatively small, so that only weak selection operates, the difference between additive and multiplicative models is unimportant. Second, the structure of the coefficient of relatedness deduced from a genetic treatment can be different from that deduced by simple inclusive fitness arguments for the asymmetric cases of sister-brother and brother-sister in haplo-diploid species. For example, the haplo-diploid sister-brother coefficient is modified from $1/4$ to $(1/4)/(1+bh/4)$, where h measures the probability that the heterozygous genotypes Aa are altruists (the homozygotes AA being altruists, and aa being non-altruists). Although these complications simply are not taken into account in the inclusive fitness analysis of phenotypes, the structural differences between the two approaches are again negligible in the limit of weak selection (small b and c). Third, nonlinear dynamical behaviour in the genetic models can lead to stable polymorphism, with both altruistic A and non-altruistic a alleles persisting together; in linear or additive models, be they phenotypic or genetic, if an altrusitic trait can invade a population it will necessarily go to fixation.

All these differences between formally exact genetic analyses of relatedness and approximate inclusive fitness analyses are small if selection is weak. Moreover, the inclusive fitness approach provides intuitive biological understanding that is quite absent from the mathematical edifices of population gentics. Although far from unanimous, people at the conference took the view on balance that rough inclusive fitness arguments are likely to remain our main guide in thinking about the evolution of social behaviour.

More important, practical difficulties in assessing the costs c and benefits b in equation (1) will usually outweigh considerations of formal rigour. Among such difficulties identified in the conference discussions are how to combine different components (such as survival and reproductive success) into an aggregate measure of inclusive fitness, and how to determine paternity.

False assumptions about paternity, in particular, are now recognized as an important hazard in empirical tests of inclusive fitness. Clearly, the accuracy of quantitative measurements of inclusive fitness made on the basis of field observations will depend heavily on the confidence with which paternity can be assigned; and it has turned out to be a very wise ethologist indeed who knows his fathers. The important attempt by Trivers and Hare (*Science* **191**, 249; 1976; see also *Nature* **260**, 9; 1976) to explain the altruism of the hymenopteran worker castes by a quantitative study of data bearing on their inclusive fitness gains has been seriously

0028-0836/80/300327-03$01.00

eroded by, *inter alia,* the discovery that multiple matings are common in the ant species on which they based their calculations. (Alexander & Sherman *Science,* **196,** 494; 1977), and that coefficients of relationship are therefore not what they might seem.

Nor are the multiple matings of insects the only hazard to inclusive fitness analysis. Students of vertebrate behaviour have only recently begun to recognize the full extent of the gene dispersal going on behind their backs in what they fondly believed to be monogamous species. P. Marler (Rockefeller University) and M. Baker (Colorado State University) pointed out, for example, that reports of healthy clutches of young hatched by the 'monogamous' mates of vasectomized birds have been in the literature for at least five years (e.g. Bray, Kennelly & Guarino, *Wilson Bull.* **87,** 187; 1975). For the reproductive strategy of the fathers of such clutches, sociobiologists have coined the term kleptogamy (or, in conversation, sneaking). These studies on bird paternity, incidentally, also testify to the complications that so often beset field experiments of this kind: for many bird species (including the redwing blackbirds studied studied by Bray *et al.*) infertile eggs are distinguishable by their colour from fertile ones, and it could conceivably be that the unfaithful wives chose to stray only after discovering their spouses to be infertile.

In general, field workers are becoming increasingly wary of assumptions about paternity, and wherever possible checking the degree of relationship between altruists and beneficiaries by isoenzyme analysis. This policy was adopted by R. Metcalf (University of California) in his cost-benefit analysis of the alpha and beta castes of paper wasps (*Polistes*). Female paper wasps may found nests and rear young as solitary individuals, or they may cooperate with a sister. In the case of cooperating sisters, one wasp, the alpha female, lays all or nearly all of the eggs so that the beta female is rearing nieces and nephews. However, the co-ops are so much more productive than the nests of solitaries that the inclusive fitness of the beta female is greater than that of a solitary one. Since this conclusion is based on calculations of the average number of genes a beta wasp will share with her nephews and nieces, by comparison with the average number shared with her own young, it is clearly essential to know for certain that she is the full sister of the alpha. The precaution taken by Metcalf, who analyzed the polymorphic enzymes of the wasps to check their relationships, is increasingly adopted by sociobiologists and has certainly helped to reveal unsuspected heterogeneity in presumed inbred colonies.

It has been generally assumed that the altruistic wasp, bird or beast itself does not have access to accurate information about its relationship to its conspecifics, and simply directs its altruistic acts towards the individuals it grew up with. But strict kin selection could still work in the face of rampant polygyny, kleptogamy and general promiscuity provided that there were in fact an innate mechanism for distinguishing degrees of kinship. Greenberg's report (*Science* **206,** 1095; 1979) that such a mechanism exists in the primitively eusocial bee *Lasioglossum zephyrum* was therefore generally agreed to be one of the most important recent contributions to the literature. There is overwhelming evidence that social insects recognize colony mates, but until recently no-one had managed to distinguish between innate and environmental factors in determining such recognition. Greenberg reared laboratory-bred bees of 14 different degrees of kinship in isolation and was able to show that when they were allowed to form colonies they preferentially admitted close kin to the nest, the probability of admission being roughly proportional to the degree of kinship. An exactly analogous mechanism was reported by K. E. Linsenmair (University of Würzburg) in a desert-dwelling social isopod. It is not yet known whether vertebrates have similar innate abilities. Waldman's and Adler's evidence for kin recognition in frogs (*Nature* **282,** 611; 1979) does not distinguish between innate and environmental mechanisms; but if innate mechanisms turn out to be widespread, this will limit the applicability of J. Maynard Smith's (Sussex University) ingenious adaptations of game theory to define evolutionarily stable strategies (ESSs) for behaviour, one of whose underlying assumptions is usually that kin recognition is based on simple proximity. The whole question of 'hidden' assumptions in evolutionary theories of behaviour is clearly a sore point with empiricists, who expressed the view that theoreticians should make them more explicit. For example, the majority of empiricists are probably not aware that most (though not all) of the ESS calculations in the current literature assume haploidy, and therefore strictly apply to nothing higher that some insects. Most of the conclusions can, however, be shown to apply to sexual diploids; and given the inevitability of simplifying assumptions, probably the most useful thing a theoretician can do is try to give some indication of how sensitive his theory is to violation of its assumptions.

On the other hand, it is incumbent on the empiricists to produce data good enough to provide a serious test of the theory. It is the shallowness of some of the earlier ethological investigations that has led to their being castigated by some as evolutionary Just-So stories. Lively discussion centred on several interesting but unfinished studies in which individual males seem to adopt one of two or more alternative reproductive strategies (for an example, fighting to maintain a territory and/or a harem *versus* kleptogamy). Such studies have so far left open many questions. Are the different phenotypes associated with different genotypes, or are they dictated by environmental constraints? Do the different strategies correspond to different categories of animal, or can, for example, a male start his adult life as a 'sneak' and later progress to ownership of a harem?

A fundamental question that has been raised regularly by the principal detractors of what has become known as sociobiology, and often ignored by its practitioners, is: what evidence is there that a particular phenotype is, in fact, adaptive? Feldman quoted the example of meiotic drive as a mechanism for preserving maladaptive genes in a population. Other extreme examples of this sort are known or suspected, and there is every reason to

100 years ago

NATURE WELCOMES *SCIENCE*

We take the following from the New York *Nation*:— "For the English-speaking race, wherever planted, we should have supposed NATURE to be a sufficient scientific medium, and entitled to universal support. We are partly confirmed in this view by the quotations from NATURE in the first number of *Science*, a quarto weekly journal, edited by Mr John Michels, and published at 229 Broadway, in this city. Nevertheless, the editor's statement that the enterprise has been begun 'after consultation with many of the leading scientists in this country,' and his list of co-labourers seem to point to a real want, and to entitle this new 'record of scientific progress' to a friendly welcome. Its present size is sixteen pages, including the advertising sheet. The opening article, on the United States Naval Observatory, is from the pen of Prof. E.S. Holden." We wish our new contemporary every success, and trust that it may be the means of spreading a wide interest in science on the other side of the water.

A violent shock of earthquake occurred at Manila and throughout the Island of Luzon on July 18, which did immense damage, totally destroying several government buildings and other houses. Some of the native inhabitants were killed, but no Europeans suffered any injury. A slight shock was felt also on the 17th inst.

from *Nature* **22**, 24 July, 276 & 276, 1880.

suppose that selectively neutral behaviour can become fixed in a population by historical or evolutionary accident.

To paraphrase one of the more vociferous participants, the Romantic Age of sociobiology, with its excitement and imaginative speculations about the explanatory power of inclusive fitness notions, is giving way to a more sober appreciation of the experimental difficulties that must be overcome before contending theories can be sorted out. For many, the meeting helped to crystallize thoughts about assembling data of sufficient resolution to distinguish between theories, and to draw up a tentative agenda of theoretical and empirical problems that deserve attention. In this context, the generic format of the Dahlem Conferences (of which there have been some 20-odd, on a diversity of topics) deserves mention: canonically teutonic, with groups and subgroups forming and reforming in intricate, pre-ordained patterns, their most obvious function is to produce a book, whatever betide. But the groups at the sociobiology meeting were skillfully chosen, blending theorists and empiricists, optimists and pessimists, romantics and realists; most important, the four rapporteurs (Feldman, Harvey, Krebs, Oster) managed to extract from the discussions reports that seem to be useful signposts. □

Malignant transformation and protein phosphorylation

from Thomas Langan

DURING the past decade protein phosphorylation reactions have been found to function in the regulation of a large number of cellular processes. In addition to extensively studied systems such as cyclic AMP-dependent phosphorylation, many other less well-characterized protein kinases and protein phosphorylation reactions occur, suggesting that regulation by protein phosphorylation is more wide-spread than currently appreciated. Recent work, stemming from the original observations of Collett and Erickson[1], has indicated that certain proteins responsible for transformation of virally infected cells to the malignant state are protein kinases, or are closely associated with protein kinases. These kinases have now been shown to have the novel property of catalyzing the phosphorylation of tyrosine residues in their substrate proteins, rather than the usual serine or threonine residues[2-5]. The findings indicate that a unique class of protein kinases may catalyze a key reaction in the production of certain types of malignancy, and there are hints that similar kinases may participate in normal regulation of cell proliferation.

The best studied system is that of the Rous or avian sarcoma virus, an RNA virus in which a single viral gene, *src*, has been shown to be responsible for transformation of cells to the malignant state[6]. A 60,000 MW protein present in transformed cells has been identified as the product of this gene by the use of deletion and temperature-sensitive mutants and, more convincingly, by direct translation *in vitro* from fragments of viral RNA containing the *src* gene[7,8]. The protein (pp60^{src}) is phosphorylated in two distinct regions of the molecule[9] and as with certain other phosphoproteins, pp60^{src} seems to be itself a protein kinase. This activity is of the cyclic AMP-independent type and was originally revealed by the ability of pp60^{src} to catalyze transfer of phosphate from ATP to the heavy chain of IgG in immunoprecipitates of viral protein, prepared using antisera from tumour bearing animals[1,10]. The reaction is clearly not of functional significance, but the ability to phosphorylate a non-physiological substrate is very advantageous for assay purposes. Extensive studies with deletion and temperature sensitive mutants[1,10-12] and the demonstration of protein kinase activity in highly purified preparations of pp60^{src} [13,14] as well as in pp60^{src} made by *in vitro* translation of viral RNA[15,16] show that the protein kinase activity is a property of the *src* gene product and that the activity is essential for transformation of cells to the malignant state. While tight association of traces of a cellular kinase with the native form of pp60^{src} cannot be completely ruled out, they support the conclusion that the *src* gene product is either a protein kinase itself, or functions in close association with a cellular protein kinase.

As well as avian sarcoma virus, protein kinase activity has been found associated with several other transforming gene products, including those from the DNA-containing adenovirus, SV40, and polyoma viruses [17-21,2], and from the RNA-containing Abeleson murine leukaemia and Fujinama viruses[3,22]. In each case protein kinase activity is detected in immunoprecipitates of viral proteins using the assay developed by Collett and Erickson. However, phosphorylation in most cases occurs not on the immunoglobulin chain, but on the viral protein itself. Whether this represents an intermediate in the normal enzymatic reaction which is stable in the absence of a suitable substrate, or an autophosphorylation which may affect function is not clear. pp60^{src} also undergoes an apparent autophosphorylation reaction when in soluble form both *in vitro* and *in vivo*, and in addition is phosphorylated by the normal cellular cyclic AMP-dependent protein kinase at a separate site in the molecule[14,9]. Whether these phosphorylation reactions modulate function is again not clear. There is less evidence that the protein kinase activity is due to viral protein for viruses other than avian sarcoma and there are some reports that activity may not be present in purified forms of SV40 and hybrid SV40 large T antigen[18,23]. However, large T antigen is different in many ways from the other viral products which show kinase activity. Kinase activity is absent from immunoprecipitates when transformation-defective mutants of adenovirus, SV40 and polyoma are used, consistent with the conclusion that the transforming activity is a kinase although the possibility of an association between the viral protein and a cellular kinase remains.

That transformation-related protein kinases catalyze the phosphorylation of tyrosine residues in their substrates was first shown by Hunter and co-workers[2] in the polyoma system, where kinase activity is mainly associated with a tumour antigen of intermediate size (middle T). Phosphorylation occurs on the phenolic hydroxyl group of tyrosine. Protein kinases associated with other viral transforming gene products also phosphorylate tyrosine residues[3-5]. Previously, phosphorylated tyrosine residues were not known to occur in proteins, although modifications such as nucleotidyl derivatives of tyrosine are found in bacterial enzymes (for example, ref. 24). As each of these kinases associated with viral transforming gene products catalyzes the phosphorylation of tyrosine residues it seems probable that a unique class of protein kinases may be involved in the transformation of cells to the malignant state. This feature may be extremely useful in locating other kinases with similar or related functions, and in locating and measuring the phosphorylation of potential substrates.

By itself, the fact that phosphorylation occurs on tyrosine rather than on serine or threonine residues gives no clue to the molecular mechanism of transformation. One possibility is that the phosphorylation of cellular substrate proteins by the viral kinase (or by a cellular kinase which is activated by association with the viral protein) leads to functional alterations which initiate the transformation process. Since this is a highly pleiotropic response, many substrates could be involved. Kinase action *in vivo* is indicated by an approximately 10-fold increase in the phospho-

tyrosine content of total cell protein during transformation by avian sarcoma virus. When the *src* gene contains a temperature sensitive mutation, phosphotyrosine content rapidly declines to normal values and rises again as cells are shifted from permissive to restrictive temperatures and back[25]. Not all of the increase in phosphotyrosine can be accounted for by the apparent autophosphorylation of $pp60^{src}$ which occurs in transformed cells, indicating that tyrosine residues in cellular proteins are phosphorylated. Two specific proteins that appear to be substrates of cellular origin are under study. One is a 50,000 MW protein found in immunoprecipitates of $pp60^{src}$ because of its affinity for the kinase protein[4] and the second is a 34,000 MW protein that is clearly identifiable in normal cells, and which undergoes a transformation dependent and temperature-sensitive phosphorylation in virally infected cells[26,27]. The 34,000 MW protein, extensively purified from normal chicken cells, is phosphorylated by purified $pp60^{src}$ kinase, and tryptic digests phosphorylated *in vitro* and *in vivo* show the same patterns of tyrosine-containing phosphopeptides in two-dimensional maps[28]. Determination of the functions of the substrate proteins may not be a simple task and it is possible that $pp60^{src}$ has additional functions which are important for the transformation process.

Tyrosine phosphorylation may not be a universal feature of transformation mechanisms as although transformation by the related Abelson virus is associated with elevated phosphotyrosine in proteins (Hunter, pers. comm.) in several other viruses including, surprisingly, polyoma and SV40, there is no elevation[25]. However, the kinases in these cases may be more specific in catalyzing the tyrosine phosphorylation reactions required for transformation, so that no increase in total content is detectable. Two chemically transformed cell lines examined also did not have elevated phosphotyrosine levels.

DNA sequences closely related to the sequences in the avian sarcoma *src* gene are present in normal cells of vertebrates ranging from birds to man[29], and transcripts of these sequences are found in polyribosomes[30], indicating that the sequences code for a protein with a highly conserved general cellular function. In keeping with this, normal cells also contain a 60,000 MW protein which is structurally related to $pp60^{src}$, as indicated by immune cross-reaction and by peptide mapping, and which is also associated with protein kinase activity acting on tyrosine residues[31,32] (Erikson, pers. comm.). The amount of the normal cell protein is some 30-50-fold lower than that of $pp60^{src}$ in transformed cells. These findings suggest that the viral protein may be related to a normal cell protein involved in some universal cellular function such as maintenance of control over cell division. Malignant transformation might result from a qualitative change in the substrates phosphorylated, or from an uncontrolled increase in a normal cell phosphorylation reaction. In either case, investigation of the substrates phosphorylated by the normal cell protein and by any similar kinases seems worthwhile. One interesting candidate has already been identified. When cell membranes from human epidermoid cells bind epidermal growth factor the binding is associated with the phosphorylation of a membrane protein (possibly the receptor for the growth factor) and this phosphorylation occurs predominantly on tyrosine residues[34] (S. Cohen, pers. comm.). Future study of this as well as other protein phosphorylation reactions involving tyrosine residues may shed light on important control mechanisms in both normal and malignant cells. □

Repressor represses cro represses repressor represses cro . . .

from Mark E. Furth

THE discovery of regulatory genes in bacteria and maize quickly invited speculation on how simple control elements such as repressors and operators might determine cell differentiation[1]. Are these elements connected in circuits to produce states of gene expression which can be propagated through many cell generations[2]? Stable regulatory circuits are easy to construct on paper, but more difficult to unravel in the laboratory. The choice between the lysogenic and lytic lifestyles of bacteriophage λ has served as one experimental model of a 'developmental switch' between alternative stable states. A regulatory circuit central to this switch has now been explained in exquisite molecular detail[3].

The circuit involves two proteins, encoded by genes *cI* and *cro*. Each protein represses the other's synthesis. The *cI* protein (often called the λ repressor) maintains the lysogenic state in which λ replicates passively, its DNA integrated into the chromosome of its bacterial host. In this state the repressor shuts off viral genes, including *cro*, which are required for active growth. The *cro* protein (called cro), in contrast, promotes lytic growth by shutting off the repressor gene *cI*. Either of the two stable states of gene expression, *cI* turned on and *cro* turned off, or *cro* turned on and *cI* off, can be maintained for many generations in cells carrying particular λ mutants[4]. These states are regulated by binding of the repressor and cro to an operator called O_R which lies between the *cI* and *cro* genes. The bound proteins control the initiation of messenger RNA synthesis at two distinct sites: the promoter P_{RM} for transcription of *cI*, and the promoter P_R for transcription of *cro* (see figure)[5,8,12]. How do the repressor and cro differentially affect the activity of these two promoters?

One key to the control of *cI* and *cro* expression lies in the fine structure of the operator. M. Ptashne and colleagues discovered several years ago that O_R contains three separate binding sites for repressor (O_R1, O_R2, O_R3; see figure)[7,17]. These sites are closely related, but the nucleotide sequence of each is unique. When cro was purified[9], its target sequences could be compared with those for repressor. Remarkably, although the two proteins show no obvious structural homology[10,11,18], they bind to the same three sites in O_R (ref. 12). However, the proteins differ in the order in which each occupies these sites. Repressor first binds coordinately to O_R1 and O_R2, and binds to O_R3 only at much higher protein concentration[13]. cro first binds to O_R3, and then to O_R1 and O_R2.[12]. This difference in the relative affinity for binding sites in the operator is critical to gene regulation, because occupation of each site by a repressor or cro molecule affects promoter activity in a specific way.

Fig. O_R region of λ DNA. Promoters P_{RM} and P_R direct transcription (wavy arrows) of genes *cI* (encoding repressor) and *cro* respectively. Repressor and cro proteins bind to sites O_R1, and O_R3. The distance between mRNA startpoints is 82 base pairs. Each binding site is 17 base pairs long.

B. Meyer, R. Maurer and M. Ptashne have identified the function of protein molecules bound to each site in the operator[14–16]. They devised a strategy to measure P_R and P_{PM} activity over a wide range of repressor and cro concentrations in intact cells, and to determine the effects of mutations in the three binding sites. The trick was to place the expression of an easily assayed enzyme, β-galactosidase, under the control of each phage promoter, and to introduce O_R mutations into the fused operons. Levels of the λ regulatory proteins were manipulated by similar genetic sleight-of-hand; the expression of *cro* or *cI* was placed under control of an inducible bacterial operon and the rate of synthesis was set by varying the concentration of the inducer. The special elegance of the approach is that it uncouples the synthesis of the regulatory proteins from the promoters which normally control their expression, so that measurements of promoter activity can be made under many steady-state conditions.

The results of studies with the fused operons show that each of the outer operator sites, O_R3 and O_R1, regulates transcription from the start-point adjacent to it, while the central site, O_R2, regulates both promoters. Either a repressor molecule or a cro molecule bound to O_R3 turns off transcription from P_{RM}, but does not turn off transcription from P_R. Conversely, either protein bound to $O_R{}^1$ or $O_R{}^2$ turns off transcription from P_R but not from P_{RM}[14,15]. Repressor, but not cro, bound to O_R2 has a second effect: it strongly stimulates transcription from P_{RM}[5,6,16].

The different order of binding of cro and repressor to the three sites in O_R, and the particular role of each site in determining promoter activity largely explain the stable states of *cI* and *cro* expression. Because cro binds preferentially to O_R3, it represses transcription of *cI* more readily than it represses transcription of its own gene. By contrast, because repressor binds preferentially to O_R1 and O_R2, it turns off transcription of *cro* more readily than it turns off transcription of *cI*. Thus, there are concentrations of cro which prevent synthesis of repressor but permit expression of *cro*, and there are concentrations of repressor which prevent synthesis of cro but permit, and actively maintain expression of *cI*.

What determines the order of occupation of the binding sites by the regulatory proteins, and how do bound protein molecules control the initiation of RNA synthesis? Ultimately, it should be possible to answer these questions at the atomic level of resolution. The present studies of molecular mechanisms focus attention on some of the protein-DNA and protein-protein interactions that contribute to gene regulation. A striking and unexpected finding is that cooperative interactions between bound repressor molecules help to govern the pattern of binding to sites in the operator.

Cro binds to the three sites in O_R independently, in the order set by the protein's intrinsic affinity for each site[12,13]. Repressor presents a more complex picture. Its intrinsic affinity for the isolated O_R1 sequence is about 15-fold greater than that for O_R2 or O_R3. Nevertheless, on an intact operator it binds O_R1 and O_R2 to about the same extent at concentrations at which O_R3 remains free. Johnson, Meyer and Ptashne attribute the coordinate binding at O_R1 and O_R2 to positive cooperative interactions between repressor molecules[13]. They argue that a molecule bound at O_R1 facilitates the binding of a second molecule at O_R2 by direct protein contact. When O_R1 is free, repressor molecules also can cooperate to fill O_R2 and O_R3. However, a molecule bound at the central site does not interact simultaneously with neighbours on both flanks, and at equilibrium the interaction between molecules at O_R1 and O_R2 is strongly favoured. A major consequence of this cooperative binding is to stabilize the state (O_R1, O_R2 bound by repressor, O_R3 free) in which cro synthesis from P_R is turned off while repressor synthesis from P_{RM} is stimulated. This is the predominant situation in a cell lysogenic for λ.

Table 1 Properties of repressor and cro

	Repressor	Cro
Gene	*cI*	*cro*
Size of monomer	236	66 amino acids
Active form	Dimer	Dimer
Order of binding to operator sites (wild-type O_R)	$O_R1 \simeq O_R2 > O_R3$	$O_R3 > O_R2 \simeq O_R1$
Cooperativity in binding to DNA	Yes	No

Table 2 Comparison of promoters P_R and P_{RM}

	P_R	P_{RM}
Intrinsic activity	High	Low
Positive control (stimulation)	No*	Yes, by repressor
Primary site for negative control by repressor or cro	O_R1, O_R2	O_R3

(*or weakly by cro: see ref. 8)

Table 3 Action at O_R2: Protein bound at O_R2

	Repressor	cro
Transcription from		
P_R:	Off	Off
P_{RM}:	High (stimulated)	Low (unaltered)

The capacity of bound repressor to prevent transcription from one promoter while enhancing transcription from another is one of the most striking features of the repressor/cro regulatory circuit. Both repressor and cro protein appear to shut off transcription simply by blocking access of RNA polymerase to a promoter[3,6,9,13,15]. However, the mechanism by which repressor boosts transcription from P_{RM} is not obvious. Meyer and Ptashne[16] have shown that repressor must directly effect this stimulation; it is not merely a consequence of turning off transcription from the nearby promoter P_R. They suggest that repressor at O_R2 interacts with RNA polymerase at P_{RM} to stabilize polymerase binding or to facilitate a subsequent step in the initiation of RNA synthesis[3,15,16]. The startpoint for transcription from P_{RM} lies only one base pair further from O_R2 than does the startpoint for transcription from P_R. Yet repressor bound to O_R2 helps RNA polymerase to initiate at one promoter, but excludes it from the other[15]. Whether repressor acts positively or negatively on transcription must therefore critically depend on the precise orientation of bound repressor with respect to the binding site for RNA polymerase. A remaining challenge is to find an exact molecular explanation for the Janus-like behavior of this regulatory protein.

Perhaps a more imposing challenge is to identify genetic regulatory circuits that control development of multicellular organisms, and which can be dissected as neatly as those of λ. One outstanding lesson from the phage model is that the action of each element of such a circuit can be finely tuned and very flexible, so that a single regulator or target sequence may affect gene expression in very different ways. ☐

The problem of defining a substorm

from S. W. H. Cowley

ALTHOUGH the correlation between periods of geomagnetic disturbance and the occurrence of auroras had been known since the time of Celcius (1741), the first scientific reference to magnetospheric substorms seems to be found in the accounts of Herrick (1838) and Olmstead (1856) who noted that auroras often display 'fits of maximum intensity' at intervals of several hours. Interest in these 'auroral fits' and their associated short-lived polar magnetic disturbances waned towards the end of the nineteenth century, and for the next sixty years interest focussed instead on world-wide magnetic storms which develop and decay on time scales of a day or two. It was not until the exploitation of ground networks of all-sky auroral cameras and magnetometers during the International Geophysical Year (IGY, 1957-8) that it was finally realized that the polar 'fits' constituted the building-blocks of world-wide storms. Magnetic storms build up when intense 'fits', now fortunately renamed 'substorms', occur very frequently.

The phenomenology of the auroral substorm described by Akasofu (1964) on the basis of the IGY data is sketched in the accompanying figure, and this was followed by a monograph (1968) in which the evolution of high-latitude phenomena (for example, magnetic disturbance, ionospheric cosmic radio noise absorption, VLF radio emissions) was linked to a common time frame defined by the auroras. Auroral light emission is produced at $\sim$100-150 km altitudes by 1-10 keV electron bombardment of the upper atmosphere, the electrons originating in the Earth's magnetosphere (the region extending $\sim$10 Earth radii on the day side and at least $\sim$1000 on the night side containing the Earth's magnetic field and excluding, at least in part, the solar wind plasma). During the early sixties detailed satellite observations in the magnetosphere out to large distances, but linked to the polar regions by the Earth's magnetic field lines, were only just becoming available, but it was already clear that large changes in the field and charged particle populations occurred, and that the substorm concept provided an organizing framework.

Akasofu's (1964) auroral substorm consisted of two phases, 'expansion' and 'recovery', both lasting 30 min — 1 hour. Onset of expansion is signalled by a sudden brightening (in $\sim$1 min), usually near midnight local time, of one of a series of quiet auroral arcs which may have existed for several hours previously (Fig. a). Brightening is followed by rapid poleward motion, forming a bulge which expands also to the east and west (Fig. b). The western end develops a large scale fold or 'surge', and the quiet arcs along which it propagates can brighten just before the surge reaches and engulfs them. In the morning the arcs break up into patches, drifting eastward at speeds $\sim 300\,\mathrm{ms}^{-1}$. Recovery starts when the bulge reaches its highest latitude, begins to contract and the auroras gradually resume their quiet-time appearance (Fig c). The occurrence of such displays is very variable, but several during one day is not unusual.

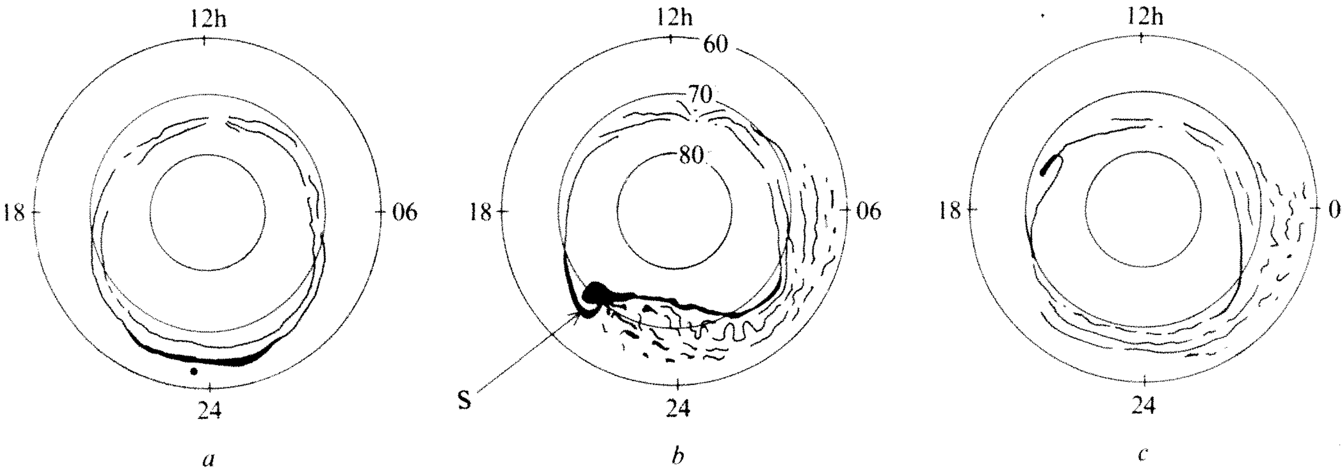
The principal magnetic signature is a decrease in horizontal field strength under the auroral bulge due to an ionospheric westward 'electrojet' current of $\sim 10^6$ amps flowing within it, although smaller perturbations are observed down to low latitudes. In addition, a spatially widespread magnetic signal usually appearing as a damped, $\sim$1 min period sinusoid is initiated at the onset of expansion. This characteristic signal is known as a Pi-2 and is thought to be excited by rapid changes in plasma flow in the magnetosphere.

In principle the substorm onset time can be obtained to within a minute or two using either auroral or magnetic data, and such accuracy is often required, for example, to establish the relative timing of rapidly changing conditions at widely separated locations (for example, ionosphere and night side magnetosphere). In practice, however, timing substorms turns out not to be at all easy, as has become increasingly evident over the past decade, due both to the incomplete coverage provided by ground-based networks and to the increasing realization of their complexity. These problems have encouraged research groups to champion differing signatures as definitions of the substorm time-frame, resulting in a great deal of both scientific and etymological confusion, and providing the basis of much heated argument.

A resolution of these problems was attempted in August 1978, when a three-day workshop was held at Victoria, British Columbia, Canada, attended by nine prominent substorm researchers. Their brief was to attempt to reach consensus on a workable substorm definition, backed by a set of useable signatures. The results of their deliberations have been published very recently (Rostoker *et al. J. geophys. Res.* **85**, 1663; 1980).

The substorm picture discussed above is extended in the new descriptive definition offered by these authors in the recognition of 'multiple onsets', arising from observations of several discrete increases of activity during the expansion phase. Each of these increases is associated with a Pi-2 burst, the formation of a new westward-travelling surge in the auroras, and, as the surge crosses the local meridian, a discrete poleward expansion of the westward electrojet. The first increase in activity is termed the 'onset', and all subsequent increases prior to the start of recovery (defined as before), 'intensifications'. It is noteworthy that their definition includes the necessary appearance of at least one Pi-2 burst, the pulsations being taken to signify that the observed event is of an impulsive nature.

Fig. Sketches of auroras during substorms viewed looking down on the north pole showing (a) thin quiet arcs lying in an oval around the pole with a brightened arc at the equatorward border signalling substorm onset, (b) bulge formation by rapid poleward motion with a westward-travelling surge at its westernmost edge and eastward moving patches in the morning hours, and (c) auroras returning to quiet conditions during recovery. The coordinates are local time hours (longitude) and magnetic latitude.



0028-0836/80/300332-02$01.00

The second and more important feature of their discussion, however, is concerned directly with the difficulties and ambiguities inherent in currently available ground-based data, and the circumstances required for the drawing of valid conclusions regarding the start of the expansion and recovery phases. It is pointed out, for example, that a single all-sky camera sees only a small part of the whole auroral display at any one time, and as a result the brightening of arcs just to the west of a surge followed by passage of the surge across the local meridian can easily be mistaken for a local onset. In the future any substorm onset time proposed on the basis of local auroral brightening should therefore, the authors say, be substantiated by showing that at the least no brightening occurred a few minutes earlier to the east of the station. Similar treatment is given to the magnetic signature, and it is finally uncompromizingly recommended that researchers use original magnetograms from "as many relevant observatories as possible" to determine individual substorm development. Standard magnetic indices, in common use at present, which are synthesized from a few auroral zone stations are to be eschewed.

Even if the above laborious practices are followed, however, not all onset and recovery times can be determined with confidence due to gaps in ground coverage. Indeed some substorms, particularly those of small amplitude which tend to occur at higher than normal latitudes, may not be detected at all. These inadequacies were particularly exposed in the last decade when the first whole auroral oval pictures became available via the imagers flown by the US Air Force Geophysical Laboratory on DMSP satellites and by Canadian experimenters on ISIS-2. In these systems the picture is built up on a line-by-line basis as the satellite traverses the polar regions at ~ 1,000 km altitudes, so that only one 'snapshot' (of the northern auroral zone) is obtained per orbit (~90 min). These images allowed a great step forward in understanding auroral morphology, but were, of course, unable to follow the changes during substorms. A radical solution to the problems emphasized by Rostoker *et al.* is therefore clear, although technically difficult and rather expensive. What is needed, as the authors point out, is a satellite auroral TV system with a resolution better than 10 km spatially and 1 minute in time, which can return images continuously for a period of several hours. Only with such data will the full story of the dynamic auroras be finally revealed. □

Radar measurements of estuarine currents and tides

from E.D.R. Shearman

An important step in the development of a new remote sensing system is reached when the research moves from comparisons with ground truth to the provision of area surveillance data in a form directly comparable with theoretical models. This point has now been reached for surface current measurement by High Frequency (HF) radar in the dekametric band as described by A.S. Frisch and B.L. Weber[1].

The discovery from which HF radar oceanography has grown was made in 1969 by D.D. Crombie[2]. In observations with a vertically-polarized 13.5 MHz radar, directed seawards from a coastal site, he detected Doppler-shifted echoes with a strong spectral line component at a shift of 0.376 Hz. This shift corresponds to a radial velocity which is that of gravity waves on the sea surface of wavelength 11 m, just half the radio wavelength. There is a selective scattering process, now known as Bragg scattering by analogy with the diffraction of X rays from the regular rows of atoms in a crystal lattice. This process sifts out from the chaotic superposition of waves of different lengths and different directions on the sea-surface those waves travelling radially towards or away from the radar and of wavelength half the radar wavelength.

By using a number of radar frequencies and by directing the radar beam in different directions it thus becomes possible to measure the wavelength spectrum and the directional spectrum of sea waves, whether wind-driven waves or swell. This has led to

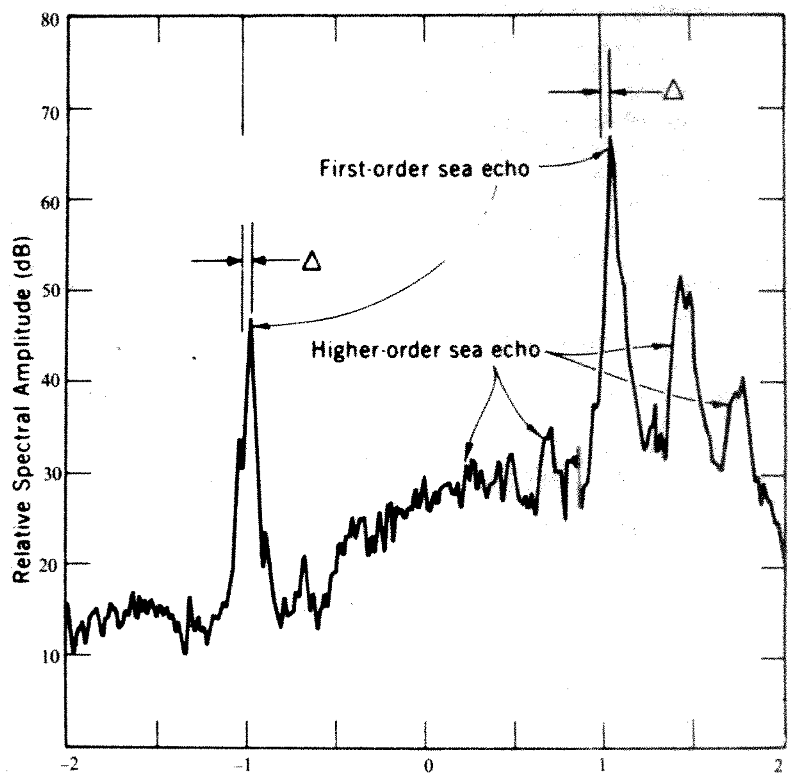

Fig. 1 Example of 9-sample average of 200 second HF ground-wave sea-echo power spectra at 9.4 MHz. Doppler frequency (horizontal axis) is normalised with respect to the expected position of the first order Bragg resonant peaks (here 0.313 Hz). Δ is the normalized shift of the record due to a surface current, as utilized in the NOAA current-measuring radar. Note the narrow Bragg peaks as seen with a narrow-beam radar. (After Barrick *et al*[7]).

E.D.R. Shearman is in the Department of Electronic and Electrical Engineering, University of Birmingham.

0028-0836/80/300333-02$01.00

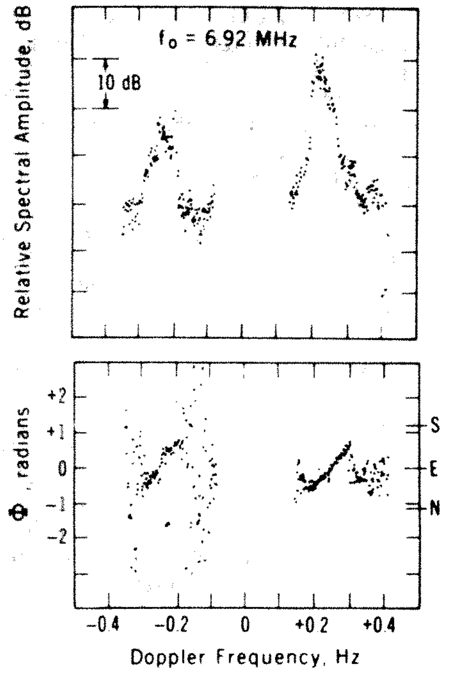

Fig. 2 Upper: Doppler spectrum of current-smeared sea echo from the Gulf Stream received on a wide-beam antenna.
Lower: Phase difference between two spaced antennas versus Doppler-shift, demonstrating that echoes from different directions are sorted by current-produced Doppler and can then be identified. (After Crombie *et al*[11]).

the remote measurement not only of wave spectra, but also, by inference, of sea-surface wind direction[3] and wind speed[4].

Theoretical investigations by Hasselmann[5] and by Barrick[6] make it possible to deduce the wavelength and the directional spectra of sea waves by inversion of second order features in the radar echo spectra from a single patch of ocean at a single radio frequency. The spectrum of Fig. 1, obtained at San Clemente Island, California[7], illustrates these first and second order features. These techniques already promise a capability for characterising sea-state over a large area of ocean. Crombie's coastal-sited 'ground-wave radar' technique can give coverage up to some 300 km with suitable power and frequency; 'sky-wave radar' using ionospheric refraction covers the area between 1,000 km and 3,000 km from the radar[8,9]. A useful review of the basic concepts of HF radar oceanography has been given by Barrick[10].

The paper by Frisch and Weber makes use of a different phenomenon from those employed in the above wave and wind measurements. In Fig. 1 it will be seen that the approach and recede first-order Bragg resonant frequencies, nominally at ±1 on the normalized Doppler frequency scale, are displaced from symmetry about zero, as if the approaching waves were travelling faster towards the radar than the receding waves away from the radar. This is what would be expected if the water surface were being carried towards the radar by the radial component of a tidal stream or current. (In the case of sky-wave propagation, such shifts can also be introduced by ionospheric motion, but this is not so for ground-wave radar).

If we consider a ground-wave radar located on the sea coast with an omnidirectional antenna, so that sea areas in all directions contribute to the received echo, a 'current-smearing' will occur. Returns from different directions will be Doppler-shifted by the current to different extents. Fig. 2 shows the results of an experiment done under conditions[11] in which reception took place on two spaced antennas. At the top is seen the current-smeared spectrum for the approach and recede Bragg resonant waves, while at the bottom is the phase difference between the two antenna signals plotted as a function of Doppler shift. This phase difference, Φ, would be expected to be given by $k_0 d \sin \alpha$ where d is the (known) spacing between the two receiving antennas, α the azimuthal angle relative to the normal to d, and k_0 is the (known) radar wave number. We see that by Doppler analysing the echoes, returns from each direction have been sorted by frequency and that it is then possible to measure their direction of arrival by simple relative phase measurement, at separated antennas. This is the principle of the NOAA current measuring radar[12].

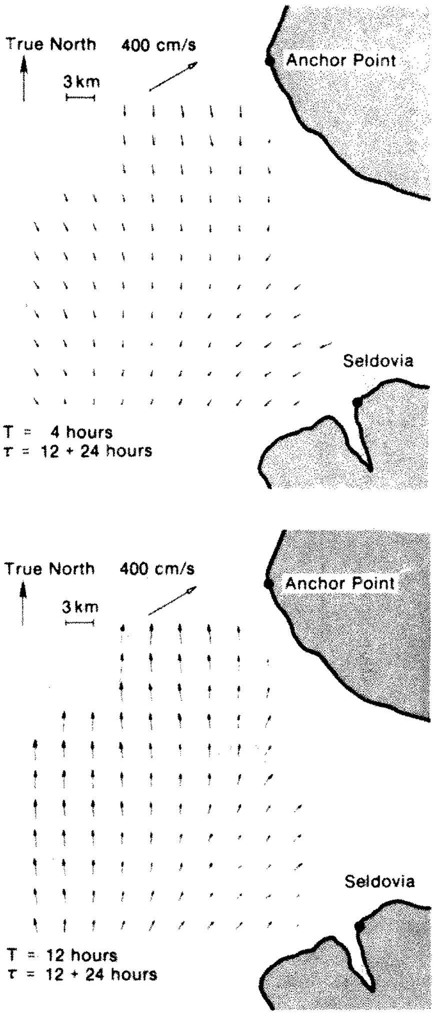

Fig. 3. Two maps depicting the tidal currents in the vicinity of Kachemak Bay at times 8 hrs apart. The current vectors are plotted at 3 km intervals relative to the southern radar site near Seldovia.

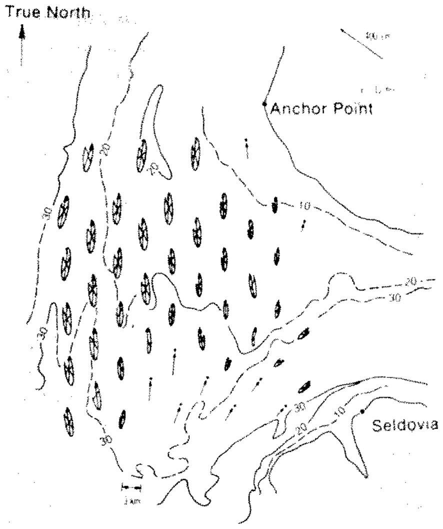

Fig. 4. Tidal ellipses for the 12 hour tidal velocity component in the vicinity of Kachemak Bay, starting at 00 hours on July 13, 1977. The arrow points to the current direction at 00 hours.

Frisch and Weber describe the deployment of two such radars in the Cook Inlet, Alaska. Fig. 3 shows a snapshot of current vectors obtained by putting together the radial current components measured from the two sites, Seldovia and Anchor Point. The data was analysed by extracting from the radar results at grid locations spaced 3 km apart, the North-South and East-West components of the current. The values of these components were available from observations taken every fifteen minutes throughout twenty-four hours. A least square fit was then carried out to estimate the nominal twelve and twenty-four hour tidal components for the surface currents as a function of position. The current velocity at the grid locations showed a considerable but orderly amplitude and phase variation over the radar coverage area.

A compact summary of the kind of results that can be obtained by this method is given in Fig. 4, here showing the tidal ellipses for the 12 hr component of tidal velocity. □

Nd–Sr isotopic relationship in granitoid rocks and continental crust development: a chemical approach to orogenesis

Claude J. Allègre & Dalila Ben Othman

Laboratoire de Géochimie et Cosmochimie, Institut de Physique du Globe, Département des Sciences de la Terre, Universités de Paris VI et VII,
2 Place Jussieu, 75230 Paris Cedex 05, France

Nd and Sr isotopic compositions of young granitoid rocks from diverse locations show that none of them is derived from an oceanic mantle. Instead a large amount of recycled older continental crust must be involved in their genesis. In contrast old granitoids (older than 2,000 Myr) seem to have initial isotopic ratios of Nd and Sr quite close to the planetary mantle evolution line. These observations are interpreted as evidence of a quasi-continuous continental growth through geological time. We propose a mixing model to explain quantitatively the generation of granitoids from mantle and recycled continental materials.

THE process of orogeny incorporates a variety of stages such as folding, metamorphism and granitization, and its main chemical result is the formation of a piece of continental crust. As granitoids are the main components of continental crust, the problem of their genesis is linked to that of the origin and evolution of continents. Two extreme theories have been proposed:

(1) continental crust is created from the mantle by a continuous differentiation process throughout geological time;

(2) continental crust has been differentiated once from the mantle, early in the Earth's history, since then this material has been continuously recycled into the new crust.

The formation of granites can also be described by two models: either as the ultimate product of magmatic differentiation, or as a product of crustal anatexis[1,2]. Although using Sr or Pb isotopes as petrogenetic tracers has clarified some problems[2–7] no widely accepted model has been proposed so far.

Following the work by Richard *et al.*[8] Nd isotopes were used for extremely powerful tracer studies[9–13]. Their usefulness is due to two geochemical properties of rare-earth elements (REEs): they are not very mobile and large geochemical fractionation of the parent/daughter Sm/Nd ratio is difficult.

This article considers the application of the coupled Nd–Sr isotopic systems to the genesis of continental crust: old and young granitoids are compared.

Petrogenesis of recent granitoids

We have investigated the Nd systematics in granitoids younger than ~350 Myr (the age correction for ^{147}Sm *in situ* decay is, therefore, rather small) representative of the various geodynamic environments: (1) island-arcs (Japan); (2) continental subduction zones (Andes); (3) complex subduction areas (southern California Batholith, Sierra Nevada); (4) continental collision zones (Himalayan and European hercynian granites). Results for the major petrographic types of granitoids are given in Table 1 and illustrated in Figs 1 and 2.

Subduction zones

Japan. We have studied two typical Japanese granitoids from Okue and Owe in the centre of Honshu Islands, which are 21- and 12-Myr old respectively. Like the whole calc-alkaline suite, these granitoids are associated with the general subduction process. $\varepsilon^{i}_{Nd} = -3.3$ and -3.1 (see Table 1 for a definition of ε_{Nd}). Because these values are significantly lower than those for mid-oceanic[8–11] and island-arc basalts[12,13], direct derivation from a downgoing plate is ruled out. These granitoids are at least partly composed of crustal material, which may have been incorporated into the subducted plate as detritial sediments, or it might result from remelting of the overlying continental crust induced by the presence of hot basic or calc-alkaline magmas.

California. Two typical batholiths occur in California: in southern California and in the Sierra Nevada. Although the tectonic situation at the time of their formation is not clear, it is considered to be related to subduction processes[14].

The southern California batholith is a complex which includes many different types of granitoids with ages ranging from 80 to 103 Myr on the east and 105 to 130 Myr on the west[14]. Detailed studies by Silver *et al.*[14–17] using Sr and Pb isotopes and trace elements, and by Taylor and Silver[18] using ^{18}O/^{16}O and ^{87}Sr/^{86}Sr ratios, have shown that the batholith can be divided into a western and an eastern part, the former being older and emplaced at a shallower depth than the latter.

The variation of ^{18}O/^{16}O and ^{87}Sr/^{86}Sr seems to confirm that several sources are involved in the genesis of this batholith. The value $\varepsilon^{i}_{Nd} = +3.6$ for the San Marcos gabbro is consistent with that of mid-oceanic ridge basalts (MORB) contaminated by some crustal material. The Rubidoux granite, a 'charnockitic granite' has $\varepsilon^{0}_{Nd} = -1.4$. which is close to the present chondritic value, while for the Lakeview Tonalite $\varepsilon^{0}_{Nd} = -9.9$ which is very different from any mantle material value and implies a large crustal component.

In the study of the Sierra Nevada batholith by Hurley *et al.*[19] using the ^{87}Rb/^{87}Sr method, some isotopic heterogeneities were pointed out within the batholith. More recent studies[20] gave a better definition of this heterogeneity: this batholith is composed of many plutons almost continuously emplaced from 134 to 85 Myr and with some older ones around 160 Myr. In the southern California batholith there is a systematic variation from west to east for both Sr and Pb isotopes. Note that the four rocks studied here clearly do not constitute a comprehensive survey of the two massives. As the ε^{i}_{Nd} vary between -7 and -3.3 and is clearly outside any mantle trend, this implies the participation of crustal material in the genesis of these batholiths. Again, none of these granitoids can be considered as the direct product of mantle type material—remelting of old continental crust is needed. This agrees with the studies of Magaritz and Taylor and Armstrong *et al.*[21,22]. Both batholiths are heterogeneous and seem to contain oceanic material mixed with previous continental crust.

Peru. The tectonic environment in the Andes is important because it has been considered as the archetypal continental growth mechanism. Although we have studied only one granitoid, more extensive research has been carried out on the different types of lavas which are widely held to be the extrusive

0028–0836/80/300335—08$01.00

equivalent of true granitoids. We have studied two andesites, three rhyolites and one dacite, from the Barrosso and Arequipa volcanic fields in southern Peru. Sr and Pb isotope studies have shown that these rocks have been contaminated by continental crust[23,24]. This contamination seems to be differential and more extensive than for other samples. The values of ε^{i}_{Nd} are all negative between −1.4 and −5.1; none of these values are thus consistent with a pure derivation from oceanic mantle. These results agree with those of De Paolo and Wasserburg[9] which are based on the analysis of one andesite and imply a crustal contamination.

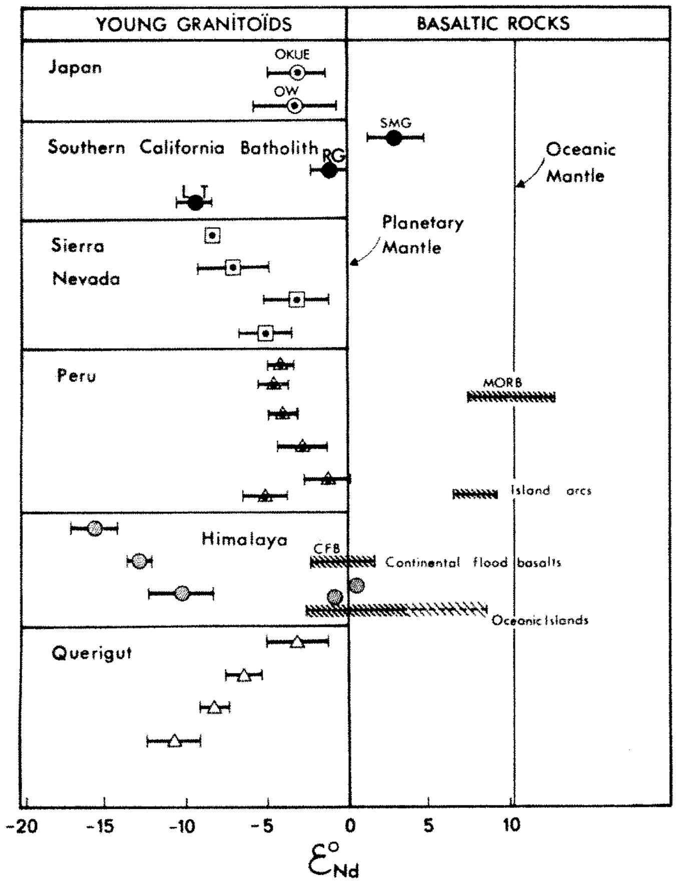

Fig. 1 Raw values of young granitoids expressed in ε^{o}_{Nd}. The reference values for MORB, oceanic islands, continental flood basalts and islands arcs are from refs 8, 9–11, 37: ⊙, Japan; ●, Southern California Batholith; ⊡, Sierra Nevada; ▲, Peru; ◉, Himalaya; △, Pyrenees, Quérigut; ◎, Costabonne; ◆, Aix les Thermes; ▲, In'zize. We adapted the technique of Richard *et al.*[8] to the granite problem. To dissolve all the accessory minerals (such as sphenes and zircons) often rich in REE, they were attacked in a Teflon bomb under pressure (see ref. 73), HNO_3 and $HClO_4$ were added, reevaporation took place and they were then dissolved in 6 M HCl. Measurements were made using the triple filament technic. The total blank is about 40 pg and is, therefore, negligible in our study. Notations are defined by:

$$\varepsilon^{o}_{Nd} = \frac{(^{143}Nd/^{144}Nd)_{sample,Today} - (^{143}Nd/^{144}Nd)_{Pla,Today}}{(^{143}Nd/^{144}Nd)_{Pla,Today}} \times 10^4$$

$$(^{143}Nd/^{144}Nd)_{Pla,Today} = 0.51264 \text{ (ref. 74)}.$$

$(^{143}Nd/^{144}Nd)_{sample,Today}$: measured value of the sample. $\varepsilon^{initial}_{Nd}$ for a sample of age T_1 is defined in the same way:

$$\varepsilon^{i}_{Nd} = \frac{(^{143}Nd/^{144}Nd)^{sample}_{I,T_1} - (^{143}Nd/^{144}Nd)_{Pla,T_1}}{(^{143}Nd/^{144}Nd)_{Pla,T_1}} \times 10^4$$

$$(^{143}Nd/^{144}Nd)_{Pla,T_1} = (^{143}Nd/^{144}Nd)_{Pla,Today} - (^{147}Sm/^{144}Nd)_{Pla}(e^{\lambda T_1 - 1});$$

$$(^{143}Nd/^{144}Nd)^{sample}_{I,T_1} \bullet (^{143}Nd/^{144}Nd)_{sample,Today} - (^{147}Sm/^{144}Nd)_{sample} \cdot (e^{\lambda T_1 - 1}).$$

The Sr isotopic composition has been measured in most samples following the technique described elsewhere[75]. For Sr, ε^{i}_{Sr} can also be defined in the same way[36].

The continental collision situation

The continental collision environment must exist in Himalayan granites and has also been proposed to account for the French hercynian segment[25].

The Himalayan granitoids can be divided into two categories: those which are situated along the Main Central thrust (MCT), a gigantic intracontinental thrust inside the Indian shield[25,26] and those which are on the edge of the Tsanpo suture, composing the Laddakh batholith.

The MCT granites are all leucogranites (aluminous, two mica alkaline granites). An age determination of 29 Myr for the Manaslu massif has been questioned[27], and the other Palung Daman and Makalu-Kakani granitoids seem to be slightly different and not well dated either[28]. However, for general stratigraphic reasons, the ages of these granites are taken as between 50 and 15 Myr (ref. 26) which gives initial $^{87}Sr/^{86}Sr$ ratios of around 0.780. Such high ratios clearly represent the remelting of old continental material, which agrees well with the petrological study by Lefort[26]. As expected, ε^{i}_{Nd} values are strongly negative, from −10.3 to −15.8 and are the lowest values ever reported for young granitoids. There is little doubt that these values, like those for Sr, indicate the almost pure remelting of old continental crust.

The Laddakh complex is a large granodiorite complex which represents the granitoids associated with the major collision between India and Eurasia. Two samples have been analysed with ε_{Nd} values of +1.8 and −1.4. Both values may be interpreted as a record of material derived from an oceanic crust contaminated by crustal material (as for California or Japan).

The 'pyrenean' granitoids have been extensively studied from the chronological, isotopic, and petrological points of view[29–34]. They were deposited during the hercynian orogeny and can be divided into two groups. The first is represented by early granites emplaced 320 Myr ago with a high initial $^{87}Sr/^{86}Sr$ ratio (0.712) characteristic of many gneissic xenoliths; a typical example is the Aix-les-Thermes 2-mica granite. The second group is younger (280 Myr) and has a lower initial $^{87}Sr/^{86}Sr$ ratio[29]. These granitoids are characterized by xenoliths of quartz dioritic composition and a complex set of different facies[32]. The Querigut granite[33] and the Costabonne granite belong to this second group.

According to Mattauer's interpretation of the hercynian orogeny in western Europe[34], these granites were generated during a continental collision very similar to the Himalayan one. All of the granites have negative ε^{i}_{Nd} values between −0.7 and −8.9 which again cannot be explained by direct derivation from the oceanic mantle. This conclusion is supported by trace element results[35].

Nd–Sr relationship on modern granitoids

The relationship between the Sr and Nd isotopic ratios of modern basalts suggested by Richard *et al.*[8] and demonstrated by others[10,11] is a very important and distinctive signature of mantle evolution[36]. It seems that the initial ratios of Sr and Nd of any material directly derived from the mantle would probably plot on this general trend. On the other hand, as we have already emphasized, the studies of Carter *et al.*[37] have shown that the Sr–Nd isotope diagram can clearly discriminate a mantle type origin from a lower or upper crustal origin. Therefore, the Nd–Sr diagram should give a clear distinction between different hypotheses of granitoid genesis. Let us consider the general trends in ε^{o} notations. The present terrestrial mean corresponds to $\varepsilon^{o}_{Nd} = 0$ ($^{143}Nd/^{144}Nd = 0.51264$) (see above) and by definition $\varepsilon^{o}_{Sr} = 0$ ($^{87}Sr/^{86}Sr = 0.70478$) (ref. 36). The oceanic mantle, and probably some of the subcontinental mantle plot in the upper left quadrant ($\varepsilon^{o}_{Nd} > 0$ and $\varepsilon^{o}_{Sr} < 0$). In this quadrant there is a negative correlation between ε^{o}_{Nd} and ε^{o}_{Sr}. Carter *et al.*[37] have shown that Lewisian granulites normally plot in the lower left quadrant ($\varepsilon^{o}_{Nd} < 0$ and $\varepsilon^{o}_{Sr} < 0$) although a few granulites do have positive ε^{o}_{Sr}. The old granitoids or gneisses in amphibolite facies

A number of ratios of ^{87}Sr/^{86}Sr, taken from the literature (for example, Aix les Thermes, and Costabonne) are given here with smaller number of digits (3 or 4) and without error bar, due to their ancient determination.

(^{87}Sr/^{86}Sr) initial ratios for Japan, Sierra Nevada, Querigut and part of Peru samples have been calculated from ages determined with other radiochronometers and with the $\lambda_{\mathrm{Rb}} = 1.39 \times 10^{-11}\ \mathrm{yr}^{-1}$. Ages for all the other samples have been determined from corresponding isochrons.

and old schists, which might be attributed to the upper or medium continental crust, plot in the lower right quadrant ($\varepsilon^{0}_{\mathrm{Nd}} < 0$, $\varepsilon^{0}_{\mathrm{Sr}} > 0$).

To compare the position of modern granites with that of other rock types more quantitatively, we have to remember that $\varepsilon^{0}_{\mathrm{Nd}}$ and $\varepsilon^{0}_{\mathrm{Sr}}$ values for the old granitoids and gneisses which form the basement in most continental areas strongly depend on their ages. Statistically the older they are, the lower their $\varepsilon^{0}_{\mathrm{Nd}}$ and the higher their $\varepsilon^{0}_{\mathrm{Sr}}$. This precludes the possibility of getting a simple field in a $\varepsilon^{0}_{\mathrm{Nd}}$–$\varepsilon^{0}_{\mathrm{Sr}}$ diagram for all types of continental crust and, therefore, we must consider each case individually.

In the ($\varepsilon^{\mathrm{i}}_{\mathrm{Nd}}$, $\varepsilon^{\mathrm{i}}_{\mathrm{Sr}}$) correlation diagram we shall consider the mantle correlation band and the quadrant defined by Carter *et al.*[37]. Plotting our results for young granitoids, we see that (Fig. 3) most modern granitoids plot in the lower right quadrant, roughly indicating that they show isotopic affinities with the upper or medium crust rather than with the granulite facies. Only the two granitoids of the southern California batholith plot in the lower left quadrant. These massifs may be derived from lower granulite crust (see ref. 37). Thus the correlation diagram qualitatively suggests that no young granitoid is an uncontaminated product of the mantle, and that they all contain some crustal recycled component. We can now study the mixing of a mantle component and a recycled crustal component more quantitatively. Such a theory was first proposed in 1965 (ref. 38) using isotopic evidence, but it can now be modelled.

The equations show (see Fig. 4*b*) that the mixing depends on three groups of parameters: (1) the isotopic compositions of the

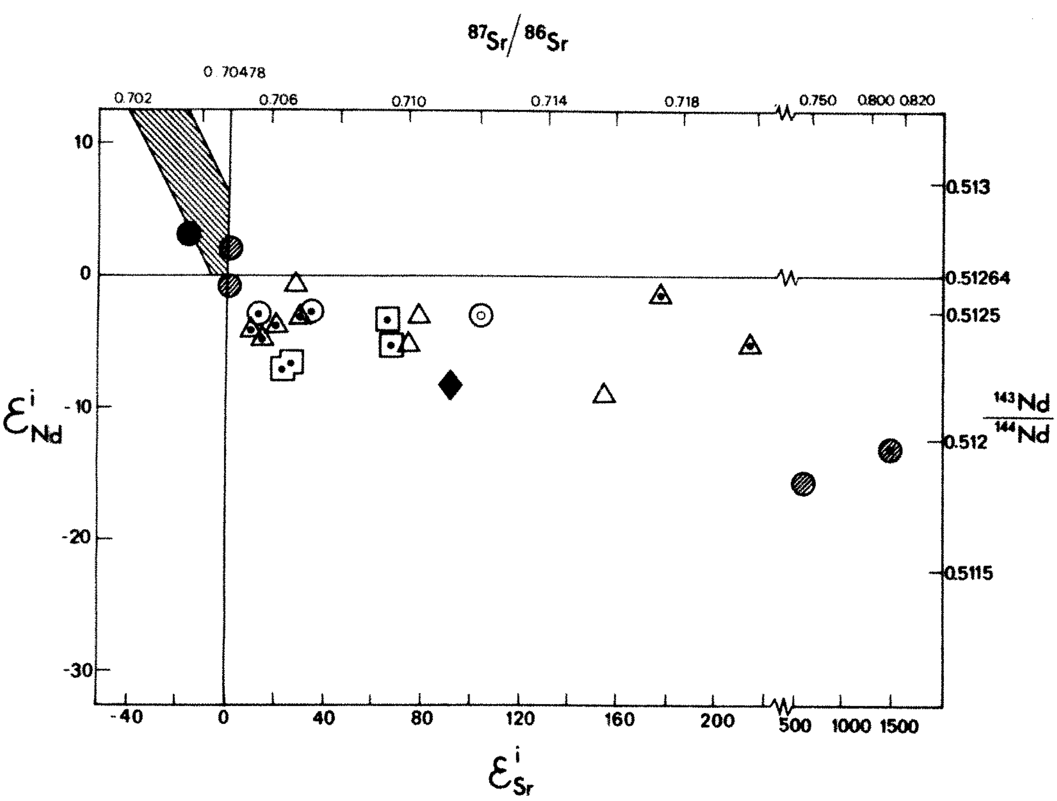

Fig. 2 Comparison of ε^i_{Nd} with ε^i_{Sr} for young granitoids. Symbols are as in Fig. 1.

two end-members, the mantle and the crustal component; (2) the ratios of Nd and Sr concentrations in crust and mantle, C^c_{Nd}/C^m_{Nd} and C^c_{Sr}/C^m_{Sr}; (3) the mass ratio of the two components, m^c/m^m.

We will select two different points for the isotopic composition of each component. We assume that the mantle component has the composition of a typical oceanic MORB mantle or that it has a planetary composition. For the crustal component we will fix the Sr isotopic ratio as $^{87}Sr/^{86}Sr = 0.720$, and take a 'young' crustal component with $^{143}Nd/^{144}Nd = 0.5125$ and an 'old' crustal component with $^{143}Nd/^{144}Nd = 0.5108$. These limits allow the observed results to be discussed in a general framework.

The mixing equations also involve the Nd and Sr crust/mantle concentration ratios. The values for both the upper and lower crustal component concentrations fall in a fairly narrow range[37,39,40]. The mantle component concentrations are more difficult to ascertain; this component may be a highly differentiated rock such as rhyolite, or a moderately differentiated one such as diorite[29]. It cannot be of typical basaltic nature because if it were the mixture with the crustal component would change the isotopic ratios so that the mixture would inherit a 'granitic' isotopic signature although it could be close to a basalt from the point of view of major element chemistry. For neodymium a crust/mantle concentration ratio of about 1 or 2 is reasonable. For strontium we can assume a crust/mantle concentration ratio of 0.3 which corresponds to the granite/diorite concentration ratio.

Most of our data plot in the field between the young and old crust mixing lines. For every young granite in Fig. 3, we can read in Fig. 4 its specific mixing ratio m^c/m^m. For a given ordinate in Fig. 4, a conservative estimate of the crust/mantle mixing ratio is provided by the interval between the ε_{Nd} values for the young and old crust mixing curves. A qualitative description in terms of young or old crust recycling can be obtained, rather than a precise young/old crust ratio or crust age. However, when the crust/mantle mixing ratio is found to be close to unity, a good approximation of crustal age is given by the Sm/Nd model age.

Most orogenic granitoids have been mixed with relatively young continental crust (Sm/Nd model ages: 600–1,200 Myr); this includes the Japan, Sierra Nevada, European Hercynian granitoids and Andean granitoids or andesites. For these areas the basement is not expected to be very old and, therefore, the results agree with the regional geology. The continental/mantle component mass ratio values are probably between 1 and 4. The highest ratio is that for the Himalayan anatectic granites which represent almost pure remelting of 1,100–2,300 Myr old basement. The hercynian granites from the Pyrenees have also a high m^c/m^m ratio.

The southern California batholith, on the other hand, plots outside the upper crust mixing curve field and would be accounted for by a mixture of mantle material and a lower crustal

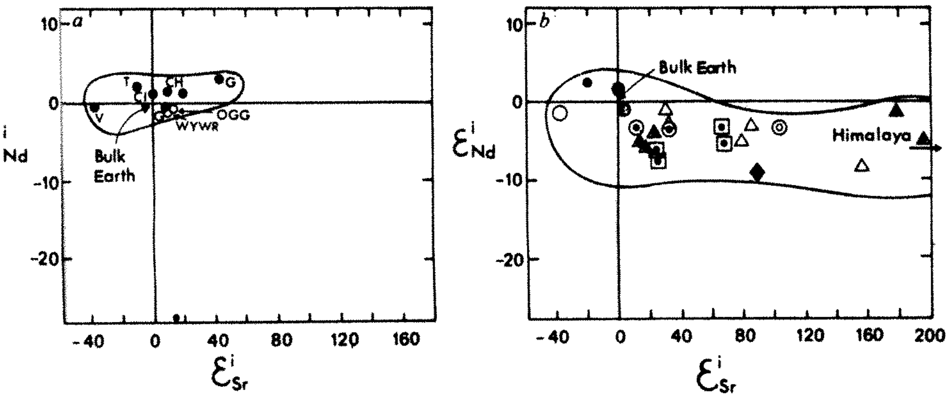

Fig. 3 *a*, *b* Comparison of ε^i_{Nd} with ε^i_{Sr} showing the contrast in the distribution of experimental points between granitoids older than 1,000 Myr (*a*) and those younger than 400 Myr (*b*).

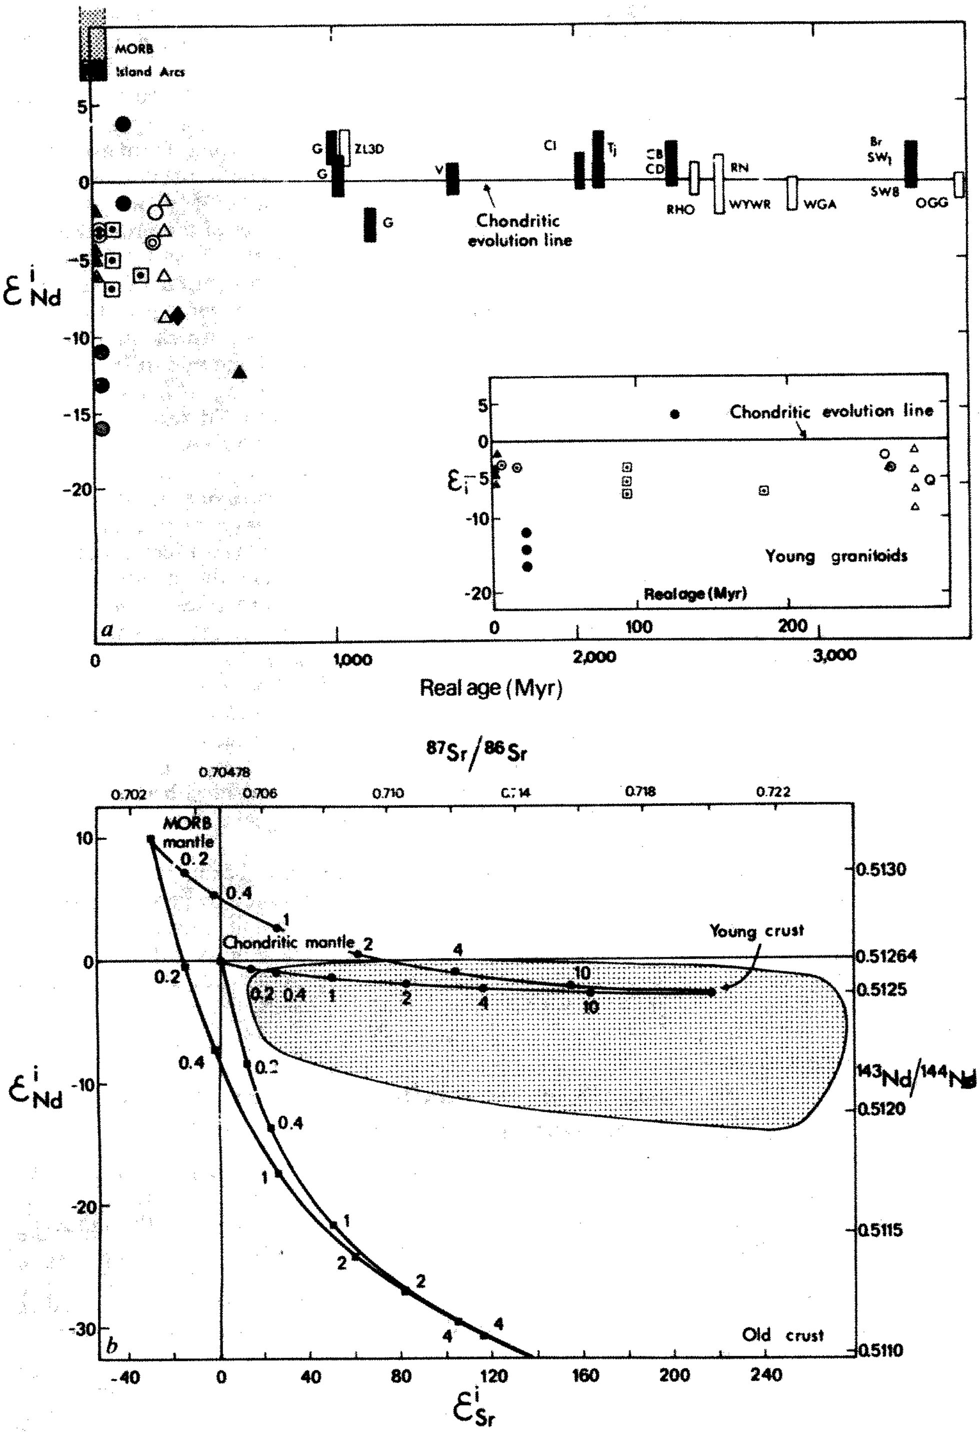

Fig. 4 *a*, Plot of ε^i_{Nd} with time (data from refs 9–12 and from the present study). As in Fig. 3 we can see the increase in deviation from the chondritic line with time. Young granites symbols are as in Fig. 1. Precambrian granites: this work: CI, Ivory Coast; Tj, Tassendjanet; C_B, C_D, North East China; SW_1, SW_8, Swaziland; V, Venezuela; G, Grenville. Other results: ZL 3D, Llano uplift; RHO, Great Dyke; RN_3, Preissac Lacorne B; WYWR, Louis Lake Gr_1 Wyoming; WGA, Anorthosite West Greenland; OGG, Amitsoq gneisses. *b*, Comparison of ε^i_{Nd} with ε^i_{Sr} illustrating the mixing model. The mixing is between two possible mantle materials (one MORB, one chondritic) and two possible continental crusts (old and young). Mixing equations:

$$R^m_{Nd}x + R^c_{Nd}(1-x) = R^\Sigma_{Nd}$$

$$R^m_{Sr}y + R^c_{Sr}(1-y) = R^\Sigma_{Sr}$$

where R_{Nd} is $^{143}Nd/^{144}Nd$ and R_{Sr} is $^{87}Sr/^{86}Sr$; R^m corresponds to the mantle input, R^c to the crustal input and R^Σ to the mixture.

$$x = \frac{C^m_{Nd}m^m}{C^m_{Nd}m^m + C^c_{Nd}m^c} = \frac{1}{1+(C^c_{Nd}/C^m_{Nd})(m^c/m^m)}$$

$$y = \frac{1}{1+(C^c_{Sr}/C^m_{Sr})(m^c/m^m)}$$

C^c_{Nd} (C^c_{Sr}) is the concentration of Nd(Sr) in the crustal component; C^m_{Nd} (C^m_{Sr}) the concentration of Nd(Sr) in the mantle component; m^c the mass of the crustal component; m^m the mass of the mantle component. The two curves indicate:

$$\frac{[\mathrm{Sr}]\text{ in mantle material}}{[\mathrm{Sr}]\text{ in continental material}} = 3.3$$

$$\frac{[\mathrm{Nd}]\text{ in mantle material}}{[\mathrm{Nd}]\text{ in continental material}} = 0.75$$

$$\frac{m_c}{m_m} = \frac{\text{mass of continental material}}{\text{mass of mantle material}}$$

The hatched area corresponds to the observed data.

component; such a conclusion does not contradict that of Taylor and Silver[18], but a more comprehensive study is needed to really understand the data. The position of the Skye anorogenic granite in the (ε^i_{Nd}, ε^i_{Sr}) diagram is close to the field of the Lewisian gneissic basement[37]. Its genesis has therefore involved remelting of an old basement.

The Nd and Sr isotopic results for most young granitoids leads to the main conclusion that there has been extensive involvement of previous continental crust. This effect is particularly important for continental collision orogenesis (almost pure crust remelting in the MCT from Himalayas). Subduction type orogeny involves more mantle material but with m^c/m^m values of 0.5–2. We can stress three points concerning the mixing process.

(1) Where the mixing[38] occurs has not been determined. It may take place in the geosyncline between volcanic rocks and detrital sediments, or during the intrusion of mantle diorite by assimilation, or even by sediments dragged down by the downgoing slab.

(2) Except for continental collision areas, the basement involved is not extremely old, which agrees with the border type models of continental growth (see below).

(3) Because Nd is extremely insoluble and not very mobile during water transport or metamorphism[41] the mixing process cannot be interpreted as selective contamination as it was for Sr or Pb. We had then to consider a volume-to-volume mixture. This is a characteristic of Nd isotopes and reinforces their usefulness.

Genesis of Precambrian granites

The Sm–Nd isotopic relationship of several Precambrian granitoid rocks have been investigated. They include:

Isua gneisses, 3,720-Myr old[42–44].

Amitsoq gneisses from Greenland, 3,650-Myr old[41–45].

Preissac Lacorne batholith from Quebec[46] and Lake Louis batholith from Wyoming, ~2,650-Myr old[47].

Lewisian gneisses, 2,920-Myr old[48].
Mountain Pass, California, with proposed[49] ages of between 1,400 and 1,700 Myr.
Llano uplift, 1 Myr old[50].

We have added several new examples:
The Swaziland (South Africa) granites, 3,400-Myr old[51].
The Tsien-Si metagranite (Republic of China), 2,400-Myr old.
The Tassendjanet granite (Sahara), 2,100-Myr old[52].
The Baoulé granite from Ivory Coast, 2,000-Myr old[53].
The Grenville granites from Ontario, 1,000–1,300-Myr old[54].
The Rapakivi granite from Venezuela, 1,500-Myr old[55].
The Pan African granodiorites from Morocco and Ahaggar, 600-Myr old[52].

For each granite, it is possible to measure the $^{143}Nd/^{144}Nd$ and $^{147}Sm/^{144}Nd$ ratios. If the geological age T_1 is known independently, the initial ratio can be calculated:

$$(^{143}\mathrm{Nd}/^{144}\mathrm{Nd})_{\mathrm{I},T_1} = (^{143}\mathrm{Nd}/^{144}\mathrm{Nd})_{\mathrm{meas}} - (^{147}\mathrm{Sm}/^{144}\mathrm{Nd})(e^{\lambda T_1} - 1)$$

De Paolo and Wasserburg[10] have shown that this calculation is reasonably reliable for Sm–Nd because this chronometer is practically insensitive to weathering and to weak metamorphism. Therefore, only a simple *in situ* age correction is needed to calculate all initial ratios $(^{143}\mathrm{Nd}/^{144}\mathrm{Nd})_{\mathrm{I},T_1}$. A convenient way of comparing the deviations from the planetary evolution curve is to use the initial $\varepsilon^{\mathrm{I}}_{\mathrm{Nd}}$ notation[10].

All of these granitoids have initial $^{143}Nd/^{144}Nd$ values which plot very close to the closed system planetary evolution line defined by De Paolo and Wasserburg[10].

Contrary to what is observed for recent granitoids, Nd isotopes favour a mantle origin for the Precambrian granitic rocks. Our present statistics on these initial ratios are poor and need to be improved. However, the general result is impressive compared with the results for modern granites, especially as our sampling covers different petrographic types in the Precambrian. The first interpretation would be that these granites were directly derived from the mantle through magmatic differentiation or segregation processes. However, we could also imagine a derivation from the mantle via a sedimentary cycle. In such processes, the sediments are volcanogenic greywackes which are melted a short time after their deposition. If this is the common process for granitoid formation, then our results indicate the participation of a large proportion of mantle material in the sedimentation during the Precambrian period. In some way these granites were freshly derived from the mantle and, therefore, the continental crust corresponding to these granites can be considered to be young.

As for modern granites, one important way of examining the Precambrian origin is to use the coupled Sr–Nd isotopes. As the initial ratio is more difficult to obtain for Sr because of the mobility of Rb and Sr, a complete study including whole rock isochrons is necessary to obtain such values.

The data for Precambrian granitoids plot around the origin of the diagram (Fig. 5*a*), even if the resulting Sr errors are larger than the Nd ones. Such a plot seems to indicate a tendency for departure from the planetary (bulk Earth) values with time, more clearly for Sr than for Nd. Comparing these diagrams with our mixing model reveals large differences in the isotopic geochemistry of Sr and Nd, and clarifies the scatter around the origin through geological time. The lower crust (granulite facies) has positive $\varepsilon^0_{\mathrm{Sr}}$ but quite negative $\varepsilon^0_{\mathrm{Nd}}$ (ref. 37). The fact that all experimental points plot around the origin of the Nd diagram eliminates the possibility of Precambrian granitoid originating from recycling of the lower crust[57].

The Nd and Sr evolution curves for the oceanic mantle have been determined by Zindler *et al.*[58] and C.J.A. *et al.*[59]. It is very interesting to plot on the same diagram the oceanic mantle evolution curve and the evolution curve for the initial ratio of granitoids (continental crust, see Fig. 4*a*). For the past 2,000 Myr, the younger the age, the more the oceanic mantle and continental crust curves diverge; this means that granitoids are not the result of pure oceanic mantle differentiation, thus recycling has been involved. This strongly suggests that the oceanic mantle isotopic evolution is due to the extraction of some material which is stored in the continental crust. A second observation is that the scatter of values for granitoids increases with time, so that the process is a statistical one. Third, we do not observe a sharp transition between old and young granitoids, but rather a continuous one. Thus, 1,000 or 500-Myr old granitoids are very important for studying the onset of the present divergence of continental crust and mantle evolution.

Various models[3,4,57,60], in which old continental crust was differentiated and then recycled through geological time, are ruled out by Nd data. Other models[2], which suggest that continental crust is derived from the mantle by a differentiation process, are not appropriate either (see Fig. 4*b*). The model of Moorbath[7] is difficult to reconcile with Nd results on young granitoids. Nd contamination is not selective or accidental, as it can be for Sr, and large masses of crustal component are involved in the genesis of young andesites or granodiorites.

One interpretation of our observations is by postulating two types of granite production processes: (1) a Precambrian type for which granitoids are derived from the mantle through complex magmatic fractionation processes (calc-alkaline differentiation); (2) a post 1,000 Myr type during which crustal anatexis became the major process.

Such a sharp transition is difficult to reconcile with petrographic observations since Moorbath *et al.* (ref. 61 and unpublished results) have clearly demonstrated the existence of crustal anatexis in the Archean, and others[62–64] have clearly demonstrated, for various types of granitoids linked with a calc-alkaline suite, that many Precambrian granites have close equivalents in modern ones.

In addition, such a sharp transition will bring back the 'catastrophy' problem usually poorly supported by geological observations. We will, therefore, assume a uniform set of processes for the genesis of granitoids through geological times, with an evolution in the characteristics of these processes. We suppose that the variation applies to the composition of the materials from which the granitoids derive.

Mantle–crust mixing model for granitoid formation and continental growth

We have seen that isotopic data for young granitoids can be understood through a mixing model involving a mantle component and a recycled crust component. Can this model be extended to the Precambrian granitoids?

Adopting the (*I*–*S*) classification of White and Chappell[65] which agrees with Didier and Lameyre's classification based on xenoliths[66], we examine the genesis of these two types of granitoids.

The (*S*) granitoids are derived from sediments or metasedimentary rocks. All sediments are composed of a recycled detrital component and a mantle component. For sediments which are abundant in metasedimentary piles such as greywackes or schists this type of dual origin is clear. In the Archean, the continental crust was not as developed as it is today: the mantle component was dominant in such sediments. With time, however, the isotopic signature shifted from a mantle value to a continental crust one. In recent times the continental component has dominated. Such a model explains quite well the observations by S. R. Taylor on shales. These authors claim that these are pure continental crust sediments while we believe that they are mixtures with a mantle component[67].

We admit that the (*I*) granitoids result from a mixture between an intrusive component of mantle origin (diorite) and its surroundings. These surroundings are composed of sediments or metasediments or granitoids.

The above reasoning may then be applied, but with a larger mantle contribution. Thus, both (*I*) and (*S*) granitoids can be explained through a mixing model, but does our model fit the data quantitatively?

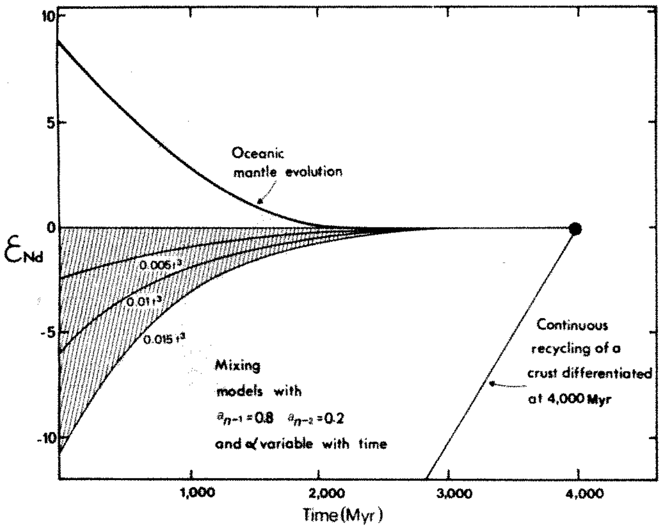

Fig. 5 Mixing model curves. Computed model with two last orogeneses entering the continental crust (last orogeny contribution is four times that of the one before). The degree of mixing between mantle and preexisting crust is assumed to be increasing with time as t^3, with more and more crust entering the orogenesis. The curves for oceanic mantle and continuously recycled crust differentiated at 4,000 Myr are also plotted as references.

Our hypothesis is based on the fact that continents have grown through geological time, although not always with the same rate. This growth takes place during orogeneses. These orogeneses are discontinuous events, at least locally. Therefore, we will use a finite difference method. Let $R_n(t)$ be the isotopic ratio (Nd or Sr) (at time t) of the granitoid formed during the nth orogenesis which occurred at time t_n (or age t_n). Let $R_{c,n}(t)$ be the isotopic ratio at time t (or age t) of the mantle. If α is the mass fraction of Nd (or Sr) from the preexisting crust involved in the mixing, then

$$R_n(t_n) = \alpha R_{c,n}(t_n) + (1-\alpha) R_m(t_n)$$

Because geological observations[68,69] and observations made on California and Laddakh granitoids suggest that the oceanic mantle is involved in continental growth, we will take the oceanic mantle isotopic ratio for $R_m(t)$. The crustal composition will be written as a polynomial:

$$R_{c,n}(t_n) = \sum_{i=0}^{i=n-1} a_i (R_i(t_i) + \mu_c \lambda (t_n - t_i))$$

with

$$a_i > 0 \quad \text{and} \quad \sum_{i}^{n-1} a_i = 1$$

and

$$\mu_c = \frac{^{147}\text{Sm}}{^{144}\text{Nd}}$$

in the continental crust. $a_i(R_{c,i}(t_i) + \mu_c \lambda (t_n - t_i))$ is the crustal contribution of the ith orogenesis to crustal composition. This approach uses the fact that μ_c is almost constant in granitoids of different ages.

The parameters a_i can be chosen in different ways: if we take $a_{n-1} = 0.8$, $a_{n-2} = 0.19$, $\sum_{i=1}^{n-3} a_i = 0.01$, recycling is restricted to the last two orogeneses. This hypothesis is supported by the erosion being proportional to the height of mountains, and is therefore only important for young mountains. It also agrees with the theory of continental growth by successive belts. We can choose a smoother law:

$$a_{n-1} = 0.4, \quad a_{n-2} = 0.3, \quad a_{n-3} = 0.2, \quad a_{n-2} = 0.08 \ldots$$

This assumption is supported by the fact that sediments are created by large rivers such as the Mississippi, the Yang Tse, the Mekong, and the Amazon, which flow through terrains of various ages.

Another hypothesis about the mixing parameter must be made. Although we assume that α is constant through geological time (this is the steady state approximation), it is more likely to have increased because during the Precambrian the mantle was more active[70–72] amd the continental crust not so developed and thus there were more volcanogenic sediments than at present. Observations of Archean sediments support this point of view[70].

As we have no evidence that continental differentiation started before 4,000 Myr, our calculations start from that date. Orogeneses are supposed to occur with a regular time interval of 500 Myr. In fact, each parameter is susceptible to variations and our model should be stochastic. However, the model is given here in its mean value form. Numerical calculations of these equations and comparison with observed data have shown that: (1) a mixing ratio α, which is constant through geological times does not fit the data; (2) the function α must depend on time as t^3 or t^4, but we cannot be more specific with the available data. (3) With the present data we cannot tell whether the last two or four orogeneses are involved in crust formation. The involvement of the four last crustal segments in the orogeneses would imply that the mixing coefficient is lower than if only two are involved. (4) The polynomial coefficient of an old orogeny may possibly become more important with time. This could occur if the Precambrian orogeny were to follow the centrifugal growing and then in modern time the plate tectonics focate the orogeny in random way relative to the age of crustal segments.

Figure 5 shows ε_{Nd} variations with time for $a_{n-1} = 0.8$ and $a_{n-2} = 0.2$ and different functions α. Hence with certain conditions the mixing model is seen to apply and now requires a more refined study, especially in the Precambrian.

Conclusion

Our model quantitatively fits the isotopic variation with geological age and explains the fact that Pb isotopes are a record of continental recycling whereas Sr is more appropriate for mantle derivation, Nd being an intermediate tracer.

We thank H. P. Taylor, P. M. Hurley, R. Kistler and Z. Peterman, J. R. Lancelot, P. Lefort, P. Brunel and S. Moorbath for samples, also P. M. Hurley, S. R. Hart, S. Moorbath, J. F. Minster, F. Albarede, and S. Fourcade for helpful discussions. D. Rousseau made some of the Sr isotope measurements. We thank P. Richard for his help in applying the Nd technique and O. Brevart for programming. S. Fourcade, O. Brevart and J. F. Minster reviewed the manuscript. This is contribution IPG 414.

Continental crust composition and nature of the lower crust: constraints from mantle Nd–Sr isotope correlation

Barry L. Weaver & John Tarney

Department of Geology, The University of Leicester, Leicester LE1 7RH, UK

Calculations suggest that if the widespread upper mantle depletion in lithophile elements, as represented by the negative correlation between Nd and Sr isotopes in basalts, has resulted from continental crustal extraction, then extraction of observed Archaean crustal compositions best explains the Nd–Sr isotope relationship. Much of the lower continental crust must, therefore, have the high Nd/Sm and low Rb/Sr ratios typical of Archaean granulites.

RECENT developments in neodymium isotope geochemistry[1–3], and the combined use of both neodymium and strontium isotope data[4–9] on mantle-derived igneous rocks, have produced information on the Rb/Sr and Sm/Nd history of their mantle source regions[6–9]. Clearly much of the present upper mantle has suffered a time-integrated depletion of Rb relative to Sr and of Nd relative to Sm. Corresponding evidence on Archaean igneous rocks[2,4,10–12] suggests, however, that the Archaean mantle had broadly chondritic Sm/Nd ratios. Because the continental crust represents a reservoir which is enriched in Rb relative to Sr and in Nd relative to Sm and, overall, has higher ^{87}Sr/^{86}Sr and lower ^{143}Nd/^{144}Nd ratios than the mantle, and because there is strong isotopic evidence that the crust has grown with time since ~4,000 Myr ago[13–15], it is a reasonable assumption that extraction of continental crust may have caused the observed Rb/Sr and Nd/Sm depletion relative to primordial ratios in the present mantle. There is no unambiguous evidence that another major high Rb/Sr and high Nd/Sm reservoir exists which might complement the generally depleted nature of present upper mantle sources. Preliminary attempts have therefore been made to assess the effects of crustal extraction[16] (and crustal contamination[17]) on the Sr and Nd isotope systematics of the upper mantle reservoir.

Here we examine the crust–mantle isotopic relationship in more detail, but with respect to specific Precambrian crustal materials rather than quoted 'average' crustal compositions. This approach is more relevant because (1) the time scale on which mantle can be completely recycled is probably of the order of several hundred million years, (2) considerable crustal growth occurred during the early Precambrian[14,15], (3) the long half lives of ^{87}Rb and ^{147}Sm necessitate a long time lapse before changes in ^{87}Sr/^{86}Sr and ^{143}Nd/^{144}Nd ratios of the magnitude observed in the present-day mantle can develop[18], and (4) there are significant differences between Archaean and Phanerozoic crustal compositions[19].

The crustal data used in the calculations are based on the Archaean Lewisian complex of north-west Scotland, a region which contains juxtaposed segments of presumed upper and lower crustal orthogneisses[20], the geochemical[20–24] and isotopic (Sr, Nd and Pb)[12,25–30] characteristics of which are relatively well known.

Sr–Nd isotope correlation and crustal extraction

Measured Sr and Nd isotopic ratios in many young basalts exhibit a strong negative correlation[5,6] shown by the 'main trend' (defined by $\varepsilon_{\mathrm{Nd}} = -2.7\ \varepsilon_{\mathrm{Sr}}$) (ref. 16; see also Fig. 3) where $\varepsilon_{\mathrm{Nd}}$ expresses the deviation (in parts per 10^4) of ^{143}Nd/^{144}Nd ratios observed in igneous rocks at present from the ^{143}Nd/^{144}Nd ratio expected in a reservoir which has always had chondritic Sm/Nd (ref. 16). $\varepsilon_{\mathrm{Sr}}$ is defined similarly for ^{87}Sr/^{86}Sr ratios relative to a reservoir with bulk Earth Rb/Sr ratios[16]. Thus rocks derived from a mantle source which has suffered a time-integrated depletion of Rb relative to Sr and Nd relative to Sm will plot in the $+\varepsilon_{\mathrm{Nd}}$, $-\varepsilon_{\mathrm{Sr}}$ quadrant on the $\varepsilon_{\mathrm{Nd}}$–$\varepsilon_{\mathrm{Sr}}$ diagram. Mid-ocean ridge basalts invariably plot in this quadrant, as do many ocean island and continental basalts, although these latter tend to plot nearer to the bulk Earth composition. Basalts derived from mantle sources which seem to have been altered by

0028-0836/80/300342—05$01.00

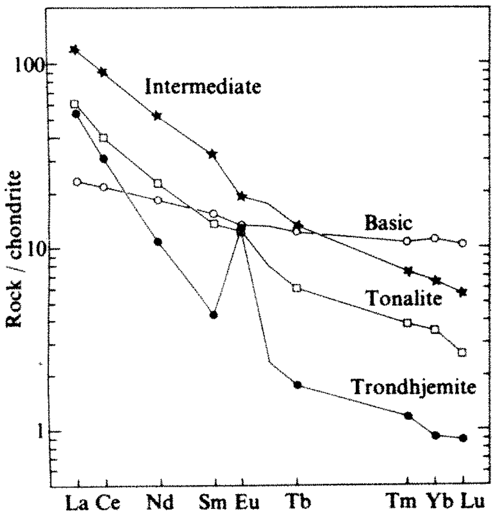

Fig. 1 Average rare-earth element patterns of the main rock types comprising the Lewisian lower crustal granulite complex, north-west Scotland (data from refs 12, 20–24, 37).

more radiogenic seawater Sr (ref. 31), or by continental material[17,32] are displaced from the 'main trend'.

The widespread upper mantle depletion in incompatible elements represented by the 'main trend' must be accommodated in models of mantle evolution. DePaolo and Wasserburg[17] consider the slope of the 'main trend' to be incompatible with upper crustal contamination of a uniform mantle reservoir, while Allègre *et al.*[18] have demonstrated that the mantle main trend correlation reflects melt extraction from the mantle rather than, for instance, mixing processes involving separate mantle reservoirs. In this case the slope of the Sr–Nd isotope correlation constrains the Rb/Sr and Sm/Nd ratios of the material extracted provided an assessment can be made of the Sr/Nd ratios of the extract and of the initial mantle source[16]. By assuming that the continental crust is the complement to the 'main trend' mantle depletion, and by noting that there was only very limited variation in the Sm/Nd and Sr/Nd ratios of the various published estimates of 'average' upper crust and total crust composition, DePaolo[16] was able to use the Sr–Nd isotope correlation to calculate the mean Rb/Sr ratio of the continental crust as lying within the range 0.044–0.10. As upper crustal compositions are quite well defined[33], it is the composition of the lower crust which is crucial in constraining models for the generation of the continental crust.

Crustal compositions

The Lewisian granulite facies gneiss complex is a prime candidate for Archaean lower crust, having the appropriate seismic characteristics[34,35] and having equilibrated in temperature–pressure conditions as high as 1,000 °C and 15 kbar (ref. 36), corresponding to depths of the order of 45 km. Nd isotope studies[12] have demonstrated that the immediate igneous precursors of these gneisses were generated from a mantle source with chondritic Sm/Nd ratios 2,920 Myr ago.

The complex is a heterogeneous mixture of ultramafic, mafic, intermediate, tonalitic and trondhjemitic gneisses, but tonalitic–trondhjemitic compositions dominate. Average rare-earth element (REE) patterns[37] for the main rock types are shown in Fig. 1. The tonalitic and trondhjemite patterns in particular are highly fractionated, with high Ce_N/Yb_N ratios (and Nd/Sm ratios) owing to the strong depletion in the heavy REE caused by residual garnet in the source during the partial melting event which produced the gneiss precursors[24,37]. Using these REE data plus previously published results for La, Ce, and Y (determined by X-ray fluorescence) on several hundred granulite samples[20], it is possible to calculate a weighted mean REE pattern for Lewisian lower crustal granulites (Fig. 2). Because of their very high Nd/Sm ratios and age, the Lewisian granulites are markedly unradiogenic with respect to Nd isotope ratios[12] in comparison with the bulk Earth. The granulites are also high in Sr, but are unusually low in Rb and other radioactive heat producing elements (K, U, Th) largely as a result of the removal of these elements by an active fluid phase during the granulite facies event[12,38]. Thus their Rb/Sr ratios are unusually low, and indeed the present day $^{87}Sr/^{86}Sr$ ratios of many granulites are below typical mantle values[39].

The amphibolite-facies gneiss sections of the Lewisian complex have a much smaller component of ultramafic, mafic and intermediate gneisses, and their mean major- and trace-element compositions are essentially identical to the tonalitic–trondhjemitic components of the granulite facies complex except that they have much higher Rb contents and Rb/Sr ratios. Although full representative REE data are not yet available for these gneisses, comprehensive X-ray fluorescence data for La, Ce and Y (refs 20–24), and limited data for Sm and Nd (ref. 12), allow a fairly accurate estimation of their Sm/Nd ratios, which must be close to the values for the tonalitic–trondhjemitic granulites. From their tectonic and metamorphic state we would regard these gneisses as being more representative of an intermediate crustal level rather than upper crust.

For comparison with these compositions we have also used the mean 'upper crust' composition and the corresponding 'lower crust' composition derived by Taylor[33] on the basis of the

UC, TC, and LC are upper crust, total crust and (calculated) lower crust compositions respectively, based on andesite model for crustal growth[33]. LGr is mean composition of Lewisian granulites (= Archaean lower crust); LAm is mean composition of amphibolite-facies gneisses from Scotland and Greenland (= Archaean intermediate crustal level). Figures in brackets are interpolated values.

* Oxides in wt%, trace elements in p.p.m.

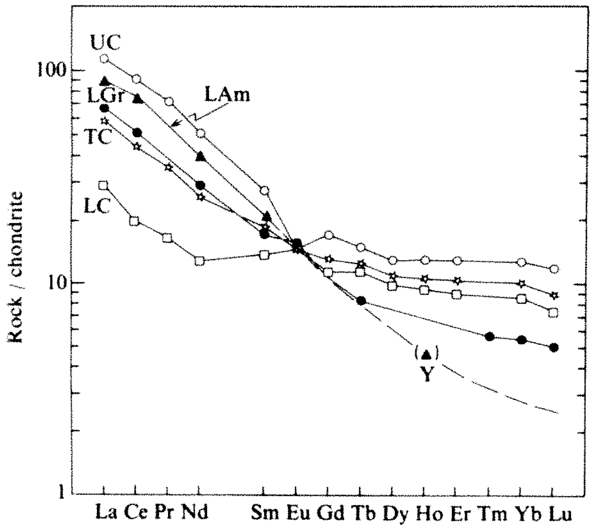

Fig. 2 Mean rare-earth element patterns of crustal components. UC, TC and LC are average upper crust, total crust and (calculated) lower crust compositions based on the andesite model for crustal growth[33]. LGr is mean rare-earth pattern for Lewisian lower crustal granulites (based on Fig. 1 plus data in refs 12, 20–24, 37). LAm, mean rare-earth pattern for Lewisian amphibolite-facies gneisses (based on data in refs 12, 20, 22, 38).

andesite model for crustal growth. Relevant data for these compositions and for the Lewisian granulite and amphibolite facies gneisses are given in Table 1, and the corresponding REE patterns are plotted on Fig. 2.

Results

The modelling of ε_{Nd}–ε_{Sr} (Fig. 3) follows the method used by DePaolo[16], except that the data in Table 1 are used to derive vectors on the ε_{Nd}–ε_{Sr} diagram for residual mantle compositions after extracting the various crustal components. Clearly a valid model should yield mantle vectors for the extraction of upper crust and lower crust which embrace the mantle 'main trend'. The vectors calculated are very dependent on the Sr/Nd ratio of mantle + crust, and less dependent on the parameter X_c (the fraction of Nd atoms in the crust + depleted-mantle system residing in the crust[16]). The values used here for the Sr/Nd ratio of mantle + crust and X_c are those of DePaolo[16]. Where upper crust and lower crust compositions have been treated separately the X_c factor has been adjusted accordingly. The method for calculating the vectors is given in Table 2 (see also ref. 16).

The slopes of the vectors for crust and mantle compositions plotted on Fig. 3 are directly proportional to the factors R_f in Table 2. The vectors for depleted mantle compositions in Fig. 3, derived respectively from the given crustal compositions, illustrate several interesting features. That resulting from the extraction of Lewisian granulites has a very steep trend. This arises because the mean Rb/Sr ratio of Lewisian granulites (0.021) is actually slightly lower than that estimated for the uniform mantle reservoir (0.029, ref. 16), hence resulting in little fractionation of ε_{Sr} in the residual mantle. Lewisian amphibolite facies gneisses, although having a rather higher mean Nd/Sm ratio than the granulites, have a much higher mean Rb/Sr ratio (0.13, Table 1) resulting in a much shallower slope of the residual vector.

The average upper crust composition of Taylor[33] has a similar Nd/Sm ratio to that of Lewisian gneisses, but has a high Rb/Sr ratio (0.31, Table 1), thus the corresponding residual mantle vector has a shallower slope than the mantle 'main trend' on Fig. 3. The calculated lower crust composition based on the andesite model actually plots in the $+\varepsilon_{Nd}$, $+\varepsilon_{Sr}$ quadrant, and the corresponding residual mantle vector has an even shallower slope than that produced by extraction of average upper crust. The andesitic lower crust, in fact, has a calculated Nd/Sm ratio less than chondritic, although the calculated full rare-earth pattern is slightly light-REE enriched (Fig. 2). However, if the upper crust was taken to be 30% of the total crust (rather than 33%), the calculated lower crust would then have a chondritic Sm/Nd ratio.

Figure 3 shows that extraction of an andesite bulk crust[33] from a mantle with chondritic Sr/Nd ratios could not produce the mantle 'main trend'. Because the vectors for the average upper crust of Taylor[33] and for the amphibolite facies Lewisian are similar, the determining factor in whether crustal extraction can reproduce the mantle Sr–Nd isotope trend is the nature of the lower crustal component. Apparently, the lower crust component in any crustal model is required to have a moderately high Nd/Sm ratio together with a very low Rb/Sr ratio—a chemical characteristic typical of Lewisian granulites. Extraction of continental crust with this composition as a component is compatible with a simple model for the generation of the mantle isotope correlation.

An independent test of mean crustal compositions can be made using the composition of the source of mid-ocean ridge basalts (MORB), assuming this to be the mantle residue complementary to the crustal extract. Thus if the Sr/Nd ratio of the MORB source can be defined it is possible to estimate the slope, on the ε_{Nd}–ε_{Sr} diagram, of the required crystal extract. Using the data of Sun and Nesbitt[41] for average MORB, together with reasonable assumptions of the residual mantle mineralogy, the degree of melting necessary to generate MORB

and utilizing published partition coefficient data for Rb, Sr, Nd and Sm (ref. 42), the composition of the MORB source can be calculated (Table 3). The R_t value for this source (Table 3), defining the slope on the ε_{Nd}–ε_{Sr} diagram, is in excellent agreement with the value of −0.25 obtained for the mantle 'main trend'. Altering the degree of partial melting required to generate MORB has little effect on the relevant element ratios (Table 3). Having obtained a value of $f_{Sm/Nd}$ for the MORB source it is also possible to calculate the present-day isotopic composition of this source, assuming the present Sm/Nd ratio has been maintained since time t. For an age of 2,500 Myr the present day MORB source would have $\varepsilon_{Nd} = 10.7$ and $\varepsilon_{Sr} = -30$, values similar to those observed in recent basalts[2,4,6]. This is at least consistent with the argument that Archaean crustal extraction may have been responsible for the widespread depletion of upper mantle sources.

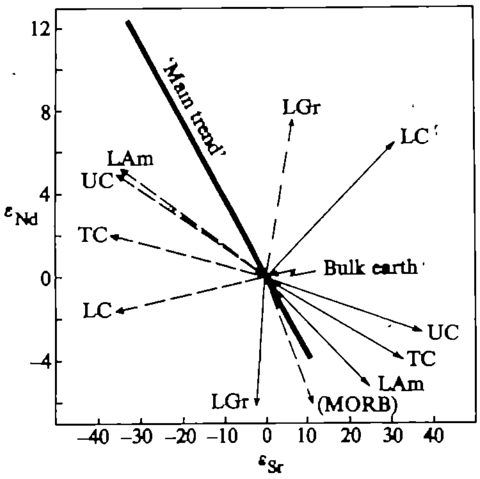

Fig. 3 Vectors showing the effect that extraction of different crustal components (Table 1, Fig 2) would have on the Sr and Nd isotope composition of residual mantle which initially had bulk Earth Rb/Sr and Sm/Nd ratios and chondritic Sr/Nd ratios. ———, Vectors for the crustal components themselves; – – –, corresponding residual mantle vectors shown as dashed lines; —–, the calculated crustal vector corresponding to the mantle source for typical mid-ocean ridge basalt.

The calculated complementary crustal component to this MORB mantle reservoir is detailed in Table 3 and defines a high (negative) slope vector on the ε_{Nd}–ε_{Sr} diagram (Fig. 3), which lies between the crustal vectors corresponding to Lewisian granulite and amphibolite facies gneisses. The trend of this vector reinforces the conclusion that a lower crust component with a composition similar to that of Lewisian granulites is necessary for reasonable models of crustal growth. Note that the present Rb/Sr ratios of Lewisian granulites are not primary values, but have been lowered by Rb removal during the granulite-facies event, while the Lewisian amphibolite-facies gneisses may have suffered some corresponding Rb-addition (as is also implied by the Sr isotope data, ref. 12). Correcting for these effects would move both Lewisian crustal vectors closer to that corresponding to the MORB source.

Nevertheless, even accepting a higher bulk crustal Nd/Sm ratio than that of average andesite, it does seem that the bulk crust must have a fairly low mean Rb/Sr ratio, as concluded by DePaolo[16], Using the R_t value for the bulk crust complement to the MORB source (Table 3) and a likely value of $f_{Sm/Nd}$ for the bulk crust (about −0.45, Table 2) yields an $f_{Rb/Sr}$ value of ~1 for the bulk crust, corresponding to a mean Rb/Sr ratio of 0.07. This value is low in relation to typical upper crustal values and must imply that a substantial proportion of the deeper continental crust has very low Rb/Sr ratios similar to those in Lewisian granulites.

Table 3 Calculated composition of MORB source and corresponding modelling parameters

	Average* MORB	MORB source†		
		$F = 0.10$	$F = 0.15$	$F = 0.20$

* Average MORB from ref. 41.

† MORB mantle source compositions calculated assuming residual mineralogy: O1 70, Opx 25, Cpx 5 and using partition coefficient data from ref. 42 and the equation:

$$C_{source} = C_{MORB}[D(1-F)+F]$$

where D = bulk distribution coefficient and F = fraction melted.

‡ R_t, $f_{Rb/Sr}$ and $f_{Sm/Nd}$ calculated as in Table 2.

§ ε_{Nd} and ε_{Sr} calculated from the relationship[16]:

$$\varepsilon_{Nd}(0) \approx 24.7\, f_{Sm/Nd} \cdot T \quad \text{and} \quad \varepsilon_{Sr}(0) \approx 16.5\, f_{Rb/Sr} \cdot T$$

Conclusions

The present modelling suggests that the Sr–Nd isotope correlation in the present upper mantle reservoir can be explained by extracting observed crustal compositions. However, crustal estimates based on Lewisian type crustal components seem to be more compatible with the isotopic constraints than crustal compositions based on the andesite model for crustal growth. Thus Archaean crust may, to a first approximation, complement the lithophile element depletion observed in modern MORB mantle sources. There are other interesting implications:

(1) Quoted 'average' upper crustal compositions are unlikely to be representative of the whole crust.

(2) The Precambrian crust, and particularly the lower crust, must have significantly higher Nd/Sm (and hence higher Ce_N/Yb_N) ratios than suggested by the andesite model for crustal growth.

(3) The higher Ce_N/Yb_N ratios implied for (and the heavy REE depletion observed in) many Archaean crustal rocks suggest a role for eclogite in Archaean crustal generation processes. Because the residues of crustal extraction need to be recycled into the mantle to generate the Sr–Nd isotope correlation, this suggests that some form of subduction may have operated in the Archaean.

(4) The requirement for high Ce_N/Yb_N ratios in the lower crust is not compatible with a lower crust dominated by the residues of partial melting or the cumulates from fractional crystallization.

(5) Even allowing for higher Ce_N/Yb_N ratios in the bulk Archaean crust, it is apparent that a substantial proportion of the deeper continental crust must have a very low Rb/Sr ratio. This may have arisen through transfer of Rb and other radioactive heat-producing elements (U, Th, K) from the deeper crust to the upper crust during the Precambrian. A consequence is that the Precambrian lower crust may constitute a substantial reservoir which is unradiogenic with respect to Pb Isotope ratios as well as to Sr and Nd isotope ratios[43,44].

Three-dimensional structure of *Escherichia coli* initiator tRNA$_f^{Met}$

Nancy H. Woo*, Bruce A. Roe† & Alexander Rich*‡

* Department of Biology, Massachusetts Institute of Technology, Cambridge, MA 02139
† Department of Chemistry, Kent State University, Kent, Ohio 44240

The crystal structure of Escherichia coli *tRNA$_f^{Met}$ an initiator transfer RNA, has been determined. While grossly similar to that of the chain-elongating yeast tRNA^{Phe}, there are three major differences. One involves the folding of the anticodon loop; in particular, the position of the constant uridine, U33. This difference was unexpected and may be of functional significance.*

ALL organisms use a specialized transfer RNA molecule, tRNA$_f^{Met}$, to initiate protein synthesis. These tRNAs are distinguished from chain-elongating tRNAs in several ways, perhaps the most important of which is that the aminoacylated initiator tRNA goes directly into the ribosomal P site while all other aminoacylated tRNAs go initially to the ribosomal A site and only later in protein synthesis translocate to the P site[1,2]. Despite significant differences in their nucleotide sequences, prokaryotic and eukaryotic initiator tRNAs are readily interchangeable in *in vitro* protein synthetic systems and thus form a single functional class. To understand the nature of the distinction between initiator and chain-elongating tRNAs, it is of value to compare the three-dimensional structure of an initiator tRNA with the known structure of the chain-elongating tRNA, yeast tRNA^{Phe} (refs 1–3). Here we report an X-ray diffraction analysis of the *Eschericia coli* tRNA$_f^{Met}$. We have crystallized this molecule in a form which diffracts to a resolution of 2.8 Å. The current analysis is based on data to 3.5 Å. The general shape of the molecule is similar to that of yeast tRNA^{Phe}, which has also been reported for yeast tRNA$_f^{Met}$ (ref. 4). One of the differences from yeast tRNA^{Phe} is in the anticodon loop and that may be functionally significant in view of recent solution studies[5].

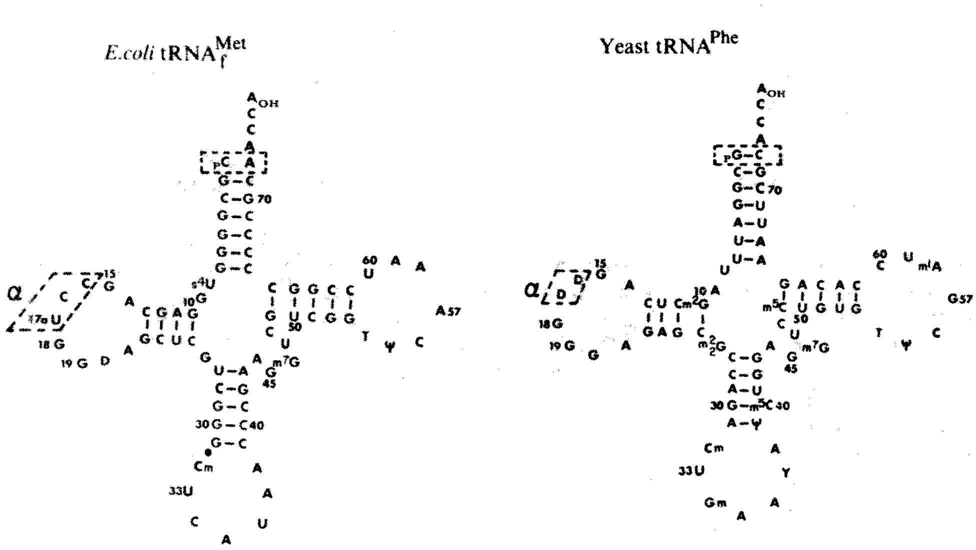

Fig. 1 The nucleotide sequence of the *E. coli* initiator tRNA, tRNA$_f^{Met}$, and the chain-elongating yeast RNA^{Phe}. The significant differences in the two sequences are indicated by the dashed boxes. The initiator tRNA contains unpaired bases at the end of its acceptor stem. The α region of the initiator tRNA contains one residue more than the corresponding region in yeast tRNA^{Phe}. The numbering system adopted here and in the text is that of Gauss *et al.*[23]

Crystallization and structure solution

E. coli tRNA$_f^{\rm Met}$ was prepared as described by Roe *et al.*[6], and Anandaraj and Roe[7]. The tRNA is crystallized in an orthorhombic lattice by vapour diffusion of 1–2% isopropanol into a solution containing 10 mM $MgCl_2$, 50 mM $(NH_4)_2SO_4$, 8 mM spermine and 2 mM $BaCl_2$ (ref. 8). Data to 3.5 Å (4,400 reflections) have been collected. Over 65% of the data in the shell 3.50–3.55 Å (217 reflections) diffract with an intensity significantly above background. Oligonucleotide binding, chemical modification, and NMR studies[2,9] all suggest that no major conformational differences exist between yeast tRNA$^{\rm Phe}$ and *E. coli* tRNA$_f^{\rm Met}$. In particular, no differences are found in the accessibility of nucleotides in E. coli tRNA$_f^{\rm Met}$, corresponding to those involved in tertiary interactions in yeast tRNA$^{\rm Phe}$, implying that the gross conformation of the two molecules is very similar. Consequently, the method of rotation and translation function searches was used to locate the initiator tRNA in its unit cell[11]. The search model was the known crystal structure of the yeast tRNA$^{\rm Phe}$.

The result of the searches was a unique position of the yeast tRNA$^{\rm Phe}$ search model in the *E. coli* tRNA$_f^{\rm Met}$ unit cell which formed a lattice without interpenetration of adjacent molecules. The initial model was formed by substituting the *E. coli* tRNA$_f^{\rm Met}$ base sequence into the yeast tRNA$^{\rm Phe}$ search model in such a way as to leave the conformation of the ribose–phosphate backbone intact. *E. coli* tRNA$_f^{\rm Met}$ contains one residue more in the variable α region of the D loop than yeast tRNA$^{\rm Phe}$ (see Fig. 1). The extra residue, C17, was not included in the initial model, nor was the 3′ terminal adenosine 76. The agreement between a molecular model and the observed diffraction data is measured by the residual function R, defined as $R=\sum\|F_0|-|F_c\|/\sum|F_0|$ where F_0 and F_c are the observed and calculated structure factors[12] which varies inversely with the agreement between model and data. The R value for the initial model was 0.44 at 6 Å, which compares favourably with residuals for protein models obtained using rotation–translation function search methods[10,13], as well as those obtained using multiple isomorphous replacement methods[14]. A complete description of the search procedure used is given in ref. 11.

Although the R for the initial model was encouraging and indicated that the hypothesis of gross similarity in conformation of *E. coli* tRNA$_f^{\rm Met}$ and yeast tRNA$^{\rm Phe}$ was correct, it also indicated that the model was far from perfect. This was further reflected by the R at 3.5 Å, which was 0.52. To determine if the disagreement was localized to some specific parts of the model, Fourier maps based on the initial model were calculated. At 3.5 Å resolution, both the difference Fourier, F_0-F_c, and the sum function Fourier, $2F_0-F_c$, showed that in most regions there was good agreement between the observed data and model but in some, the model was clearly wrong. These latter regions included the acceptor terminus, the D loop, and the anticodon loop. Fourier maps were also calculated from partial models in which those regions most at variance with the observed data were omitted; these included the entire anticodon loop, the entire D loop, the acceptor end. In both the F_0-F_c and $2F_0-F_c$ maps calculated using the partial models, chains of continuous electron density were seen which could account for the omitted portion of the model. Thus the phasing from the remainder of the model was sufficiently accurate to fix the positions of the omitted portions.

The initial model was rebuilt using the University of North Carolina molecular graphics facility. Electron density maps (F_0-F_c and $2F_0-F_c$) based on the complete model as well as those based on partial models were used to guide the fitting. The entire molecule was fitted to density and residue C17 inserted. The refit model was idealized using a restrained least-squares procedure[15]. The idealization involved both local geometry (bond angles and lengths) and hydrogen-bonding geometry of residues in the four stem regions. No attempt was made to preserve interactions between residues corresponding to those involved in tertiary bonding in yeast tRNA$^{\rm Phe}$ (refs 1–9). Limited refinement of the idealized model has been refined together (for example, the anticodon loop and stem, the D and T loops). No refinement of the complete molecule at one time has been done. An isotropic temperature factor of 40 Å has been assigned to the molecule and has not been refined. The current residual at 3.5 Å is 0.35. A fuller description will be given elsewhere (manuscript in preparation).

Fig. 2 Crystal packing diagrams of the *E. coli* tRNA$_f^{\rm Met}$ and yeast tRNA$^{\rm Phe}$. The two packing diagrams are shown for comparative purposes. The diagrams show the projection of the molecular packing in the *bc* place. Molecules which lie above are drawn in heavier lines than those below. Crystal symmetry elements are indicated. The empty regions are solvent channels which in both crystals extend through the crystal along the *a* axis direction. The intermolecular contacts in the two crystals can be seen to be totally distinct. The *E. coli* tRNA$_f^{\rm Met}$ crystals belong to the orthorhombic space group $C222_1$, with cell dimensions $a=32$, $b=85$, and $c=240$ Å.

The lattice of *E. coli* tRNA$_f^{\rm Met}$ is shown in Fig. 2 with, for comparison, the orthorhombic lattice of yeast tRNA$^{\rm Phe}$. Long solvent channels extend through the crystal along the a axis direction in both lattices. The lattice contacts in the initiator tRNA crystal include interactions between the T stems of twofold related molecules, between the acceptor terminus of one molecule with the T and D loops of a C-centred related one, and between the anticodon loops of twofold related molecules. These interactions are all distinct from those seen in either the orthorhombic or monoclinic lattices of the yeast tRNA$^{\rm Phe}$ (refs 16, 17). Hence, any similarity in the overall shape of the *E. coli* initiator tRNA and the yeast tRNA$^{\rm Phe}$ cannot be attributed to crystal lattice forces.

The form of the molecule

Figure 3 shows side views of both *E. coli* tRNA$_f^{\rm Met}$ and yeast tRNA$^{\rm Phe}$. The two molecules are broadly similar in shape, the most striking difference being found in the acceptor ends. In the

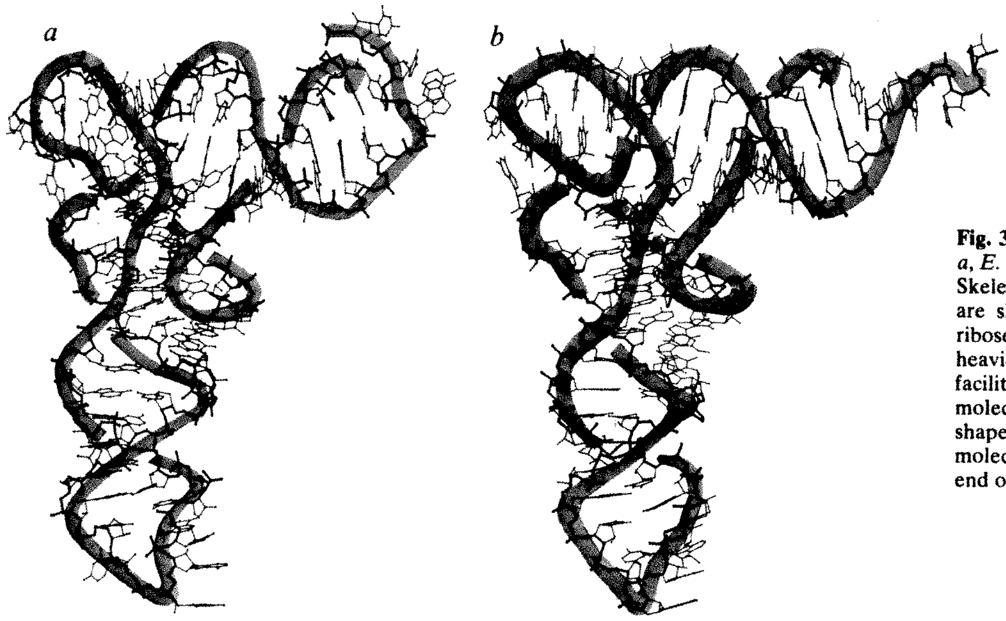

Fig. 3 A comparison of the structure of *a*, *E. coli* tRNA$_f^{Met}$ and *b*, yeast tRNA^{Phe}. Skeletal diagrams of the two molecules are shown. The continuous phosphate–ribose backbone has been drawn in heavier lines and shading has been used to facilitate tracing of the chain. The two molecules are seen in the fully extended L shape. The acceptor termini of both molecules are located at the upper right end of the L's and the anticodon loops at the bottom.

initiator tRNA, the last five nucleotides at the 3′ terminus curl back toward the acceptor end, rather than continuing the helical organization of the acceptor stem, as in yeast tRNA^{Phe}. This difference in the acceptor ends of the two molecules may arise from the fact that the *E. coli* initiator tRNA, as most other prokaryotic initiator tRNAs, has an unpaired set of bases at the end of its acceptor stem (Fig. 1).

Several sections of the 3.5 Å electron density map based on the current model are presented in Fig. 4. The sum function Fourier map, $2F_0 - F_c$, is shown to allow assessment of both the quality of the fit and the noise level of the map. The phosphate–ribose backbone is found in strong electron density, as are virtually all of the bases. A few bases do not lie entirely in density, which indicates that their position will probably shift slightly with further refinement. The low density peaks found in solvent regions indicate the noise level of the maps. No solvent has been included in the current model. Figure 4*a* shows a portion of the map including the 5′ side of the anticodon loop (see Fig. 4*e*). The position of uracil 33 differs in the initiator tRNA from that in yeast tRNA^{Phe} and will be discussed below. All of residue 33: phosphate, ribose, and base, lies in strong density. Figure 4*b* shows portions of the D stem and loop and the T loop. The D loop of the initiator tRNA was fitted using maps based on partial models to insert the extra residue in the α region. The base of residue 16 in the α region can be seen to lie in strong density, as do the bases of the D stem seen between phosphate 15 and ribose 23. The acceptor stem density is shown in Fig. 4*c*. The present model includes P76, the terminal phosphate, but not adenosine 76. The strong peak of density to the upper right of P76 is probably occupied by the ribose and the elongated extension may be the position of adenine 76. The strong density to the left of P76 is occupied by phosphates 73–75, which are part of the curled portion of the acceptor terminus (see Fig. 3). Figure 4*d* shows the anticodon arm at the point where the anticodon stem and D stem join to form one helix. At the left is a large region with a number of small peaks, which corresponds to the long solvent channel seen in Fig. 2. Figure 4*f* shows the D loop, T stem and acceptor stem. The generally good fit of the helix can be seen. Note the density corresponding to phosphate 73 which begins the curl seen in the acceptor terminus.

Figure 5 has stereo side and end views of *E. coli* tRNA$_f^{Met}$, and for comparison, yeast tRNA^{Phe}. In the side view of the initiator tRNA (Fig. 5*a*), one can see four of the five unpaired residues at the 3′ end (A76 is not yet in the model). Residue 72 is base-paired to residue 1 in chain-elongating tRNAs and eukaryotic initiators[1,2]; here it is rotated away from the base-pairing plane. The plane of adenine 72 is almost perpendicular to that of C1, and is in a curved stacking array with bases 73, 74, and 75. The 3′ terminus in this tRNA curves over the minor groove of the acceptor helix, bringing phosphate 76 close to phosphates 3 and 4 of the opposite strand. The significance of this conformation is not clear. Schulman *et al.*[18] have shown that modification of C1 to U1, with the resulting formation of a normal Watson–Crick base pair with A72, does not interfere with initiator function, but does enhance the ability of the initiator tRNA to bind to *E. coli* elongation factor, Ef-Tu. The curved stacking array of bases 72 through 75 appears to be stable in the crystal. It would be of interest to determine its stability in solution.

Although eukaryotic initiators differ from other tRNAs in the T loop, prokaryotic initiators differ in this loop only in the presence of A57 rather than the more common G57[1,2]. The major difference seen here in the initiator tRNA structure compared to yeast tRNA^{Phe} is the position of residue 57. A57 in the initiator tRNA is intercalated between G18 and G19 of the D loop, as is G57 in yeast tRNA^{Phe}, but is not drawn in as far as the backbone of the D loop (compare Fig. 5*a* and *c*). The position of G57 in yeast tRNA^{Phe} may be stabilized by the hydrogen bonds formed between N2 of G57 and riboses 18 and 19 (refs 19, 20). Such stabilizing forces are not possible when adenine is substituted for guanine, which may account for the differences. The current model of the initiator tRNA has not been constrained to include any tertiary interactions. The only constraints imposed have been on residues involved in the hydrogen-bonded stem regions. Most of the base positions in the current initiator tRNA model have been shifted from their original positions in the initial model by the refitting process. Tertiary interactionscannot be identified with certainty at the resolution of this report. However, they can be tentatively identified by the relative geometry and proximity of the bases. For example, O6 of G9 appears to be within hydrogen-bonding distance of the amino group of C12, an interaction which may be similar to that in yeast tRNA^{Phe} between A9 and A23. Most of the tertiary interactions seen in yeast tRNA^{Phe} appear also to exist in *E. coli* initiator tRNA. The precise identification of these interactions as well as the identification of the interactions of magnesium ions and spermine must, however, await the higher resolution analysis.

The major differences between the two structures are found outside the core region of the molecule. There are two significant sequence differences between *E. coli* tRNA$_f^{Met}$ and yeast tRNA^{Phe} (Fig. 1). The first is found at the end of the acceptor stem and may give rise to the difference in conformation of the 3′ OH end of the two molecules described earlier. The second is the size of the α region of the D loop. This region of the initiator structure was fit using Fourier maps based on a model in which the entire D loop was omitted. The α region residues are shown shaded in Fig. 5*a*, *c*. In the initiator tRNAs these residues are associated with strong density (see Fig. 4*c*) and appear to be more rigidly fixed than the two α residues in yeast tRNA^{Phe}. D16 and D17 in yeast tRNA^{Phe} point away from each other, while the three α bases in the initiator tRNA are close together, with C17 and U17a stacked upon each other (Fig. 5*b*). Although the α region in this initiator tRNA is one residue larger than that of yeast tRNA^{Phe}, it does not project further from the body of the molecule than the α region of yeast tRNA^{Phe} (Fig. 5*b*, *d*). Instead, the D loop accommmodates the extra residue by folding toward the body of the molecule, giving rise to a more tightly organized loop than in yeast tRNA^{Phe}. This may explain why tRNAs have a maximum of three nucleotides in the α region[1,2,8]: there is simply not enough room for an internally directed segment to accommodate a fourth nucleotide without encroaching on the body of the molecule.

The anticodon loops of *E. coli* $\text{tRNA}_\text{f}^{\text{Met}}$ and yeast tRNA^{Phe} are superficially similar in that the anticodon bases have roughly similar stacking (Figs 3 and 5*a*, *b*). However, an important difference lies in the orientation of the conserved residue U33 which is 5′ to the anticodon. In yeast tRNA^{Phe}, U33 folds into the anticodon loop and forms a hydrogen bond between N3 of U33 and phosphate 36 (refs 19, 20). U33 in *E. coli* $\text{tRNA}_\text{f}^{\text{Met}}$ has an almost opposite orientation; it is thrust away from the anticodon loop into the solvent region. An intermolecular lattice interaction involving uracil 33 may help stabilize its orientation; however, its identification is still tentative. The effect of this difference in U33 orientation on the anticodon loop folding in the two molecules can be seen in Fig. 5*b*, *d*. The loop in yeast tRNA^{Phe} is symmetrical while the loop of *E. coli* $\text{tRNA}_\text{f}^{\text{Met}}$ is skewed, so that the anticodon bases are in different positions relative to the anticodon stem in the two molecules. The orientation of residue 33 in the initiator tRNA involves a position of the ribose so that the 2′ hydroxyl of ribose 33 could perhaps form a hydrogen bond with phosphate 36. Phosphate 36 is also in a slightly different position than in yeast tRNA^{Phe}, being closer to the backbone of the 5′ side of the anticodon loop. Residues 34 and 35 are forced off to one side, producing the skewed shape of the loop. The shape of the anticodon loop may thus be determined by the group hydrogen bonding to phosphate 36: one conformation of the loop is found if the hydrogen-bonding group is ribose 33 and another if it is uracil 33. The two conformations show a marked difference in the position of phosphate 35 which in the initiator tRNA extends away from the anticodon loop in contrast to its more proximal position in the yeast tRNA^{Phe}.

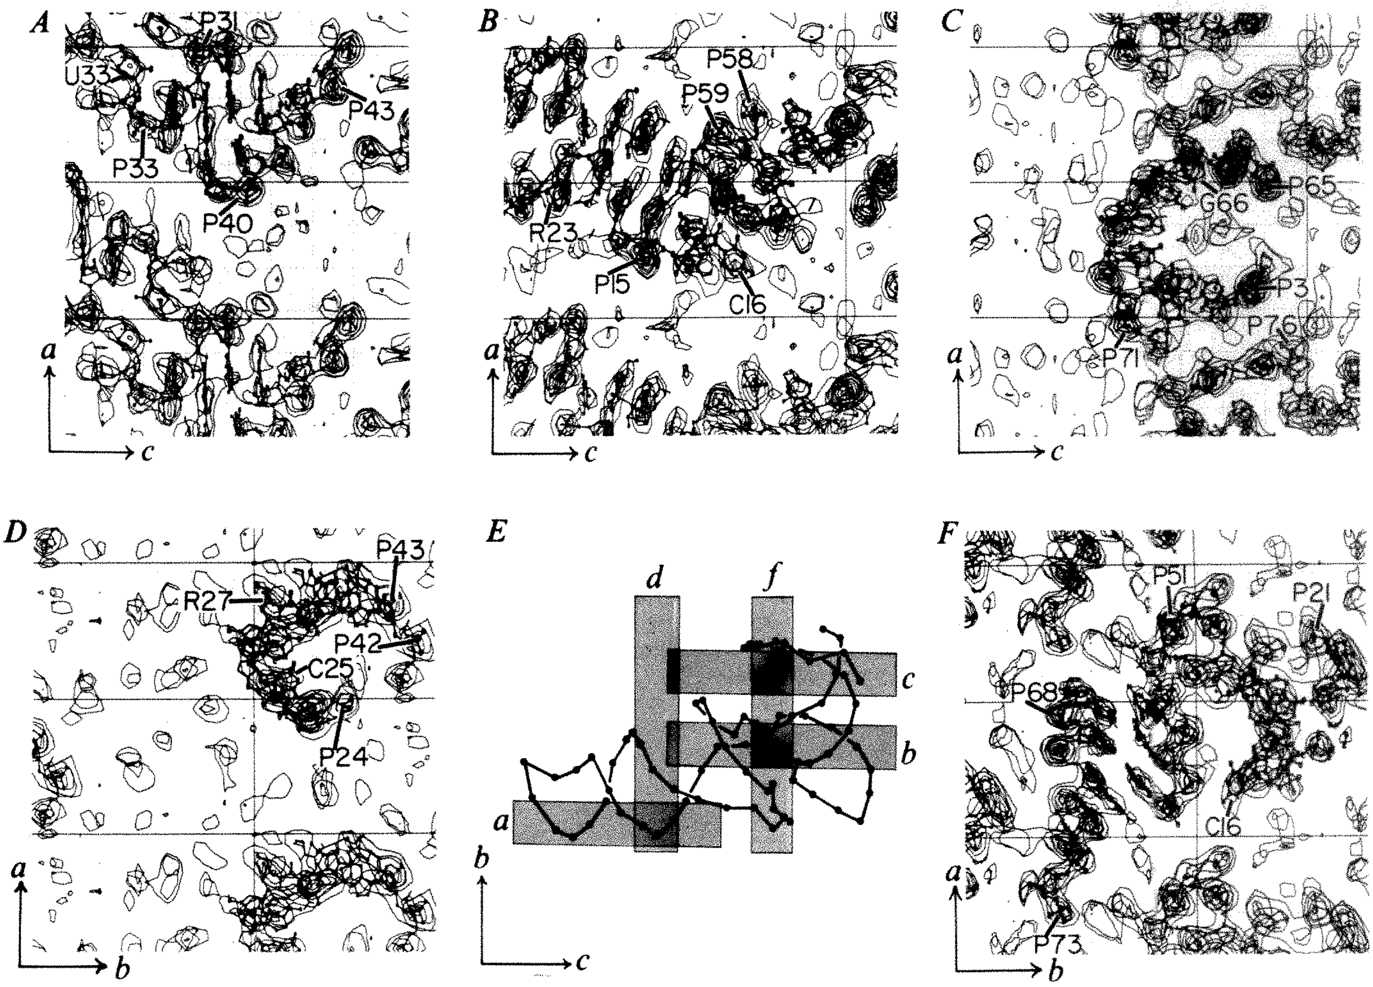

Fig. 4 Five different sections of the sum function Fourier map, $2F_0 - F_c$, are shown. Each section is the superposition of seven sections with a total thickness of 8 Å. In *e*, a schematic diagram is given which includes a plot of the phosphorous atoms in the backbone. The molecule is shown in the orientation of Fig. 2. The shaded bars indicate the regions of the molecule seen in the correspondingly labelled density section. The bars are all 8 Å wide and extend over 50 Å in the direction perpendicular to the page. The scale of this schematic is not the same as that of the density sections. In *a*–*d* and *f*, one-and-a-half unit cells are shown in the *a* direction. The horizontal lines are drawn at $x = 0$, $\frac{1}{2}$, and 1. The distance between each pair of lines is therefore 16 Å. In *b* and *c*, the vertical line is drawn at $z = 1/2$, and in *d* and *f*, at $y = 1/2$. In all sections the model has been drawn in addition to the contours of electron density. The principal molecule is drawn in heavy lines, symmetry-related molecules in light lines. The contouring begins at $0.275\ \text{e}\ \text{Å}^{-3}$ with intervals of $0.300\ \text{e}\ \text{Å}^{-3}$. In indicating various parts of the molecule, we have used P for phosphate, R for ribose, and A, G, C, U for bases.

Fig. 5

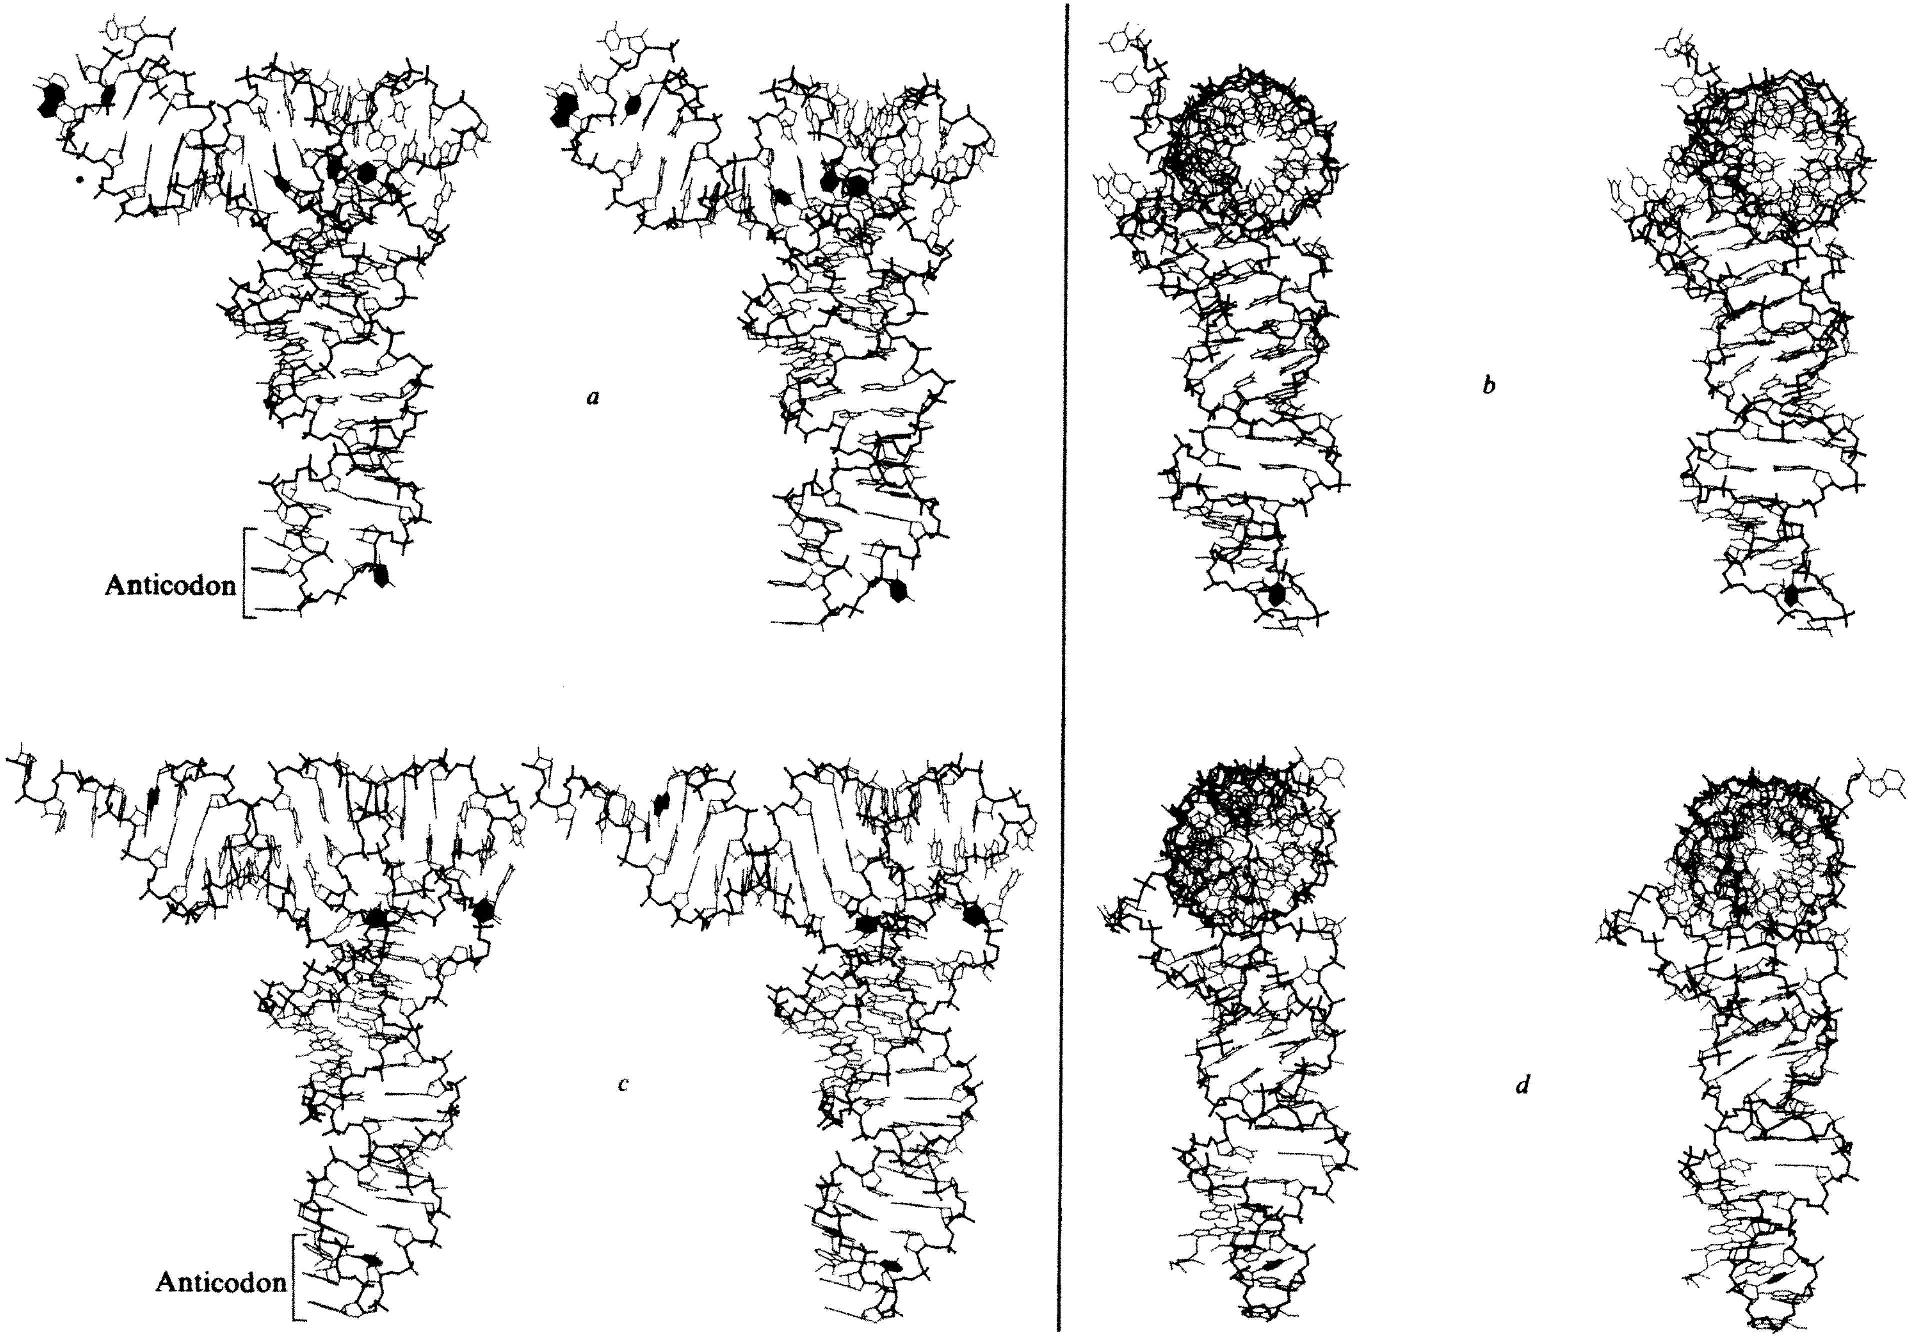

Fig. 5 Stereo diagrams of *E. coli* $\text{tRNA}_f^{\text{Met}}$(*a*, *b*) and yeast tRNA^{Phe} (*c*, *d*). *a* and *c* show side views of the two molecules and *b* and *d* views looking down the acceptor helix. In *a*, residues C1, A72, C16, C17, U17a, and U33 are shaded. Only residue U33 is shaded in *b* and *d*. In *c*, residues G1, C72, D16, D17, and U33 are shaded. The backbone of each molecule is emphasized with heavy lines.

Two different kinds of molecules

The structure presented here is based on data to 3.5 Å resolution and has been partially refined to a residual of 0.35. We have been able to interpret the structure at this resolution in more detail than might be expected because we have interpreted it comparatively with the refined 2.5 Å structure of the yeast tRNA^{Phe}. There are three regions in which the structure of the *E. coli* $\text{tRNA}_f^{\text{Met}}$ differs substantially from that of yeast tRNA^{Phe}. The first is the 3′ end of the molecule. The conformation observed in the initiator tRNA demonstrates the flexibility of this end of tRNA molecules which is consistent with its biological role: the transfer of the nascent polypeptide chain from one tRNA to the next[1,2,9]. The second difference is found in the α region of the D loop. The initiator tRNA accomodates its larger α region not by extending it further into solvent, but by drawing it closer to the body of the molecule, giving a more compact structure than seen in yeast tRNA^{Phe}. The third difference concerns the conformation of the anticodon arm. In their 4.5 Å analysis of yeast $\text{tRNA}_f^{\text{Met}}$, Shevitz *et al.* found an overall similarity in the shape of the yeast initiator tRNA to that of yeast tRNA^{Phe}, with a difference existing in the anticodon arm[4]. It will be of interest to compare the structures of the *E. coli* and yeast initiator tRNAs once the details of the latter are available. A recent biochemical study has implicated the anticodon loop conformation in distinguishing initiator tRNAs from chain elongation tRNAs by their endonuclease cleavage patterns[5]. In the present study, the major difference in the anticodon region concerns itself with the orientation of uridine 33. In *E. coli* $\text{tRNA}_f^{\text{Met}}$, the base projects away from the loop while in yeast tRNA^{Phe}, it points into the loop[19,20]. The effect of the different orientation is a position of ribose 33 which appears to allow the formation of a hydrogen bond between O2′ of the ribose with phosphate 36. It is important to emphasize, however, that the identity of this hydrogen bond, as of all the tertiary hydrogen bonds discussed above, is tentative until the higher resolution analysis is complete. Phosphate 36 is drawn toward the centre of the loop while phosphate 35 is forced away from the centre, giving rise to the skewed appearance of the loop (Fig. 5*b*) in contrast to that of yeast tRNA^{Phe} (Fig. 5*d*). The two loop conformations lead to a slightly different stacking arrangement of the anticodon bases. Although the position of uracil 33 in *E. coli* $\text{tRNA}_f^{\text{Met}}$ may be stabilized by a lattice interaction, it is not likely that the loop conformation is entirely determined by this interaction.

The difference in the anticodon loop conformation was not anticipated from either the nucleotide sequence or the results of earlier solution studies. The implication from the recent nuclease digestion study[5], however, is that the conformation detected there for the *E. coli* initiator tRNA is the same as that found in both lower and higher eukaryotic initiators. The generality of an initiator tRNA anticodon loop conformation may be the determining factor which permits initiators to enter the bind at the P site of the ribosome while chain-elongating tRNAs bind initially at the A site. The external position of uracil 33 and its concomitant failure to participate in hydrogen bonding within the anticodon loop offers an explanation for the cytosine in position 33 in higher eukaryotic initiators. In cytosine, N3 is not protonated so that a hydrogen bond between the base of residue 33 and phosphate 36 of the type seen in yeast tRNA cannot exist. However, even with cytosine in position 33, the hydrogen bond between ribose 33 and phosphate 36 suggested in the *E. coli* initiator tRNA could exist. One should recall here that higher eukaryotic initiators can be used in *in vitro E. coli* protein synthetic systems and vice versa[21].

The uridine swivel hypothesis

tRNAs move from the A site to the P site in the ribosome. The conformational difference in the anticodon loop which we observe between the chain-elongating yeast tRNA^{Phe} and the initiator *E. coli* $\text{tRNA}_f^{\text{Met}}$ may be a conformational shift which occurs when tRNA moves from one site to the other. A chain-elongating tRNA moving from the A site to the P site may interact with an element of the ribosomal machinery which flips the anticodon loop from one conformation to the other with a swivel motion of U33. If so, does the externally oriented uracil 33 play a structural role when the tRNA occupies the P site? Perhaps a ternary complex forms involving messenger RNA and tRNAs in the A and P sites, such that uracil 33 of tRNA hydrogen bonds to the anticodon arm of the A-site tRNA. This hydrogen bond could involve a 2′ hydroxyl of the A-site tRNA and O2 of uracil 33. In such an hypothesis, cytosine in position 33 would not modify the stability of the system. Furthermore, the hypothesis allows a plausible positioning of the tRNAs in the A and P sites in which the anticodon bases hydrogen bond to adjacent nucleotide triplets on the messenger RNA, and the CCA ends of the two molecules are close enough to effect a transfer of the nascent polypeptide chain. In this arrangement, the two codons of the message must be unstacked as suggested a few years ago[22]. A further description of this proposed ternary complex will be published elsewhere. The observed difference in the anticodon loop conformation of the *E. coli* initiator tRNA and the yeast tRNA^{Phe} may thus provide clues as to the manner in which tRNAs associate with each other in the ribosome.

This research was supported by grants from the NIH, NSF, NASA, and the American Cancer Society. We thank Dr F. P. Brooks and his colleagues at the Department of Computer Science, University of North Carolina at Chapel Hill, for their assistance with the GRIP-75 molecular graphics facility. We also thank Dr Gary Quigley for use of the program to plot Figs 2–5 and the coordinates in Figs 2 and 5, and both him and Andrew H.-J. Wang for their encouragement, advice, and assistance.

Insertion of the eukaryotic transposable element Ty*1* creates a 5-base pair duplication

Philip J. Farabaugh & Gerald R. Fink

Section of Biochemistry, Molecular and Cell Biology, Cornell University, Ithaca, New York 14853

The his4–912 *mutation results from insertion of a transposable element into the 5′-non-coding region of the* his4 *gene of yeast. A duplication of 5 base pairs of wild-type* his4 *DNA flanks the inserted element. The major class of His$^+$ revertants result from excision of most of the transposable element, leaving an inserted segment of 334 base pairs flanked by the 5-base pair repeats.*

TRANSPOSABLE genetic elements in bacteria are capable of transposition to new sites and promoting chromosomal rearrangements including deletions, inversions and fusions[1,2]. The existence of eukaryotic transposable elements has been suggested on genetic and biochemical grounds. In maize, the genetic 'controlling elements' are capable of transposition to new sites and of catalysing gross rearrangements of the genome[3]. Reiterated DNA elements which have the same structure as a bacterial transposon have been isolated from *Drosophila*[4] and the yeast *Saccharomyces cerevisiae*[5]. The location of these elements varies between strains. The genetic properties of maize controlling elements and the biochemical properties of the *Drosophila* and yeast elements suggest that transposable elements similar to those found in prokaryotes exist in eukaryotes. In no case has an unstable mutation been shown biochemically to be the result of the insertion of a transposable element.

The *his4-912* mutation is due to the insertion of a transposable element (Ty*1*) into the *his4* locus of yeast[6]. The mutation is unstable and has given rise to translocations, deletions, a transposition and an inversion[7]. DNA sequence analysis of the wild-type *his4* gene and the *his4-912* mutant indicates that transposition of Ty*1* creates a 5-base pair duplication of DNA previously at the site. Excision of the element by recombination between the terminal 334-base pair repeats results in reversion to a His$^+$ phenotype. In *his4-912*, Ty*1* inserted into the 5′-non-coding region of the *his4* gene. The phenotype of the His$^+$ revertants of *his4-912* suggests that Ty*1* does not disrupt the *his4* promoter but that it interferes with *his4* expression by transcriptional competition.

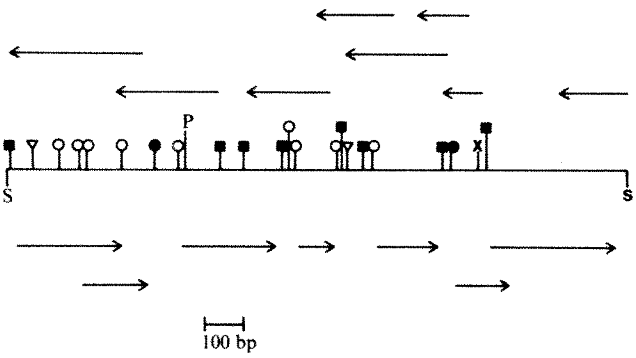

Fig. 1 The sequencing strategy for the 1,577-base pair (bp) *His4$^+$ Sal*I fragment. Those restriction sites used to determine the sequence are indicated: *Sal*I(S), *Hinf*I (■), *Taq*I(○), *Msp*I(▽), *Xho*I(×), *Sau*3A (●) and *Pvu*II(P). Each arrow above and below the map indicates the extent of the 3′ to 5′ sequence determined from a single experiment; the head of the arrow indicates the position of the nucleotide identified farthest from the end label. The restriction fragments for sequence analysis were generated by cleavage of either the *Sal*I plasmid (YIP302) or the *Sal*I fragment and labelled at their 3′ ends with either [α-^{32}P]dATP or dCTP using reverse transcriptase[29]. The labelled fragments were isolated and subjected to the Maxam–Gilbert chemical sequencing procedure and the reaction products separated by electrophoresis as described[30] except that 80-cm gels were used to enable us to read sequences very far from the label (±350 base pairs). The products were visualized by autoradiography and the sequence read from the film.

Analysis of *His4$^+$* and *his 4-912*

The *his4* locus was cloned as a 20×10^3-base pair *Bam*HI fragment on pBR313 (YIP300)[8]. Existing deletions of portions of *his4* localize the beginning of the gene to 500 base pairs from the end of an approximately 1,500-base pair *Sal*I fragment[9]. The Southern blot of labelled *his4* DNA to DNA from a *912* yeast strain and the restriction map of the *912* clone demonstrated that the *912*-insert was a Ty*1* element transposed to the same *Sal*I fragment[6].

We present here the DNA sequence from this *Sal*I fragment in *His4$^+$* and compare it with the DNA sequence from the *Sal*I fragment in *his4-912*. We analysed fragments of the *His4$^+$* segment which end at *Sal*I, *Hinf*I, *Taq*I, *Msp*I, *Xho*I and *Pvu*II sites to determine the complete nucleotide sequence of the wild-type 1,577-base pair fragment (Fig. 1). The *his4* coding frame extends through the last 474 base pairs of the top strand of the fragment. Many nonsense codons are dispersed throughout the region in the other two coding frames. Two early *his4$^-$* mutations differ from the wild-type sequence within this segment (T. Donahue, personal communication). The protein specified by the *his4* coding frame begins Met-Val-Leu-Pro-Ile; the amino terminus of the *his4* protein is the tetrapeptide Val-Leu-X-Ile (X was unidentified, ref. 10 and R. Bigelis, personal communication). These data show that the coding region for the amino-terminal portion of the *his4* protein begins at position +1 shown in Fig. 2.

The plasmid containing the *his4-912* mutation (YIP312) includes 19×10^3 base pairs of yeast DNA (the restriction map, as previously determined[6], is shown in Fig. 3). To analyse more easily the DNA sequence in the region of the two junctions between *his4* and the insert, we cloned the two *Sal*I fragments which span these junctions in pBR322 (YIP312-1 and YIP312-2; Fig. 3). The junction closest to *his4* was sequenced from fragments produced by cleavage of YIP312-1 with *Sal*I, *Hinf*I, *Sau*3A, *Taq*I and *Bgl*II. The junction distal to *his4* was sequenced using the restriction sites for the enzymes *Hinf*I, *Msp*I and *Sau*3A, which lie within a 900-base pair *Pvu*II fragment of YIP312-2 (Fig. 4*b*). The sequence of the *his4*-proximal junction extends 715 base pairs into the insertion element and the *his4*-distal sequence extends 369 base pairs in from the other junction (Fig. 2).

Ty*1* is a transposable element

The Ty*1* element is a 5,600-base pair region flanked by direct repeats of approximately 250 base pairs ('δ regions')[5]. The element is present in about 35 copies dispersed throughout the

Fig. 2 Comparison of the *His4*⁺ and *his4–912* sequences indicates the location of Ty*1*. The *his4-912* sequence (roman letters) is homologous with the *His4*⁺ sequence (italic letters) up to position −161 from the right (the direction to *his4*) and −157 from the left. The sequence of 5 base pairs from positions −157 to −161 (large letters) is duplicated at either end of the element. The 334-base pair region into the element from either junction is a direct repeat of the δ element (indicated by bars above and below the Ty*1* sequence). The 5,600-base pair internal region of Ty*1* lies between the two δ elements. The sequence of 36 base pairs in from the right hand and 382 base pairs in from the other have been determined. At the junctions between the δ elements and the 5,600-base pair region there is a second 5-base pair duplication 5′-TGGTA-3′ (underlined). The non-coding region of *His4*⁺ (italics) includes two possible Hogness boxes (underlined) that could be associated with mRNAs beginning on the *his4*-side of the first ATG in the *his4* non-coding region (underlined).

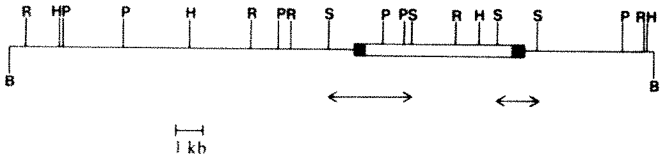

Fig. 3 The restriction map of the *his4-912* plasmid (YIP312) as described by Roeder and G.R.F.[5]. The sites for the enzymes *Bam*HI(B), *Eco*RI(E), *Hin*dIII (H), *Pst*I(P) and *Sal*I(S) are indicated. The boxed region represents the Ty*1* insert, and the δ repeats are indicated by the solid regions. The portions of this plasmid cloned in YIP312-1 and YIP312-2 are indicated by double-headed arrows below the map.

yeast genome and the δ regions are present in over 100 copies both as part of Ty*1* elements and as independent units. The Ty*1* element was inferred to transpose because it appeared in different locations in several strains of yeast. However, in no case was transposition directly observed.

The sequence of *his4-912* demonstrates that Ty*1* transposed into *his4*, as only the element itself has moved into the new site. The element which has inserted into *his4* is approximately 5,600 base pairs flanked by a perfect 334-base pair direct repeat. The *his4* wild-type sequence begins precisely at the ends of the terminal repeats, so no DNA other than Ty*1* has been inserted. Because insertion includes only Ty*1*, it could not have been caused by homologous recombination involving sequences flanking its original site. The DNA sequence of the *his4-912* mutation is consistent only with transposition of an intact Ty*1* into the 5′-non-coding region of *his4*.

The Ty*1* element in *his4-912* is flanked by a duplication of 5′-TAAGA-3′ (Fig. 5). This duplication was created during transposition, because the sequence appears only once in *His4*$^+$ DNA (nucleotides −161 to −157). The creation of flanking duplications is a characteristic of all prokaryotic transposable elements; both 5-base pair (IS*2*, Tn*3*, Mu and γ–δ) and 9-base pair duplications (IS*1*, Tn*5*, Tn*9*, Tn*10*) have been observed (summarized in ref. 11). Our finding that Ty*1* insertion creates a duplicated sequence in the target suggests that the mechanism of transposition is similar between a eukaryote and the prokaryotes.

A feature of the Ty*1* sequence which we cannot explain is the existence of a 5-base pair duplication of 5′-TGGTA-3′ at the internal δ junctions of Ty*1* (Fig. 2). The existence of a duplication of the sort created by Ty*1* transposition suggests that these junctions have also been created by transposition. There is no simple transposition process known or postulated that could account for this structure. It is also possible that this is either a random occurrence of a 5-base pair duplication or that the duplication is required for Ty*1* function.

The insertion of Ty*1* creates a 24-base pair inverted repeat

Although in *Escherichia coli* the insertion of transposable elements is not a site-specific event, the sites of insertion cluster in specific regions ('regional specificity') and many insertion mutations are found in these regions at a few specific sites ('hotspots'). Many transposons demonstrate regional specificity [Tn*3* (ref. 12), Tn*7* (ref. 13), Tn*9* (ref. 14), Tn*10* (refs 15, 16), Tn*501* and Tn*802* (ref. 17)]. DNA sequencing of Tn*10* (ref. 18) and Tn*3* (ref. 19) insertions shows directly that these elements have insertion hotspots. The hotspots for insertion of Tn*3* occur near a sequence in the target DNA which is homologous to the termini of the element. The insertion of Tn*3* at the hotspots creates an inverted repeat between the homologous sequences in the element and the site. Thus, some sequence homology is responsible for the specificity of insertion, although homologous recombination is not involved.

A sequence created by the insertion of Ty*1* into *his4* suggests that transposition is directed by limited sequence homology. The sequences 12 base pairs in either direction from one mutation junction form an inverted repeat with its centre of symmetry precisely at the junction (Fig. 5). The sequence, 5′-ACCCATTTCTCA/TAAGAAAAGGAT-3′ (the slash is the centre of symmetry and the junction), includes nine matches and two purine–purine matches. The sequence at the end of δ could be required for recognition of the preferred insertion site. The recognition does not involve homologous recombination, as that process would create a flanking direct repeat.

Excision of Ty*1*

The major class of His$^+$ revertants is caused by a sequence alteration at the *912* site. These revertants are His$^+$ at 37 °C and His$^-$ at 23 °C (ref. 7). The *his4* region from these revertants has suffered a large deletion of Ty*1* DNA, but still retains approximately 300 base pairs of the element[6]. The fact that the δ element is the same size as the remaining insert suggested that reversion resulted from recombination between the direct terminal repeats of δ, leaving a single δ. This process is called excision. The Tn*9* element, which is flanked by a direct repeat of IS*1*, also undergoes an excision of this sort[20].

We cloned the *his4* region of one cold-sensitive revertant, *his4-912R1*, using a modification of a previously described procedure[6]. Sequence analysis of the *his4* region from *his4-912R1* shows that the mutation results from the presence of a single δ element which is identical to those at the end of Ty*1* in *his4-912*. The δ element is flanked by the identical 5-base pair duplication flanking *his4-912*. We have sequenced 250 base pairs towards and into the *his4* gene and found no additional differences from *His4*$^+$. The sequence is entirely consistent with the recombination model for excision. Excision of Ty*1* by this specialized recombination could be responsible for the distribution of δ sequences in the yeast genome. As many as 50 δ sequences independent of Ty*1* are dispersed throughout the genome. These δ elements could mark the sites of previous Ty*1* excisions.

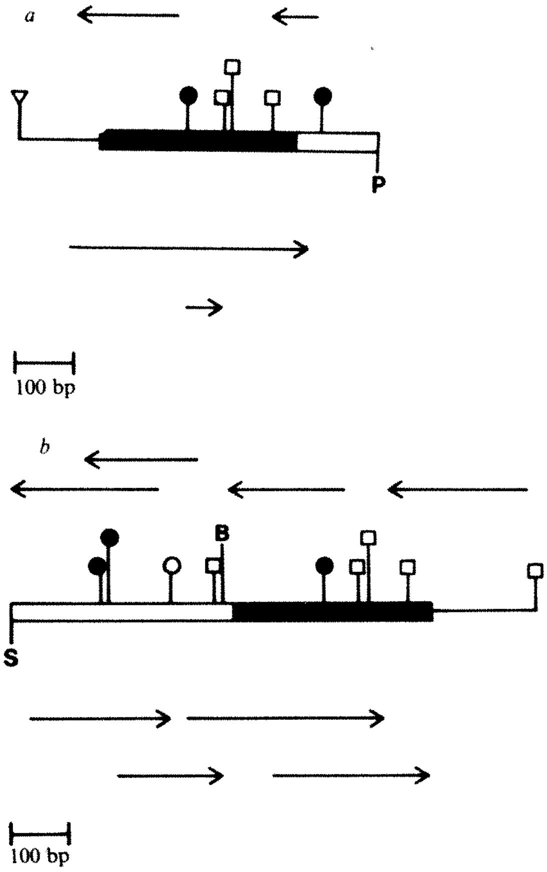

Fig. 4 The sequencing strategy for the two junctions of Ty*1* in *his4-912* is shown as described in Fig. 1 legend; the site for the enzyme *Bgl*II is indicated (B). The Ty*1* element is represented as in Fig. 3. *a*, The strategy for the *his4*-distal (left) region from plasmid YIP312-1. *b*, The strategy for the *his4*-proximal (right) region (YIP312-2).

Fig. 5 The sequences of *His4*$^+$ and *his4-912* junctions. The arrows are at the junction points. The regions homologous to *His4*$^+$ in the sequences of the two junctions are shown in roman lettering, the Ty*1* element in italics; the 5-base pair duplication is indicated by large letters. The lines in either direction from the right junction demonstrates the inverted repeat; a (–) indicates identity and a (Λ) indicates purine–purine partial identity.

Ty*1* is inserted into the region of the *his4* promoter

A comparison of the sequences of *His4*$^+$ and *his4-912* demonstrates that in the *his4-912* mutation Ty*1* lies in the 5′-non-coding region, 161 base pairs from the ATG responsible for initiation of *his4* translation (Fig. 2). Because the sequence encoding the *his4* polypeptide is unaffected and the mutation is distant from the structural gene, the His$^-$ phenotype of *his4-912* is likely to result from a block in the expression of the gene at the level of transcription.

Unfortunately, we do not know exactly where *his4* transcription begins. Comparison of the *his4* sequence with that of known eukaryotic promoters limits the position possible for *his4* transcriptional initiation. Regions where eukaryotic RNA polymerase II initiates have two common features. Translation begins at the first AUG following the site of transcriptional initiation[21]. As shown by studies on the *cycl* gene of *S. cerevisiae*, the only signal required for initiation of translation is the AUG[22]. This observation is supported by comparisons of 5′-non-coding regions of many eukaryotic mRNAs[23]. Based on these considerations the *his4* message must initiate downstream from the first ATG in the non-coding region (−88) between −87 and +1.

The second common feature of eukaryotic promoters is a sequence which is thought to be a recognition site for RNA polymerase II. Nearly all promoters have a sequence similar to 5′-TATAAATA-3′ (the 'Hogness box') which is centred approximately 28 base pairs on the 5′ side of the initial nucleotide of the message[24]. The promoter regions of the yeast genes *his3*[25], *cycl*[26], and the gene encoding glyceraldehyde-3-phosphate dehydrogenase[27] all include a sequence related to the Hogness box. If *his4* mRNA begins between −87 and +1, any Hogness box must lie between nucleotides −120 and −25. Two sequences similar to the Hogness box occur in this region: 5′-TATATAATA-3′, centred on −119, and 5′-CATAAAAA-3′, centred on −67. The His$^-$ phenotype of *his4-912* does not result from disruption of the DNA sequence in the region of either Hogness box.

Preliminary RNA blotting experiments indicate that the normal *his4* message is not produced in *his4-912* (C. Ilgen, personal communication). One possible explanation for the His4$^-$ phenotype of the *his4-912* mutation is that transcription initiated within the Ty*1* element disrupts the initiation of transcription at the normal *his4* promoter. The other possibility is that Ty*1* inserted into a site required for polymerase recognition. This would mean that the promoter includes sites in the region of −161 as well as the Hogness box.

The *his4-912R1* revertant created by excision of most of the Ty*1* element can distinguish between these two possibilities. In *his4-912R1* there is no new promoter either at the *his4*-proximal junction of the insertion or in the insertion itself, as this region is identical to that of *his4-912*. A promoter created at the *his4*-distal junction would result in transcription of the element itself. The element includes nine ATG codons each followed by several in-frame nonsense codons before the beginning of *his4*. Such a transcript would fail to express *His4*$^+$ because translation would initiate and terminate before the *his4* gene. The simplest hypothesis is that the *his4* promoter is located between the *his4-912* site (−161) and the beginning of the gene. The His$^-$ phenotype of *his4-912* could be attributed to transcriptional competition. Deletion of most of the element by excision eliminates the Ty*1* transcript so that initiation at the *his4* promoter occurs normally. The residual cold sensitivity of *his4-912* is not explained by this model. This phenotype could be due to some other pleiotropic effect of the δ element (such as that due to a minor transcript), or the presence of a δ element could alter the *his4* promoter. Many predictions of this model are being tested by RNA blotting experiments.

Sequence analysis of the Ty*1* element from *his4-912* demonstrates that Ty*1* is a transposon and is capable of transposition by a mechanism similar to that of bacterial transposons. Southern blotting analysis of His$^+$ revertants of *his4-912*[5] suggest that the element is also capable of promoting chromosomal aberrations similar to those catalysed by bacterial transposons. One mutant may be the result of a transposition-mediated inversion, similar to those seen with bacteriophage Mu[28]. The Ty*1* element also promotes events which differ from any observed in bacteria. These include deletions ending at apparently random locations in the element, chromosomal aberrations with breakpoints outside the element, and 'concerted' events[6,7], and suggest that the mechanism of action of Ty*1* is significantly different from that of prokaryotic transposons.

We thank Deborah Chaleff, Thomas Donahue, John Lis and Shirleen Roeder for their critical reading of this manuscript and for helpful discussions. This work was supported by NIH grant GM15408. P.J.F. was an American Cancer Society Postdoctoral Fellow. Experiments involving recombinant DNA techniques were carried out according to the NIH guidelines.

A signal sequence is not sufficient to lead β-galactosidase out of the cytoplasm

Escherichia coli *strains have been constructed in which* lacZ, *the gene for the cytoplasmic enzyme β-galactosidase, is fused to* lamB, *the gene for an outer membrane protein. One such strain produces a β-galactosidase which remains cytoplasmic even though it possesses the complete signal sequence of the* lamB *protein precursor at the amino-terminal end.*

ACCORDING to the signal hypothesis, proteins secreted from eukaryotic cells are synthesized as precursors with an extra NH_2-terminal sequence of predominantly hydrophobic amino acids[1,2]. That 'signal sequence' initiates binding of the translation complex to the endoplasmic reticulum, facilitating transfer of the protein across the membrane concomitant with translation. In most cases the signal sequence is removed by a 'signal peptidase' from the growing polypeptide during transfer, giving rise to the final protein product, which is localized on the luminal side of the endoplasmic reticulum. Evidence for this scheme in animal cells has come from the isolation, *in vitro*, of numerous precursors of secreted proteins, the discovery that they have extra amino acid sequences (15–30 residues) at their NH_2-terminus and the demonstration that secreted proteins are synthesized on polysomes bound to the endoplasmic reticulum whereas cytoplasmic proteins are synthesized on free polysomes[3–7]. On the basis of similar evidence, the hypothesis was extended to include the localization of non-cytoplasmic proteins in bacteria, with the cytoplasmic membrane having a role analogous to that of the eukaryotic endoplasmic reticulum[8–13]. (By non-cytoplasmic we mean proteins of the cytoplasmic or outer membranes, of the periplasmic space, or truly secreted proteins.)

We are using a genetic approach to evaluate the importance of the signal sequence in the export process[14–18]. One non-cytoplasmic protein which we have been studying is the product of gene *lamB* in *Escherichia coli.* Located in the outer membrane, it is involved in the transport of maltose and maltodextrins, and also serves as a receptor for several bacteriophages, including λ (refs 19–22). Comparison of the NH_2-terminal sequence of the mature protein[23] with that of the primary gene product[24,25] showed that *lamB* protein is synthesized as a precursor containing 24 extra amino acids at the NH_2 terminus. Mutations affecting this extra sequence prevent the export of the protein, which remains in the cytoplasm as an uncleaved precursor[26]. From this we conclude, as predicted by the signal hypothesis, that the extra sequence in the precursor of non-cytoplasmic proteins is essential for their export.

The question then is whether such an extra sequence possesses all the information required to lead any polypeptide out of the cytoplasm.

By means of gene fusion we have already shown that a polypeptide coded by a *lamB–lacZ* hybrid gene was exported, to some extent, to the outer membrane, although β-galactosidase, the product of *lacZ*, is normally cytoplasmic[15]. The amount of *lamB* DNA present in this hybrid gene (called 42-1) was 200–300 codons (out of a total of about 500 for the entire gene). We now describe two other fusion strains, in which there is much less *lamB* DNA in the hybrid gene. Our results demonstrate that the presence of a signal sequence at the NH_2 terminus of β-galactosidase does not suffice to lead this polypeptide out of the cytoplasm.

Construction and characterization of fusion strains

The application of gene fusion *in vivo*[27] to the selection of strains with *lamB–lacZ* hybrid genes has been described previously[15] (Fig. 1). It involves the insertion of phage Mu DNA into the *lamB* gene, the integration of a λ*plac* prophage into the Mu prophage, and a deletion of the Mu prophage. Two fusions will be described here, 61-4 and 52-4, derived from Mu insertions 61

Table 1 Purification of the hybrid proteins

	61-4		52-4	
	Total activity (units)	Specific activity (units per mg protein)	Total activity (units)	Specific activity (units per mg protein)
French press extract	9.9×10^8	2.5×10^4	3.3×10^9	5.1×10^4
38% Ammonium sulphate precipitate	4.3×10^8	7.6×10^4	1.8×10^9	2.2×10^5
DEAE-Sephadex A50 eluate	3.0×10^8	5.5×10^5	1.2×10^9	4.4×10^5

The 61-4 and 52-4 hybrid proteins were purified from 700 g and 1,000 g, respectively, of cells grown to late exponential phase at 30° C in M63 minimal medium[34] supplemented with 0.8% maltose. The purification was essentially as described by Miller[34] except that: (1) the extraction was carried out in the presence of 30 $\mu g\ ml^{-1}$ *p*-toluylsulphonyl fluoride to inhibit proteases present in the extract, (2) a precipitation step with 3% streptomycin sulphate was carried out before the ammonium sulphate precipitation, (3) DEAE Sephadex A50 was used instead of DEAE cellulose, (4) the sucrose gradient step was omitted and (5) 10^{-4} M Na-EDTA and 10^{-1} M β-mercaptoethanol were present in all buffers. The purified proteins were kept in the form of a 50% ammonium sulphate precipitate.

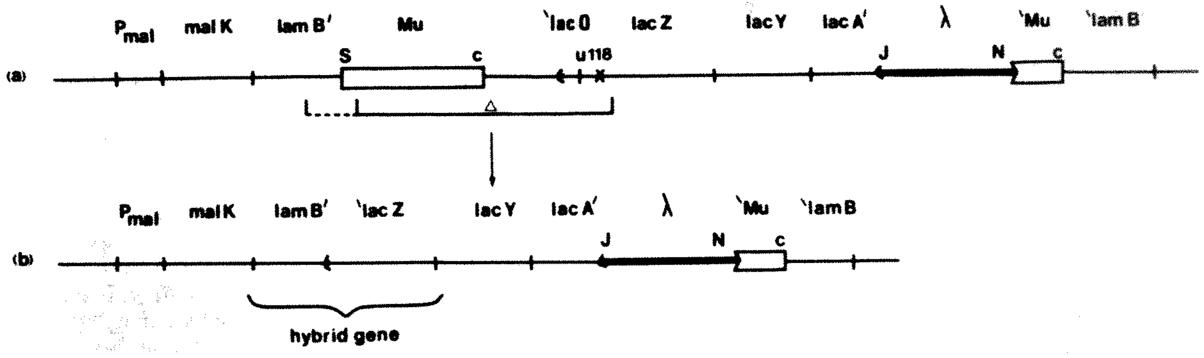

Fig. 1 Scheme for isolating *lamB–lacZ* fusion strains. Because the whole procedure has been previously described[15], only the last step is shown here. A thermoinducible Mu(cts) prophage was first inserted into *lamB* and a λ*plac Mu* prophage was then inserted into the *Mu* prophage, by recombination between homologous Mu DNA sequences. The structure of the resulting strain is shown in *a*. Pmal is the promoter of the *malK-lamB* operon. The S- and c-ends of the Mu prophage[44] are indicated. Primes, as in *lamB'* or *'lacO*, indicate that the genetic region referred to is deleted on the side the prime is written. U118 is an ochre mutation located in codon 17 of gene *lacZ* (ref. 45). Deletion events (Δ) removing all or most of the Mu(cts) prophage and extending past the U118 mutation yield strains whose genetic structure are shown in *b*. Such strains can be selected as thermoresistant (loss of the thermoinducible Mu(cts) prophage) and Lac$^+$ (elimination of U118 and production of a hybrid protein which has β-galactosidase activity).

and 52, respectively (Fig. 2). The presence of *lamB* DNA within the 52-4 hybrid gene was demonstrated by deletion mapping[15,28,29]. Because fusion 61-4 was derived from a Mu insertion located at the very beginning of *lamB*, the presence of *lamB* DNA in this hybrid gene could not be ascertained by this technique. Accordingly, we had to insure that *lacZ* was not fused to the promoter proximal gene *malK*. This was accomplished by demonstrating (as described in ref. 30) that the introduction of a non-polar amber mutation in *malK* (*malK*3 or *malK*4), in the *cis* position with respect to these fusions, had no effect on the synthesis of β-galactosidase. The introduction of such a mutation into known *malK–lacZ* fusions leads to the disappearance of β-galactosidase activity.

To locate the hybrid proteins in the cell, we prepared extracts and separated the cytoplasmic and envelope fractions as described elsewhere[14–16]. The hybrid proteins can be detected either by their enzymatic activity or by their migration on polyacrylamide gels in the presence of SDS. About 10% of the β-galactosidase activity sediments with the envelope in the case of 61-4, and 15% with 52-4. However, these figures, which result from assays carried out on unwashed envelope pellets, certainly represent overestimations of the amount of hybrid protein which is truly membrane bound. Indeed, when extracts of wild-type strains are centrifuged in the same conditions, about 10% of authentic β-galactosidase also sediments with the envelopes. The gel pattern in Fig. 3 confirms that the hybrid proteins are mostly cytoplasmic: the amount of envelope-bound protein is undetectable with 61-4 and is less than 3% with 52-4. Figure 3 also shows that the 61-4 polypeptide is slightly shorter than 52-4.

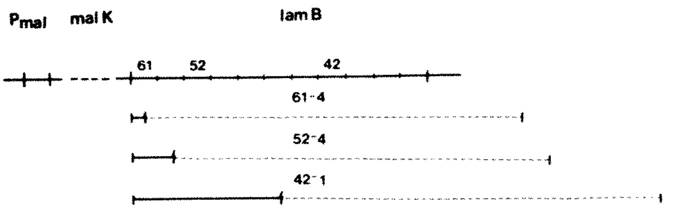

Fig. 2 Genetic structure of the *lamB–lacZ* fusions. Previous work[28] allowed us to divide gene *lamB* into 11 deletion intervals. The position of Mu insertions 61, 52 and 42 is shown on the first line. The structure of fusions derived from these Mu insertions is indicated below the map, with the *lamB* part of the hybrid gene shown as a heavy line and the *lacZ* part as an interrupted line. Only fusions 61-4 and 52-4 are described in this article, fusion 42-1 is described elsewhere[15]; it produces a hybrid protein which is partly exported to the outer membrane (see Fig. 3).

When 61-4 or 52-4 cells are submitted to cold osmotic shock[31], less than 2% of β-galactosidase activity, but about 90% of maltose binding protein[32], are released into the medium. Thus, the two hybrid proteins are not in the periplasmic space.

According to our fractionation data, therefore, the 61-4 and 52-4 hybrid proteins are chiefly in the cytoplasm, perhaps a very small fraction of the latter being bound to the membrane. That location accords with the growth properties of these two strains, which grow normally in the presence of maltose, an inducer of the *malK–lamB* operon, whereas other *lamB–lacZ* strains (such as 42-1, Figs 2, 3), which export some of the hybrid protein to the outer membrane, are sensitive to maltose[15,16].

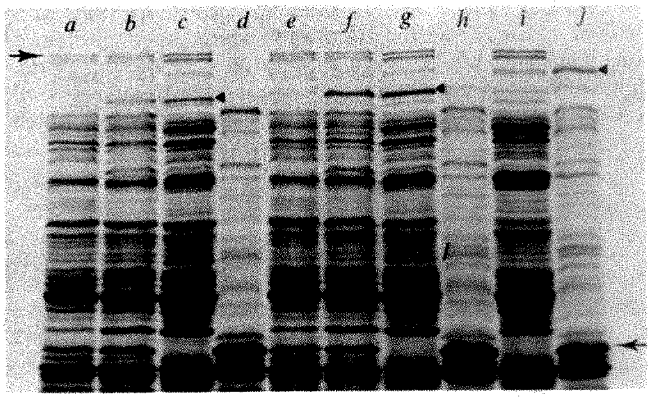

Fig. 3 SDS-polyacrylamide gel electrophoresis of whole cell extracts and cellular fractions of *lamB–lacZ* fusion strains. Whole cell extracts were prepared by growing the cells in the indicated media to mid-logarithmic phase, resuspending in 0.1 volume SDS sample buffer[46] and boiling for 2 min. Cytoplasmic and membrane fractions were prepared as previously described[14] by centrifuging at 100,000*g* for 1 h extracts obtained by sonication. All 'induced' samples correspond to cells grown at 30 °C for 4 h in maltose-glycerol M63 minimal medium supplemented with 5% complete medium (LB). 'Uninduced' samples correspond to cells grown in glucose M63 medium. The acrylamide concentration was 9%. Channels *a–d* are various preparations from the 61-4 fusion strain, channels *e–h* correspond to the 52-4 strain and channels *i* and *j* to the 42-1 strain. *a* And *e* are uninduced whole cell extracts; *b* and *f* are induced whole cell extracts; *c*, *g* and *i* are induced cytoplasmic fractions; *d*, *h* and *j* are induced membrane fractions. The membrane fractions displayed here correspond to 7.5 times more cells than the cytoplasmic fractions. The solid arrowheads indicate the *lamB–lacZ* hybrid proteins. The complete arrows indicate cytoplasmic and membrane markers: at the upper left the β and β' subunits of RNA polymerase and, at the lower right, major outer membrane protein Ia.

Fig. 4 Amino-terminal sequence of the 61-4 *lamB–lacZ* hybrid protein. All sequencing was done using 0.1 M Quadrol in a Beckman 890C sequencer. The CNBr2* fragment was sequenced using a dual wash program[47]. The intact carboxymethylated protein was sequenced with a program similar to that of Hunkapiller and Hood[48]. All other procedures were as described previously[36] except that, recently, identification has also used HPLC. ● Indicates residue identified. The numbers above the sequence correspond to the position of the residue in the 61-4 protein, the numbers below correspond to the position of the residues in the *lamB* and *lacZ* gene products. According to the DNA sequencing data the *lamB* gene starts on the mRNA with two successive AUG codons. Therefore, the *lamB* protein precursor might be expected to start with two successive methionine residues. However the two hybrid proteins described here start with a single methionine residue, and there is some evidence that this is also true of the *lamB* protein precursor synthesized *in vitro* (ref. 25). We do not know whether this is due to an initiation of translation at the second, rather than the first AUG, or to a proteolytic cleavage of the first methionine. This introduces an ambiguity in the numbering of residues in the *lamB* gene product. We decided to call residue number 1 the single methionine which could be detected at the NH_2-terminal end of the hybrid proteins.

The 61-4 and 52-4 hybrid genes were transduced into other strains of *E. coli* K12 (see below). The transductants grew normally in the presence of maltose and synthesized a cytoplasmic β-galactosidase. Thus, the original fusion strains carried no unlinked mutation which might have prevented the export of hybrid protein.

Purification of the hybrid proteins

To facilitate purification we used genetic techniques to increase the amount of hybrid protein synthesized by fusion strains. Any hybrid gene obtained by our technique of gene fusion is located close to a λ prophage (Fig. 1). Induction of fusion strains with UV light yields λ transducing phages which carry the hybrid gene. When such phages are used to lysogenize another strain, multiple lysogens are obtained at a very high frequency, and these can be recognized by the amount of β-galactosidase which they synthesize[33]. After infecting MC4100 cells (deleted for the *lac* operon[27]) with a λ61-4 or a λ52-4 transducing phage, we selected presumed triple lysogens, which synthesized approximately three times as much β-galactosidase as the original fusion strain. Although they were of limited stability, these polylysogens could be used for protein purification, provided the number of transfers after their isolation was minimized.

Hybrid proteins were purified essentially according to the scheme used for authentic β-galactosidase[34] (Table 1). The 52-4 protein had a stability comparable to that of authentic β-galactosidase. The 61-4 protein, on the other hand, was rather unstable. For instance, it lost 90% of its activity after 10 days at 4 °C when kept in solution after elution from the DEAE Sephadex column.

Determination of NH_2 terminus of hybrid proteins

Hybrid protein sequences were analysed by techniques developed for use on a hybrid protein containing β-galactosidase and *lac* repressor sequences[35]. In wild-type β-galactosidase, the first two methionine residues are at positions 2 and 92 (ref. 36), and residues 3–92 yield a cyanogen bromide fragment called CNBr2. Hybrid proteins obtained as described in Fig. 1 legend always lack at least the first 17 amino acids of wild-type β-galactosidase, eliminating the first methionine. If the amino acid sequence which replaces the normal β-galactosidase NH_2 terminus contains no internal methionine, only one new fragment (CNBr2*) should result from treatment of the hybrid protein with cyanogen bromide. Indeed, with the 61-4 hybrid protein a single additional cyanogen bromide fragment was found that reacted with antibodies directed against wild-type CNBr2. The NH_2-terminal sequence of this peptide is the same as that of the intact hybrid protein (Fig. 4). The 52-4 hybrid protein, on the other hand, yielded three new peptides, due to the presence of methionine residues at positions 18 and 23 in the *lamB* portion of the hybrid protein[25]. To establish the sequence of the 52-4 hybrid protein up to the β-galactosidase sequence, it was therefore necessary to analyse the NH_2-terminal sequence on the intact protein, to purify the CNBr2* fragment and sequence its NH_2-terminal region, and to purify and sequence the smallest of the additional cyanogen bromide fragments.

As Figs 4 and 5 show, the 61-4 and 52-4 proteins contain *lacZ*

Fig. 6 A reconstruction of the events which yielded the 61-4 fusion. The fragment of *lamB* sequence on the first line is from ref. 25. The Mu sequence on the second line is from Kahman and Kamp[39] and Allet[40]. (The sequence published by Allet[41] differs in two respects from that presented here: (1) the "A" underlined here is missing and (2) the prophage sequence would start at the "G" immediately following this "A".) Only the 'sense' strand of the DNA is shown here. The NH_2-terminal sequence of the 61-4 protein (shown on the last line) can be explained if we assume that the original Mu insertion and the final deletion (see Fig. 1) occurred as shown here by the two arrows.

polypeptides in which the first 26 or 19 amino acids, respectively, have been replaced by 11 or 40 other amino acids. The 61-4 polypeptide is therefore 15 amino acids shorter than the authentic *lacZ* polypeptide, whereas the 52-4 polypeptide is 21 amino acids longer. The fact that these sequences could be determined unambiguously shows that there was no extensive site-specific cleavage in the NH_2-terminal region of the hybrid polypeptides (see also Fig. 3).

Discussion

Because the NH_2-terminal sequence of the 61-4 hybrid protein contains only the first two amino acids of the precursor of the *lamB* protein (Fig. 4), it is not surprising that the hybrid protein remains in the cytoplasm. Indeed, other experiments have shown that most or all of the 24-amino acid signal sequence is essential for export of *lamB* protein from the cytoplasm[16,26,29]. This is also consistent with the observations that *phoA-lacZ* and *malE-lacZ* hybrid proteins containing truncated signal sequences remain in the cytoplasm, whereas wild-type *phoA* and *malE* products are exported to the periplasm[37,38]. The amino acid sequence also revealed that the deletion generating the fusion removed the first 26 codons of the *lacZ* gene. This is the largest amount found missing in any fusion strain synthesizing a hybrid protein still endowed with β-galactosidase activity[35,37].

One unexpected feature of the 61-4 protein is that its amino acid sequence in residues 3–11 is found neither at the NH_2-terminal end of the *lamB* protein precursor nor at that of β-galactosidase. This sequence is actually that which would be coded by the DNA sequence located at the S-end of prophage Mu[39,40]. Therefore, we believe that, in the case of the 61-4 strain, the deletion which constituted the final event in the creation of the fusion (Fig. 1) failed to remove a small portion of prophage Mu (Fig. 6). (There is some controversy regarding the nucleotide sequence in Mu DNA; our results could not be explained using the sequence originally reported by Allet[41]).

As might have been predicted from genetic data (Figs 1, 2), the 52-4 protein does not contain Mu-coded amino acids (Fig. 5). From residue 1 to 39 its sequence corresponds to the NH_2 terminus of the *lamB* protein precursor. Except for residue 40, which corresponds to the fusion joint, the rest of the sequence is from β-galactosidase. Therefore, this protein contains the entire signal sequence of the *lamB* protein precursor and is, nevertheless, chiefly located in the cytoplasm (Fig. 3). One interpretation of this result would be that the signal sequence is not sufficient information to initiate the transfer of a polypeptide through the cytoplasmic membrane. If the additional information required were encoded over a large fraction of the polypeptide, alternatives[42] to the signal hypothesis would have to be considered. Another possibility is that the signal sequence does suffice to initiate the transfer but that severe restrictions exist as to which amino acid sequences can be extruded through a membrane[43]. The enzyme β-galactosidase, which is normally cytoplasmic, may contain unfavourable sequences[17]. These sequences might block the transfer of the 52-4 protein at an early stage, so that this protein, weakly bound to the membrane by its NH_2-terminus, may fall back into the cytoplasm as synthesis proceeds. Whatever the interpretation, the fact remains that adding a signal sequence to at least one cytoplasmic protein—β-galactosidase—is not a sufficient condition to alter to any significant extent the cellular location of this protein.

We thank M. Hours for growing the cells necessary for protein purification. Spontaneous production of cosmological fluctuations

Craig J. Hogan
Institute of Astronomy, Madingley Road, Cambridge CB3 0HA, UK

In the 'standard' hot big bang, fluctuations which give rise to galaxies and galaxy clusters must be present in the initial conditions; that is, they are already present at the earliest epoch when general relativity is valid. In a structureless big bang there seems to be only one way that the necessary fluctuations can be explained within the scope of conventional physics: a uniform universe with low specific entropy ($S \lesssim 1$) can spontaneously generate fluctuations by shattering into macroscopic fragments. Such a critical point probably occurs at nuclear density during the transition from pion condensate to nucleon gas; shattering at this epoch would create fragments of the order of a Chandrasekhar mass, providing both the lumpiness necessary to produce galaxy clusters and a potential energy source for the microwave background radiation.

The universe seems to be uniform on the very largest scales, and we know that it is fundamentally non-uniform on the smallest scales. Furthermore, we know that small irregularities introduced into a homogeneous Friedmann universe can grow with time. The obvious temptation is to try to show that all inhomogeneity, even on astronomical scales, ultimately originates from quantum effects operating in a universe which is initially as uniform as possible. Proposals along these lines have been made using, for example, Heisenberg uncertainty in the metric[1] and thermal fluctuations in particle positions[2]. Several authors have also invoked various types of phase transitions, including vacuum phase transitions at very early times[3,4], a nucleated quark–nucleon phase transition[5], and the conventional solid- or liquid–gas transitions[6,7]. Critical-point transitions are particularly good for generating fluctuations spontaneously because they afford an enormous amplification of quantum discreteness which is in principle limited only by conditions of causality: if such a transition occurs, matter is unstable and must shatter into macroscopic fragments[6,7]. A uniform expansion can 'tear apart' a uniform medium to leave a highly non-uniform expanding 'gas' of macroscopic lumps. Some fundamental constraints on such schemes are described here and a model proposed which does not rely on a speculative departure[1–3] from classical general relativity.

Although some quantum inhomogeneity always exists, it is possible to show that in the standard hot big bang no classical process can create the actual observed scale of inhomogeneity. Let us assume that quantum effects operating at epoch t_1 introduce density fluctuations with amplitude $\delta\rho/\rho \equiv \delta_M$ on a comoving scale labelled by its baryon charge M. At the present time t_0, ignoring dissipation effects and assuming $\Omega = 1$, linear Lifshitz gravitational growth gives

$$\delta_M(t_0) = (a_1/a_0)^2 (t_0/t_1)^2 \delta_M(t_1) \tag{1}$$

independent of the equation of state, where a is the scale factor. If gravitating energy and momentum are locally conserved in the sense required by classical general relativity[9] (which is generally true even during vacuum phase transitions[3,4]), then the spectrum of growing fluctuations introduced by any irreversible process on scales larger than the horizon must be[8,10–12,32]

$$\delta_M(t_1) \propto M^{-7/6} \tag{2}$$

This spectrum has been shown[10,12,32] to arise in a perfect fluid with an arbitrarily variable equation of state; any conservative matter is gravitationally identical to such a fluid on scales sufficiently large that the off-diagonal components of $T^{\mu\nu}$ are uncorrelated. Moreover, causal processes cannot move matter further than ct_1, so the density contrast on the horizon scale must be less than unity:

$$(\delta\rho/\rho)_{ct_1} \equiv \delta_H(t_1) < 1 \tag{3}$$

Using equation (2), causality limits the amplitude of $(\delta\rho/\rho)$ on any mass scale:

$$\delta_M(t_1) < (M/M_H(t_1))^{-7/6} \tag{4}$$

where M_H is the baryon charge within the horizon at t:

$$M_H(t_1) = M_H(t_0)(a_1/a_0)^{-3}(t_1/t_0)^3 \tag{5}$$

Thus in an initially uniform universe

$$\delta_M(t_0) < (a_1/a_0)^{-3/2}(t_1/t_0)^{3/2}(M/M_H(t_0))^{-7/6} \tag{6}$$

The actual universe is observed[8] to have $\delta_M \simeq 1$ on a length-scale $r_* \approx 3h^{-1}$ Mpc (where $h \equiv H_0/100$); since $ct_0 = 3{,}000\ h^{-1}$ Mpc, we need $\delta_{M_*} = 1$ for

$$M_*/M_H = 10^{-9} \tag{7}$$

This requirement, the Friedmann relations between a and t, and equation (6) put a lower limit on (a_1/a_0), that is an upper limit $z_{\max}$ on the redshift at which fluctuations can be created by a causal process. The reason for this limit is that with an initial spectrum of the form of equation (2) the amplitude $(\delta\rho/\rho)_H$ on the horizon scale (or any constant fraction thereof) decreases with time; although the amplitude of fluctuations increases, the universe actually grows 'smoother' with time. No classical process at a redshift greater than $z_{\max}$ can generate fluctuations which give rise to the observed structure.

Now in a hot universe[13]

$$(a_1/a_0) \cong (t_1/t_{eq})^{1/2}(t_{eq}/t_0)^{2/3} \tag{8}$$

where the epoch of equal matter and radiation densities is

$$(t_{eq}/t_0) = 10^{-7}\ (S/10^8)^2 \tag{9}$$

where S denotes the specific entropy in the fireball phase (again assuming $\Omega h^2 = 1$). The maximum redshift at which fluctuations can form if $\Omega h^2 \leqslant 1$ is

$$z_{\max} < 10^9\ (S/10^8)^{-2/3} \tag{10}$$

corresponding to a total (radiation + matter) density

$$\rho_1 \lesssim 2 \times 10^3\ (S/10^8)^{-4/3} \quad \text{g cm}^{-3} \tag{11}$$

But a high-entropy plasma with $S \gg 1$ is known[6] to be stable against any instability of the type required up to $\rho \simeq 10^{14}$ g cm^{-3}, so there is never any opportunity for fluctuations to form however matter behaves[15] at higher densities. The conclusion is that in a hot universe the macroscopic structure of the universe cannot be explained by any conventional physics—it must originate at an epoch when either classical causality or mass–energy conservation breaks down, and therefore lies in the domain of some theory of 'quantum gravity'. This conclusion (which has been assumed by most authors) remains valid even for 'tepid' universes[16] with a primordial S as low as 10.

Let us consider a cold degenerate universe[6,7,10,17] with $S \lesssim 1$. Particle interactions which might cause phase instabilities can be important even at relatively modest densities ~ 1 g cm^{-3}, as in the models of Zel'dovich and Layzer where the cosmic medium shatters due to solid-body or Van der Waals forces. The maximum redshift for forming fluctuations in a pressureless ($p \ll \rho c^2$) universe is

$$z_{\max} = (M_*/M_H(t_0))^{-14/9} \cong 10^{14} \tag{12}$$

corresponding to a density of

$$\rho_1 \lesssim 2 \times 10^{13}\ \text{g cm}^{-3} \tag{13}$$

so the limits imposed purely by causality present no problem for

0028-0836/80/300360—03$01.00

this type of model—there is a wide range of z in which fluctuations could be generated. Equation (13) shows that for any primordial S and any assumptions about supernuclear matter, a phase transition at strongly supernuclear density cannot by itself explain cosmic inhomogeneity unless correlated domains form on scales much larger than the horizon—again, requiring either special (non-uniform) initial conditions or a modification of general relativity[3,28]. We also know, from equation (11), that if a phase transition at nuclear density generates too much entropy (that is $S \gg 10$) it cannot be responsible for cosmic structure, so our model is constrained to remain cool.

One can place more stringent limits on t_1 by considering the process in more detail. In a shattering- or cracking-type phase transition, the size of the lumps created, and hence the distance over which matter is moved, is determined not by the velocity of light, but by the velocity of sound. Thus in equation (4) we should replace M_H by M_S:

$$\delta_M(t_1) \lesssim (M/M_S)^{-7/6} \tag{14}$$

where

$$(M_S/M_H)_{t_1} = (c_S/c)^3 = (p/\rho)^{3/2} \tag{15}$$

Because pressure forces balance cohesive forces in the solid phase, this condition is equivalent to Layzer's: the characteristic size arises because if the expansion energy of a 'fragment' exceeds its cohesion energy, it shatters into still smaller fragments until the two are about equal. Let us assume that the cosmic medium consists of e^-, p^+, and ν in equal abundance[10], so that the pressure is due mainly to degenerate relativistic electrons and neutrinos. Now $p \simeq \rho/3$ when the Fermi energy of the electrons $E_f \gtrsim m_p c^2$, thereafter, p/ρ decreases as a^{-1} until $E_f \sim m_e c^2$, and then like a^{-2}. Thus

$$(M_S/M_H)_{t_1} \lesssim (3a_1/a_2)^{-3/2} \tag{16}$$

where a_2 is the scale factor when $E_f \simeq m_p c^2$ (ref. 14):

$$z_2 = (a_0/a_2) = m_p c n_0^{-1/3}/\hbar(3\pi^2)^{1/3} \simeq 8 \times 10^{14} \tag{17}$$

But then equations (14), (7), and (1) say that the sound speed decreases so fast with z that the final fluctuations are maximized if $z \sim z_{max}$; that is, instabilities at lower or higher redshifts are always fundamentally insufficient to produce the observed clustering, but if a cold universe is unstable at nuclear density the amplitude is about right. (In fact, Zel'dovich and Layzer find that the amplitude of fluctuations from planet-sized lumps resulting from shattering at $\rho \sim 1$ is insufficient and needs to be supplemented with subsequent growth far in excess of the linear growth rate (equation (1)).

Thus, if a phase transition occurs in cold matter at $\rho \sim 10^{13-14}$ g cm^{-3} it would yield lumps of order the horizon size at that epoch, the Chandrasekhar mass:

$$M_H \simeq (\hbar c/G m_p^2)^{3/2} m_p \simeq 2 M_\odot$$

and would produce $(\delta\rho/\rho) \simeq 1$ on present day mass-scales of the order of 10^{12}–$10^{15} M_\odot$, possibly enough to explain the observed astronomical inhomogeneity. The surprising thing is that such a phase transition probably exists[18,31].

Recent theoretical work on the composition of cold matter in neutron stars indicates that the favoured phase at $\rho \approx 10^{15}$ g cm^{-3} is probably a solid Bose lattice of pions held in place by strong nuclear forces[18]. At lower densities the Fermi energy of pion decay products decreases, and at some point the equilibrium state becomes a Fermi gas of baryons and leptons. An additional uncertainty is introduced in cosmological cold matter because the relative chemical potentials of fermion species depend on the cosmological lepton–baryon ratio n_L/n_B (in neutron stars lepton number is not conserved because neutrinos can escape). Although more calculations are necessary to include this effect, it seems likely that a phase transition from pion condensate to Fermi gas occurs for at least some values of n_L/n_B. This phase transition is of the right type, and occurs at about the unique right time as calculated above, to produce the observed astronomical inhomogeneity.

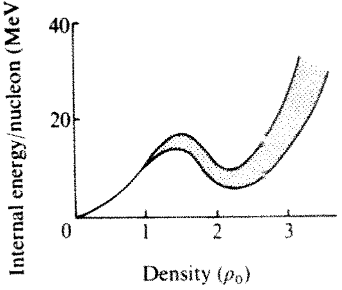

Fig. 1 Equation of state of cold matter around nuclear density.

Figure 1, after Irvine[18], shows the specific internal energy of cold matter $E(\rho)$ near nuclear density $\rho_0 \equiv 3 \times 10^{14}$ g cm^{-3}. There are theoretical uncertainties (shaded region), but it is clear that at zero temperature the conditions for thermodynamic instability[29] exist:

$$\begin{aligned}(\partial E/\partial \rho) &< 0\\ (\partial^2 E/\partial \rho^2) &< 0\end{aligned} \tag{18}$$

which require the solid Bose condensate to shatter at $\sim 2\rho_0$ into macroscopic fragments. (Note that matter with $S \gtrsim 1$ would not have this property: the internal energy then varies monotonically with ρ because it is dominated by thermal photons and neutrinos.) Chaotic conditions and large-scale motions persist for about a Hubble time, leaving lumpy single-phase matter with $\delta\rho/\rho \gtrsim 1$ at a mean cosmic density of the order of $\rho_1 \sim 10^{13-14}$ g cm^{-3}.

As the Jeans mass in a cold universe decreases with time after t_2, it is probable that fragments would collapse and survive as compact bound objects, providing a natural source of 'missing mass'. We also know that the fragments are initially of the order of a Chandrasekhar mass—they might end up as black holes, neutron stars, main-sequence hydrogen-burning stars or supermassive stars ($\gtrsim 100\ M_\odot$), depending on the exact details of the fragmentation and subsequent coalescence. Such objects are natural candidates for the energy sources necessary to explain the microwave background in a cold model[19–21].

There are some weak points in the above hypothesis which also provide crucial observational tests. Some potential problems are: (1) a fluctuation spectrum as steep as equation (2) cannot explain both galaxies and galaxy clusters if only gravitational forces are at work[8], it forms galaxies too early and hence with too high a density; (2) it is not certain that enough inhomogeneity on galaxy clustering scales $\gtrsim 10^{15} M_\odot$ can be generated with only the linear growth rate (equation (1)); and (3) the cosmic helium abundance cannot be calculated—even if n_L/n_B were known, the chaotic conditions caused by the phase transition would invalidate previous cold-universe calculations[10,22] by increasing the entropy and upsetting the equilibrium abundance of various particle species (for example, collapsing fragments would squeeze neutrinos into the confining Fermi gas). The first two of these problems can be solved by invoking hydrodynamic effects, for example, primordial fragments may form into super-massive exploding stars[21,30] which could unbind dense systems on scales $\lesssim 10^{12} M_\odot$ and/or amplify fluctuations on scales $10^{12} \lesssim M \lesssim 10^{15} M_\odot$. Such objects would certainly leave an imprint on the anisotropy[23] and spectrum[24–26] of the microwave background; they might also create helium and/or deuterium[27]. A fairly rigorous prediction of any shattering model is that present-day fluctuations on scales $\gg 10$ Mpc should be unaffected by such events and should still show the original $(\delta\rho/\rho) \propto M^{-7/6}$ spectrum.

Although there are complications with a cold big bang, it is clear from the preceding discussion that any other model attempting to produce structure in an initially uniform universe is likely to encounter difficulties of a much more fundamental nature unless it tampers with classical general relativity. If the structure we see today is not the shattered remnant of a cold universe, then it must be a relic of the preclassical era.

Some diurnal properties of clouds over the martian volcanoes

Discrete white cloud systems have long been recognized as a martian atmospheric phenomenon. However, it was not until the Mariner 9 mission in 1971–72 that the cloud systems were found to be closely related to topographic features, in particular, the giant volcanoes on the Tharsis Ridge. Using the available Earth based observations, Smith and Smith[1] investigated the seasonal and diurnal behaviour of the clouds the Olympus Mons and Elysium regions. They found that the cloud activity was generally confined to late spring and early summer seasons in the northern hemisphere. This corresponds to $L_s = 60$–$150°$, where L_s is the aerocentric solar longitude and $L_s = 0$ for spring equinox in the northern hemisphere. The Viking Orbiters have observed martian atmospheric phenomena for eight seasons. During this period, the volcanoes have been frequently, but often irregularly, monitored. Unfortunately, the changes in the spacecraft orbit have meant corresponding variations in the surface resolution,.viewing geometry and local times of the observations. However, the available observations do provide important new insights into the diurnal properties of the volcanic cloud systems, which we describe here.

Cloud systems appear over the volcanoes in certain seasons of the martian year, and these spacecraft observations are in general agreement with the times of meteorological activity suggested by the ground based studies of Smith and Smith[1]. In the Elysium region, clouds were observed during the period $L_s = 46$–$141°$, while during $L_s = 230$–$17°$ there was no apparent atmospheric activity. Except for a period between $L_s = 2100$ and $L_s = 300°$, some form of cloud activity was observed throughout the year in the Tharsis region. However, this period of apparent inactivity corresponds to the time of two major dust storm events observed by the the Viking spacecraft (see, for example, ref. 2). This area of the planet was noticeably dusty, and frequently only the summits of these volcanoes were visible through the dust clouds. During these dust storms, the atmospheric water vapour abundance was greatly reduced[3] as the particles absorbed the atmospheric moisture. Furthermore, the thermal properties of the atmosphere were also affected by the presence of the dust, suppressing the diurnal variation and reducing the vertical structure[4,5]. These substantial changes to the thermodynamic state of the atmosphere account for the absence of clouds due to the dust storm period.

The cloud systems observed from the Earth cover areas of 10^5–10^6 km^2 and are first seen at periods around local noon. From Viking studies, we have found many much smaller clouds in the Tharsis region, occupying regions of only $\sim 5 \times 10^3$ km^2, which often develop in the early morning. Figure 1 shows such a localized cloud system for the Ascraeus region at $L_s = 225°$. Here we concentrate on a study of the diurnal properties of orographic cloud systems, monitored near Elysium, Olympus Mons, and the two northern peaks of the Tharsis system.

Figure 2 shows the development of a cloud system associated with Elysium from 07.00 to 12.51 LT at $L_s = 92.7°$, shortly after summer solstice. All of the clouds seen here are smaller than the classic afternoon clouds seen from the Earth. Each of the views in Fig. 2 were imaged in four filters. By comparing these images condensate clouds can be separated from surface details produced by slopes which appear as bright areas through all filters. In the first three pictures, the sunward facing slopes are brightly highlighted in a manner frequently observed at Elysium. The clouded western flanks show greatly reduced contrast as the wavelength is increased, unlike the sunward slopes which appear equally bright at all wavelengths. At 07.00 LT, the entire region is lightly clouded and surface features may be seen

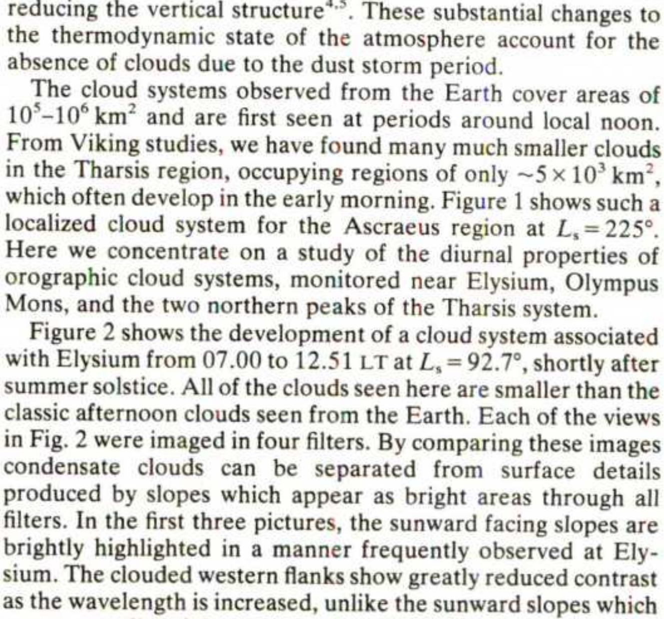

Fig. 1 Viking Orbiter 1, revolution 225, frame 5. A turbulent region of cloud is observed on the western flanks of Ascraeus Mons for 14.03 LT through a violet filter for $L_s = 210°$.

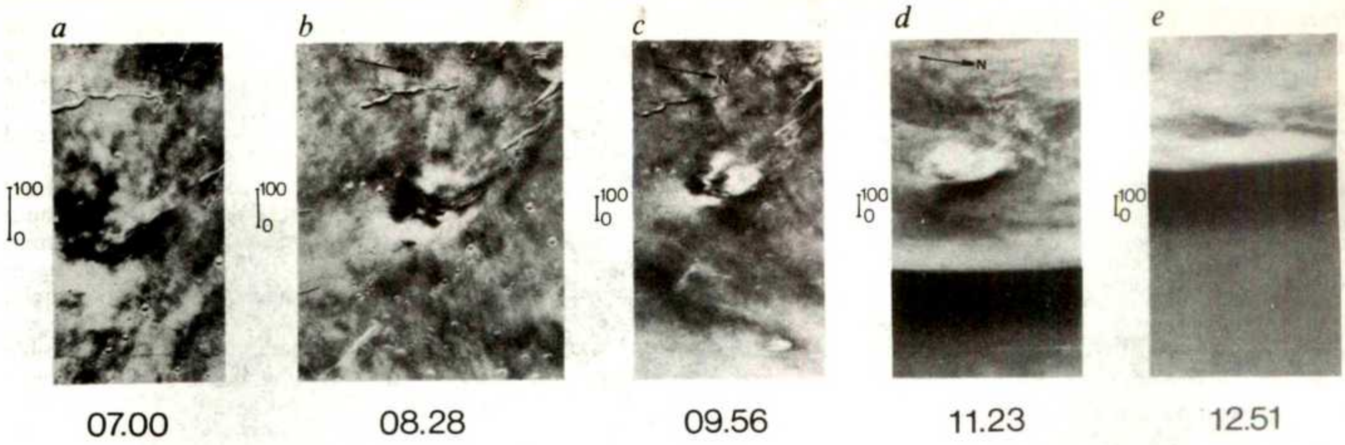

Fig. 2 The daily cycle of a cloud in the lee of Elysium Mons is shown as five time-sequence photographs taken between 07.00 and 12.51 LT. The LT of the frames are 07.00 (*a*), 08.28 (*b*), 09.56 (*c*), 11.23 (*d*) and 12.51 (*e*). The arrow-shaped lee wave cloud on the extreme left photograph is replaced by an almost circular region of cloud on the extreme right photograph. These photographs were taken by Viking Orbiter 1, orbit 710, through a violet filter for $L_s = 92.7°$.

through the denser patches, although with reduced contrast. The most prominent cloud is seen to the WNW of Elysium in the vague shape of an arrow whose head points towards the summit of the volcano. This cloud is more opaque than the mist in the surrounding region. The region has apparently not changed appreciably in the second view, obtained at 08.28 LT. The cloud to the WNW is still quite apparent although it is more concentrated than in the earlier view. By 09.56 LT (Fig. 2*c*), this cloud has clearly split into two pieces, with the main portion displaced substantially towards the north, while a plume, reminiscent of those seen in the Tharsis region[6] appears to the west. The larger component of the cloud is roughly 100 km in diameter.

The cloud's rapid growth seems to be starting in the 11.23 view shown in Fig. 2*d*. The dimensions of this cloud are roughly 200 km, so that the effective area has roughly quadrupled in the hour and a half since the previous picture. The region is somewhat hazy, and a field of scattered clouds seems to be developing to the north-west of the main cloud. The approximately 70° emission angles roughly double the effective optical depth from the earlier view and, therefore, enhance the haziness of the region. In the final view 12.51 LT, the cloud has grown to dimensions of ~350 km.

Figure 3 summarizes a diurnal sequence in the vicinity of Ascraeus Mons for $L_s = 121.5°$. The first images, corresponding to 05.50 and 07.30 LT show a pervasive fog which nearly obscures surface features on the flanks of Ascraeus. Comparison with the USGS topographic map of Mars suggests that the top of the cloud bank is ~15 km below the summit so that this is a very low lying cloud layer.

The cirrus-like clouds to the south-west of the summit in Fig. 3*a* seem to be of the variety catalogued by Briggs *et al.*[6] one (martian) year earlier. They are well over the terminator and, on the basis of their illumination, would have to be at least as high as the summit, which is 27 km. Two discrete clouds are seen to the west of the volcano in Fig. 3*b*. Ascraeus frequently exhibits clouds in this location and they sometimes take the form of extensive plumes such as those reported by Briggs *et al.*[6]. Apparent shadows suggest that these may be quite high, perhaps 10–15 km above the volcano summit. This feature is confined to the early morning hours at all seasons, and is a lee wave cloud system formed on the leewardside of the volcano. These features imply the existence of easterly winds at high altitudes in agreement with the predictions of circulation models[7,8].

The general cloudiness at low levels is still seen in Fig. 3*c*, obtained when the local time is 09.26 at the summit of Ascraeus. However, a variety of waves are present with wavelengths around 10 km. The orientation of the waves suggests streamlined flow around the volcano, but the presence of waves at opposed angles may imply a more complicated situation. There are no obvious surface features that could affect the flow and be identified as the source of the waves. However, in view of the wide variety of undulations on the planet, it is still possible that these waves are topographically induced. The time localization of these phenomena suggests that they may be the result of a change in the characteristics of the boundary layer which is strongly influenced by the thermal properties and opacity of the atmosphere. Bright areas to the east of the volcanoes are probably incidence angle effects since they have disappeared in the later view. It is not possible to make a more positive statement because the images are available only in the violet filter (450 nm).

By 11.23 LT (Fig. 3*d*) large clouds are seen developing to the west and south of Ascraeus and to the west of Pavonis, which suggests that these are the nuclei of two components of the w cloud monitored by the Earth based observers (see, for example, ref. 11). Cloudiness is also seen to the east of Ascraeus towards the canyons and the clouds in these peripheral areas appear distinctively convective. Estimates of heights from other pictures using presumed shadows suggest that these clouds are relatively low with altitudes of 4.5–6.5 km above the surface.

The present visible observations are supported from the Orbiter measurements of the thermal characteristics and water vapour distribution of the atmosphere. This then allows the composition of the clouds to be determined by the procedures developed by G.E.H.[9]. We find that the low lying fogs and the convective afternoon clouds (see also ref. 10) are water ice clouds. In this season, the atmospheric temperatures are far above the CO_2 condensation temperatures. The cirrus-type clouds are more difficult to characterize owing to their very diffuse nature. Certainly, as Hunt[11] has shown, we cannot yet exclude the possibility of CO_2 clouds at these high altitudes.

The diurnal development of clouds, shown in Figs 2 and 3, is related to the local stability and circulation of the atmosphere as influenced by the topography and local thermal properties of the surface. The volcanic areas have low surface inertias and this permits unusually large diurnal temperature variations in these areas[10]. Night-time cooling produces denser cold air at low elevations favouring the formation of the observed radiation fogs in the early hours of the morning. The water vapour content of the martian atmosphere seems to be limited by the amount which can be contained in a saturated, night-time atmosphere[12]. Regions of locally large cooling are, therefore, favoured sights for fogs. The atmospheric stability associated with these conditions, together with the downslope winds, favour early morning gravitational wave effects such as are seen particularly in the Tharsis region.

The rapid warming of the surface as noon approaches will lead to increased lapse rates and, perhaps, to eventual instability.

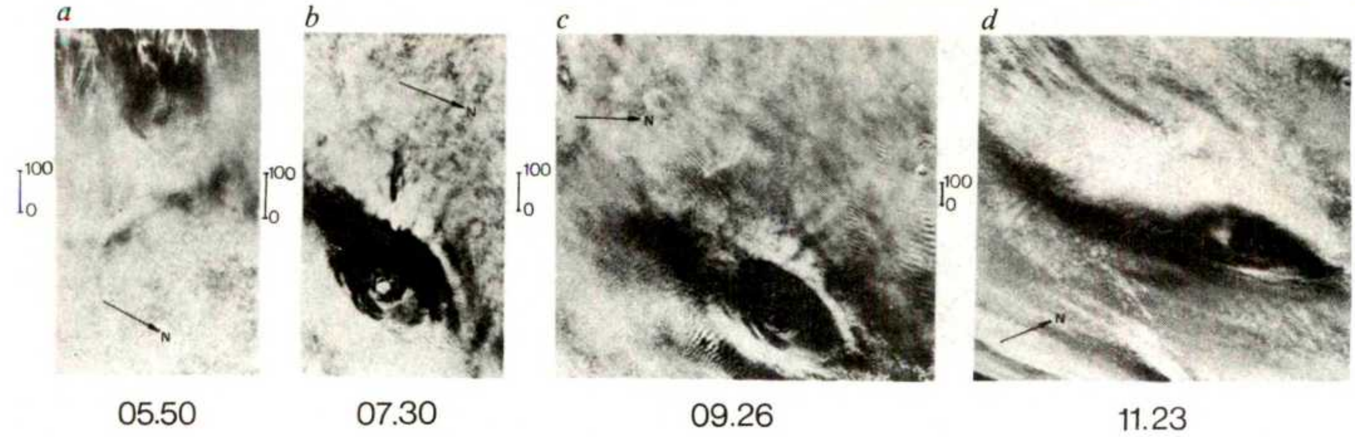

Fig. 3 The morning cycle of cloud in the vicinity of Ascraeus Mons shown as four time-sequenced photographs, taken between 05.50 and 11.23. The LT of the frames are 05.50 (*a*), 07.30 (*b*), 09.26 (*c*) and 11.23 (*d*). The scale and direction of north are shown. These photographs were taken by Viking Orbiter 1, orbit 774, through violet filter for $L_s = 121.5^\circ$.

Lindal *et al.*[14] have noted that lapse rates approach adiabatic only in these latitudes and seasons. The resulting convection will produce cumulus-like clouds by adiabatic cooling; this is supported by observations of such clouds in the region. Upward circulation in the atmosphere has been predicted to the west of the large volcanoes due to thermal forcing effects[13]. Cloud formation will also be enhanced by this convergence due to the positive vertical velocities; winds from the west due to this low level convergence may also contribute to adiabatic cooling of the parcels of air as they are carried up the slope of the Tharsis Ridge. The combination of these three effects seems plausible as an explanation for the diurnal cycle observed.

The reason for the pronounced seasonal variation is less easily seen, however, The spring and summer seasons in the northern hemisphere correspond generally to higher insolation and larger water vapour content in the atmosphere than does the rest of the year. As both factors should influence cloud formation, the general correlation is not surprising. However, in detail these factors fail to explain the abrupt boundaries of activity at $L_s = 60^\circ$ and $L_s = 150^\circ$ for Ascraeus and Elysium. The water at 25°N peaks at L_s between 140° and 150°, when the cloud activity is ending, and only gradually drops to equinox[15]. The large martian orbital eccentricity causes the insolation at noon at 25° latitude to be actually greater at the equinoxes than at solstice. Possibly, circulation changes when the south cap becomes stationary at $L_s \sim 150^\circ$ may effect the change; such circulation changes, from easterly to westerly winds, are predicted at that time by GCM[7]. If this change from easterly to westerly winds occurs the formation of convective clouds to the west of the volcanoes may be inhibited.

The Tharsis volcanoes are cloudy for a more extensive period and this is consistent with all these factors as the circulation and insolation at the equator do not vary as they do to the north. The cessation of activity from $L_s = 210^\circ$ to $L_s = 300^\circ$ is clearly associated with the major dust storms. These not only reduce the water content of the atmosphere drastically, but also tend to make the vertical profiles more isothermal than would normally be expected.

Black-body radiation as an inertial confinement fusion driver

F. Winterberg

Desert Research Institute, University of Nevada System, Reno, Nevada 89507

To ignite a thermonuclear microexplosion a power source of $\gtrsim 10^{14}$ W is required with an energy of $\gtrsim 10^6$ J focused down to $\lesssim 0.1$ cm. To meet these driver requirements, charged particle beams[1] and even hypervelocity projectiles[2] have been proposed as an alternative to lasers for which an energy $\gtrsim 10^6$ J is considered very large. Although charged particle beams and hypervelocity projectiles promise much larger energies the problem of the large driver power of $\gtrsim 10^{14}$ W remains. We propose here a two-stage driver concept which eliminates this problem. In it the initial energy is drawn from any of these drivers but is used here to generate an intense black-body radiation source. This black-body radiation is then used to drive the thermonuclear microexplosion target. This concept not only permits the initial driver power to be reduced by about two orders of magnitude from $\gtrsim 10^{14}$ W down to a few 10^{12} W, but also greatly relaxes the beam-focusing requirements as compared with direct pellet fusion.

The idea is depicted in Fig. 1. The thermonuclear target T is placed inside the centre of a small cavity filled with a tenuous high atomic number gas, for example, krypton or uranium hexafluoride. The inside of the wall is lined with a dense material P, for example gold or uranium. P is surrounded by an ablative layer A of low atomic number material. Beams B hitting the ablator from all sides ablatively implode the cavity. The implosion makes the wall P implode with the velocity v into the tenuous gas inside the cavity. This results in a shock

0028-0836/80/300364—03$01.00

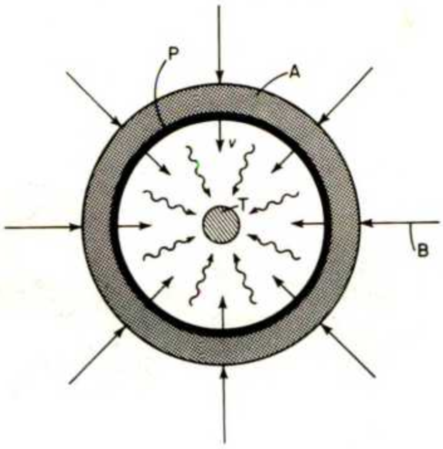

Fig. 1 The two-stage driver equipment: T, thermonuclear target; P, lining of dense material surrounded by an ablative layer A. Beams B, hit the ablator from all sides.

wave moving into this gas. The temperature T behind this shock wave is related to the implosion velocity[3] and one finds

$$T=\frac{A}{3R(Z+1)}v^2 \tag{1}$$

where A is the atomic weight, R the gas constant and Z the degree of ionization. Z depends on T and a useful approximation is

$$Z \simeq 6.6\times 10^{-3}T^{0.41} \tag{2}$$

The shock-heated high temperature gas, by bound–free, bound–bound and free–bound transitions, will then become an intense source of photons, and as a result the kinetic energy in the shock wave will be rapidly converted into black-body radiation. This happens on an atomic time scale of $\lesssim 10^{-8}$ s. The resulting black-body radiation is further compressed and greatly amplified by the cavity implosion, and is finally delivered to the target surface, assumed to be spherical of radius r_p at the rate

$$P(t)=4\pi r_p^2\sigma T^4 \tag{3}$$

where σ is the Stefan–Boltzmann constant. A power of 10^{14} W for a pellet surface of $\sim 10^{-1}$ cm^2 is reached at a temperature of $\simeq 3.6\times 10^6$ K. To store energy of $\simeq 10^7$ J at this temperature in the form of black-body radiation would require a volume of 75 cm^3; this suggests we use higher temperatures, as for a given energy the volume decreases as T^{-4}. For $T=10^7$ K the cavity volume would be only $\simeq 1.3$ cm^3. In the absence of photon losses through the cavity wall the black-body radiation changes with the cavity volume V as $VT^3=$constant, or with the cavity radius r as $rT=$constant. Therefore, if the initial cavity temperature is $T=5\times 10^6$ K, a twofold reduction in the cavity radius would raise the temperature to 10^7 K with a 2^4 fold increase in the radiative power delivered to the thermonuclear target. The initial and final radiative power would thus be $\simeq 3.6\times 10^{14}$ W and 5.75×10^{15} W. From equations (1) and (2) to reach the initial temperature would require $A=200$, $v=46$ km s^{-1} and krypton with $A=83$, $v \simeq 71$ km s^{-1}.

To make a shock wave in the tenuous gas the collision mean free path must be small compared with the cavity radius and one finds that the atomic number density must be $\gtrsim 10^{18}$ cm^{-3}. On the other hand, to store most of the incident energy into black-body radiation, the gas density cannot exceed $\sim 10^{21}$ cm^{-3}. Finally, if the thermonuclear target were to be bombarded with the full power derived from the Stefan–Boltzmann law, the cavity would have to be optically transparent, because otherwise the photons would diffuse through the gas at a much lower average velocity. Whether or not the gas is optically transparent is determined by the opacity coefficient[4]

$$\kappa \simeq 4.34\times 10^{25}\rho T^{-3.5} \tag{4}$$

from which the photon path length $\lambda_p=(\kappa\rho)^{-1}$ is derived. To make $\lambda_p > r \sim 1$ cm requires $\rho \lesssim 0.3$ g cm^{-3}, which for $A=200$ is an atomic number density of $\lesssim 10^{21}$ cm^{-3}. Therefore, an atomic number density of $\simeq 10^{19}$ cm^{-3} would satisfy all the conditions.

The concept depends on the black-body radiation photons being sufficiently confined during the cavity implosion. The diffusion of the photons through the cavity wall is given by the energy flux

$$j=\frac{\lambda_p c}{3}\frac{\partial}{\partial x}(aT^4) \tag{5}$$

where $a \equiv 4\sigma/c$. λ_p is the photon path length in the wall, which like the path length in the cavity must be computed using equation (4). Putting $j=aT^4v_d$ and $\partial(aT^4/\partial x) \simeq aT^4/x$ where x is the distance the photons have travelled into the wall with the diffusion velocity v_d, one finds

$$v_d/c \simeq (1/3)(\lambda_p/x) \tag{6}$$

For $T=10^7$ K, $\rho=18$ g cm^{-3} (uranium) one finds $\lambda_p \simeq 2\times 10^{-4}$ cm, and requiring $x \lesssim r \sim 1$ cm, that $v_d > 20$ km s^{-1}. Therefore, a cavity implosion velocity of $v \gtrsim 50$ km s^{-1} should be sufficient to confine the photons effectively.

Because the radiation flux absorbed by the thermonuclear target is inversely proportional to the opacity of the target and which according to equation (4) is proportional to $T^{-3.5}$, the power absorbed will rise in proportion to $T^{7.5}$ or $r^{-7.5}$. If, for example, the cavity radius decreases twofold, the power absorbed increases by the factor $2^{7.5} \simeq 180$. Most of the energy is, therefore, delivered to the pellet at peak power towards the end of the implosion process. This power amplification is due to the initial driver energy intermediately stored here in the form of black-body radiation which is only delivered at the end of the implosion process. Because of this the initial driver power can be reduced by a factor of about 100.

The short wavelength of the black-body radiation, given by $h\nu=kT$, and which is in the soft X-ray domain, is much better

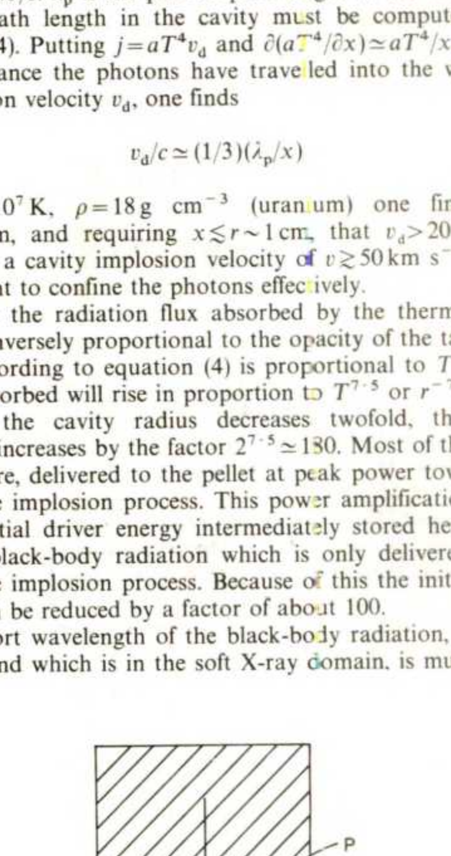

Fig. 2 A combination of the two-driver process with impact fusion. P, a hypervelocity projectile; C, conical cavity carved out of the anvil, AN; T, thermonuclear target.

suited than laser light to reach high density target compression, as it is matched to a plasma frequency of $\sim 10^4$ times compressed hydrogen. Furthermore, because of the isotropy of the radiation, there is no stimulated Brillouin backscattering as in laser fusion. A likely candidate to drive the cavity implosion seems to be an intense light ion beam (which can already be produced at the required power level) which is sufficiently well focused because the target area of the cavity is much larger than that of the pellet.

The rather low implosion velocity of $\sim 50\,\mathrm{km\,s^{-1}}$ suggests combining this concept with impact fusion where a hypervelocity projectile P accelerated to $v \sim 50\,\mathrm{km\,s^{-1}}$ implodes and amplifies black-body radiation in a conical cavity C carved out the anvil AN with the thermonuclear target T inside this same cavity. This concept is shown in Fig. 2.

Overlap of intense charged particle beams for intertial confinement fusion

J. A. Halbleib, P. A. Miller, L. P. Mix & T. P. Wright

Sandia National Laboratories, Albuquerque, New Mexico 87185

One approach to controlled thermonuclear fusion for power production requires the irradiation of centimetre-size targets containing heavy hydrogen (D–T) fuel by intense charged particle beams (CPB). Beam energy and pulse length requirements are ~1 MJ and 10 ns. In certain studies[1] the CPBs are beams of light ions, such as helium, with kinetic energies per nucleon in the range 1–5 MeV. These beams can be transported by preformed, current-carrying, plasma discharge channels. The fields from the channel currents (supplied by capacitor banks) confine the CPBs. These channels can be laser-initiated in a background gas that has a pressure between 10 and 100 torr. This gas blanket enables first wall loading, by X rays, shocks and thermal radiation to be mitigated. Although intense relativistic electron beams (REBs), which were developed before intense light ion beams, have achieved higher intensities[2], ion beams have more favourable deposition characteristics in targets[3]. Proton beams have driven exploding pusher targets[4] to implosion velocities of 20 cm μs^{-1} and have attained power of ~1 TW cm^{-2}, which is a factor of 40 below that estimated (G. Allshouse, personal communication) to be necessary for target ignition and for net system energy gain. To close the gap between present capabilities and future requirements, beam bunching and beam overlap are being studied. The current density gain *G* is important to the CPB overlap process and is the ratio of beam current density at the target surface to that of the individual beams in the transport channels; it depends on particle species, transverse energy, geometry of the channel-target interface, and so on. Detailed calculations[5–7] indicate that for electron beams, $G < 3$, while for practical cases of light ions, *G* can exceed 10. This is due to the difference in masses and effective temperatures of the two types of beams. Sources providing multiple ion beams are not available to test this overlap theory experimentally, hence it has been tested using a multiple electron beam system. Here we outline the experiment and describe the apparatus, and then summarize the theoretical treatment of beam overlap, describe diagnostic procedures, and compare the experimental results with calculations.

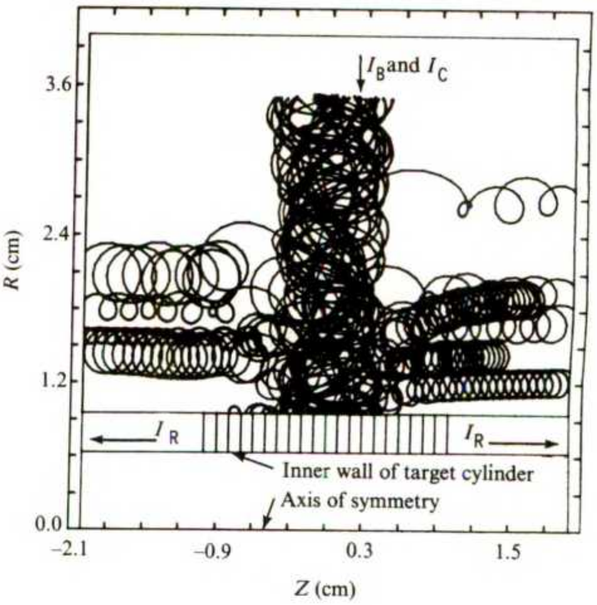

Fig. 1 *R–Z* trajectory plot for beam electrons incident on a 1.9 cm o.d. target cylinder. Target zoning for deposition analysis is indicated but trajectories inside the target are suppressed. I_B, I_C, and I_R are magnitudes of the beam currents, channel conduction currents and return currents ($3I_C$), respectively; directions of the electron flows are indicated by the arrows.

Several electron beams were generated simultaneously and transported through plasma channels[8,9] to a common cylindrical target. Targets with different diameters were used, and the total energy delivered to the targets was measured. As the diameter of the target decreases, progressively less of the energy reaches the target. The experiment aimed to measure the dependence of delivered energy on target diameter and to compare this with theoretical predictions. Agreement would imply that the physical models are correct in the present energy density regime, however, further work would still be required to investigate collective effects which may be important with higher-energy density systems[1,10–12].

The electron beam source was the Proto II accelerator[13] at Sandia National Laboratories. The front end of the accelerator could drive 12 separate electron beam diodes in parallel. These diodes were arranged in coplanar fashion in a 1-m diameter circle. On each accelerator shot, 12 pinched electron beams were generated, with six of these being stopped by 0.64 cm-thick solid aluminium or copper anodes. The other six were extracted from the diodes through thin compound diaphragms in the centres of the anodes. The six extracted beams were transported by preformed plasma channels of which the target was the common terminus. The channels were formed in parallel by the discharge of a 20 μF capacitor bank system charged to 65 kV. System inductance was 330 nH. The six plasma channels used for beam transport were formed in the ambient laboratory atmosphere and were guided by 25 μm diameter tungsten wires.

The phenomonology and limitations of plasma channel transport have been discussed in more detail elsewhere[1]. Basically, the channels start with initial diameters <1 mm and expand with radial velocities of ~1.5 mm μs^{-1}. The central part of each channel consists of singly ionized air at a few electron volts temperature, with a mass density reduced below ambient by a factor near four. There is much evidence that the tungsten wire plays a role only in initiating the discharge, and that it does not 'explode' nor affect subsequent channel dynamics. Thus the channels' features should be the same as if they had been laser-initiated. As the channels expand, the current rises to a peak in 4 μs; at this time the accelerator is fired. The conductivity of the channels is high enough to provide space-charge and current neutralization of the beam fields. Thus, ideally there are

0028–0836/80/300366—03$01.00

no collective effects, and the beam is guided only by the channel fields from the channel current. Consequently the peak current in each channel must be the Alfvèn current, which is ~65 kA for the 1.5 MeV electrons.

For this experiment, Proto II was operated in a mode that provides a pulse with nominal parameters of 1.5 MV, 3.5 MA, 20 ns FWHM, 5 TW, and 100 kJ. Thus the energy and power of each individual beam were ~8 kJ and 0.4 TW, and were transported 0.46 m. The aluminium targets had diameters ranging from 6 to 32 mm.

The time independent theoretical model for channel transport is based on an earlier technique[14] which combines coupled electron/photon collisional transport with electron transport in static, externally applied electric and magnetic fields of arbitrary spatial dependence. As the relatively short pulse REBs are not injected until the highly conducting plasma channels have been well established, the electrons of the charge and current neutralized beam are assumed to follow single particle trajectories in the quasi-static externally applied field of the channel conduction current. While the material geometry in the numerical model is constrained to be two-dimensional, cylindrical, and invariant with respect to rotation about an axis of symmetry, particle trajectory descriptions are fully three-dimensional. This three-dimensional capability is essential in the present application because of the azimuthal dependence of the multibeam source and because of the preferential orientation of the X-ray pinhole camera whose exposure environment is to be predicted by the model.

Figure 1 shows an *R–Z* plot of a random sample of trajectories for a 1.91-cm o.d., 1.27-cm i.d. cylindrical target. Only that portion of the electron trajectories outside the target is plotted. Experiments have confirmed efficient transmission along the plasma channels[6]. Consequently, trajectories are initiated in the model calculations at a distance of one betatron wavelength (~2.3 cm) beyond the geometrical beam 'overlap radius' (~1.2 cm) to ensure spatial phase mixing[15]. The overlap radius is defined as the radius at which the edges of the individual beams and channels start to merge. The magnetic field is a superposition of the fields due to the six-channel conduction currents and the axial return currents in the target cylinder. Field effects are ignored inside the solid target because of the high collision frequency. On the other hand, collisional effects are ignored outside the target.

Because the target radius is about three-quarters of the geometrical overlap radius in this calculation, ~100% of the beam strikes the target[5]. The beam/target coupling efficiency (per cent of the beam energy deposited in the target) is about 80%. Fig. 1 shows most of this energy is deposited within the beam radius. A few of the reflected electrons reenter the target. However, the majority of the reflected electrons (~20% of the beam energy) is lost through axial drift in the field of the return currents.

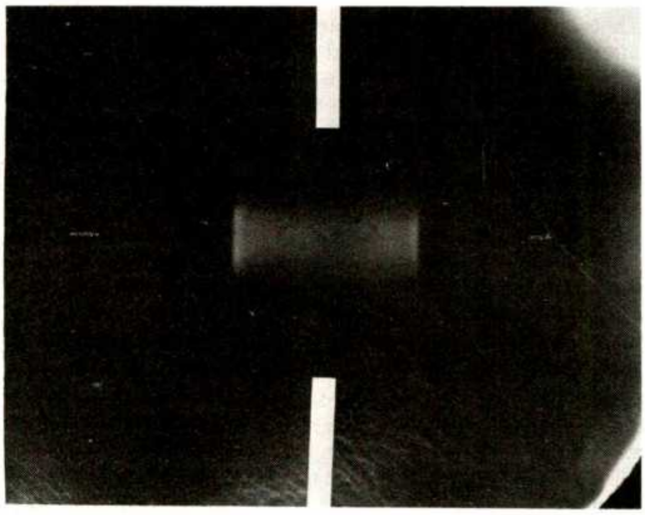

Fig. 2 X-ray pinhole photograph of six beams incident on a 1.9-cm o.d. target. The vertical axis of the cylinder is indicated.

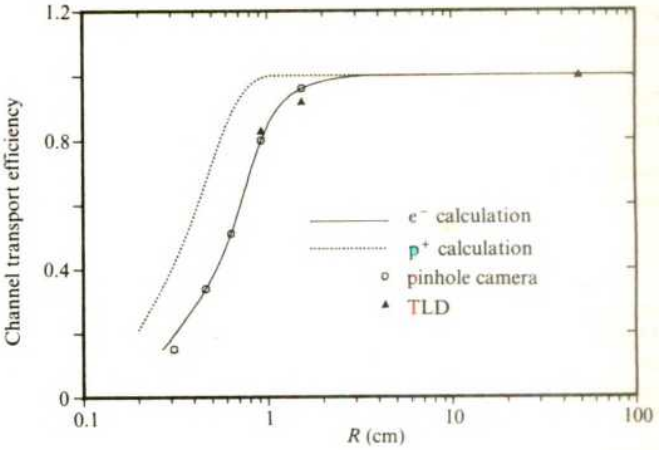

Fig. 3 Beam-target coupling efficiency as a function of target radius. For the 2-MeV proton reference calculation, the maximum angle of injection of protons into the channels was taken to be 8°.

The numerical model was also used to predict the coupling efficiencies and three-dimensional energy deposition profiles as a function of the target o.d. In addition, spatially and spectrally resolved predictions of the X radiation emitted within a small solid angle about a direction corresponding to the orientation of an experimental pinhole camera were obtained. According to the calculated results, the total X-ray emission in the direction of the pinhole should be proportional to the coupling efficiency.

The fraction of the beam energy transported to the central target cylinder was determined from measurements of the bremsstrahlung produced by the electron beams. An X-ray pinhole camera in the plane of the transport channels viewed the cylinder transverse to its axis. Thermoluminescent dosimeters (TLDs) were positioned at one end of the central target cylinder. Additional TLDs were placed behind the solid aluminium anodes of those beams which were not transported to provide a reference measurement of the dose expected when 100% of the electrons were stopped in aluminium.

Both diagnostics relied on the theoretical calculations presented above for interpretation of the results. The absolute TLD measurements were calculated to depend strongly on the kinetic energy of the electrons striking the aluminium (roughly as the square of the energy). The uncertainties in the absolute voltage monitor calibrations would have made this technique inaccurate if only one TLD reading had been made. However, the ratio of the TLD doses from the cylindrical targets to those from the solid anodes was calculated to be independent of voltage, to within the accuracy of the Monte Carlo calculation, over the range 0.5–1.6 MeV. This ratio was used to determine the transport efficiency for the 3.2-and 1.9-cm diameter cylinders.

The presence of electron drift losses near the ends of the cylinders would have complicated interpretation of TLD data for the smaller diameter cylinders. However, the X-ray pinhole camera was able to resolve this loss spatially and thus was used to infer the transport efficiencies to smaller cylinders. A typical X-ray photograph is shown in Fig. 2. Previous work[16] has shown that the image on the developed film is proportional to the energy absorbed in the film emulsion in this regime, and absolute calibrations were not required. The spatial distributions in the X-ray images were in good agreement with the theoretical predictions. The observed X-ray intensities were compared with the predicted intensities calculated using the techniques described above. By normalizing the experimental photographic intensities to the theory for the 3.2-cm diameter cylinder, the absolute transport efficiencies could be inferred for smaller diameter cylinders.

Figure 3 compares the transport efficiencies predicted using the numerical model and the experimental data. Surprisingly, the agreement between theory and experiment is much better than possible inaccuracies predict. The only significant disagreement occurs for the smallest cylinder for which the measurement is ~5% below the calculated transport efficiency of 19%. This result is strong support for the models used to calculate plasma channel formation, channel overlap geometry, electron and photon transport, and for the experimental procedures used. Figure 3 also shows a calculated prediction of transport efficiency for protons injected into the same channel system used here for the electron beams. The ions would reach a smaller radius with higher efficiency than do the electrons, and thus would irradiate a target with higher power. This result, along with their more favourable energy deposition properties[3] and the recent rapid advances in ion diode research[1,4], makes light ions more attractive than electrons for ICF use.

We thank P. Davis, D. Noack, R. Noack, W. Simpson and D. Zagar for technical assistance, and the data acquisition and Proto II operations crews for their perseverence and help. This work was supported by the US Department of Energy under Contract DE-AC04-76-DP000789.

Opto–acoustic study of weak optical absorption of liquid methane

C. K. N. Patel, E. T. Nelson & R. J. Kerl

Bell Laboratories, Murray Hill, New Jersey 07974

The first opto-acoustic absorption spectra of liquid methane at 94 K in the region of 5,500–7,500 Å is reported here. The observed absorption bands are very weak with peak absorption coefficients of 16×10^{-3} to 1×10^{-4} cm^{-1} and are of importance in the study of spectra of outer planets (such as Jupiter and Neptune) for detecting the existence of liquid methane on these planets.

Methane is a minor constituent of the atmospheres of the outer major planets[1], Uranus, Neptune, Jupiter and Saturn, as well as of Titan, the largest satellite of Saturn. This is deduced from the absorption bands of CH_4 which dominate the visible and near IR spectra of these planets[2]. The long effective optical path lengths in the atmosphere of these planetary bodies enables the absorption bands to be readily observed using ground based telescopes. Further, the temperatures on some of these planetary bodies are such that CH_4 could exist as liquid droplets[3] or even as an ocean[4] on Titan. To provide correlations with laboratory data, and to deduce the CH_4 concentration of the atmospheres of the above planets from the optical astronomy data, an accurate determination of the positions of these weak absorption bands, their band strengths, and temperature dependences is needed. Because CH_4 at pressures of tens of atmospheres or even at liquid densities (~590 amagats) is very transparent in the visible region the laboratory data are difficult to obtain. Conventional optical absorption spectroscopy in the ~4,000–11,000 Å region has recently been carried out using a multipass cell to obtain absorption pathlengths of ~1 km for room temperature CH_4 at pressures up to 20 atm (ref. 5) resulting in density–pathlength products of up to 20 km amagat. Longer path lengths of up to 3.86 km at lower pressures were used in earlier studies[16,17]. These data show several absorption bands of generally decreasing strength towards shorter wavelengths. Conventional optical spectroscopy of liquid CH_4 has been recently reported[6] in the region of 6,190–19,000 Å using a cell length of ~3 cm. The sensitivity of these studies, however, is such that the shortest wavelength absorption feature reported is at $\lambda\sim6{,}190$ Å with a peak absorption coefficient of $\sim4\times10^{-3}$ cm^{-1}. The signal-to-noise ratio reported for this peak is only about 5 : 1, that is, the 6,190 Å peak height is ~5 times the system noise. If we extrapolate from Giver's high temperature gas data[5], liquid CH_4 should exhibit weaker absorption bands all throughout the visible region (4,000–7,000 Å). Measurements of these absorption bands are clearly beyond the capabilities of the conventional spectroscopy studies of Ramaprasad *et al.*[6] who used a density path length product ~19 m amagat although some improvement is possible by using longer (but perhaps experimentally difficult) path lengths. Note that the multipass long cell technique used by Giver[5] is not applicable to liquid CH_4 studies because of obvious practical problems.

We report here optical absorption spectrum of liquid CH_4 at ~94 K in the 5,500–7,500 Å region. Several absorption bands are observed, the strongest one being at 13,700 cm^{-1} with an absorption coefficient of $(1.6\pm0.2)\times10^{-2}$ cm^{-1} and the weakest one at 15,515 cm^{-1} with an absorption coefficient of $\sim(1\pm0.3)\times10^{-4}$ cm^{-1}. The signal-to-noise ratio for the weakest peak reported is such that we should be able to observe absorption features as small as $\sim10^{-6}$ cm^{-1}. Our measurements were carried out using an opto–acoustic (OA) detection technique[7] which has been shown to be ideally suited for measuring absorption coefficients of room temperature liquids at levels as low as $\sim10^{-7}$ cm^{-1} and which we have adapted for the study of cryogenic liquids. The OA cell used in the present liquid CH_4 measurements had an effective density path length product of ~6.33 m amagat. In addition to the position and the strengths of the absorption bands, we report their bandwidths, asymmetries and identifications. In general, the absorption peaks arise from combinations of harmonics of the various vibrational fundamentals of CH_4. Further, the absorption bands for liquid CH_4 show asymmetries and frequency shifts (from the gas phase data) which are reminiscent of the liquid benzene results[8].

The measurements were carried out using a pulsed laser immersed transducer OA gated detection technique[7], modified for low temperature studies. The all stainless steel OA cell[9] was attached to a liquid N_2 cryostat such that any desired temperature between 80 and 200 K can be obtained. Methane (Matheson, Ultra-High Purity grade) was directly condensed into the low temperature cell and its pressure was monitored using a capacitance manometer. Tunable pulsed laser radiation was obtained from either a flashlamp pumped dye laser (pulse energy ~1–3 mJ, pulse duration $\tau_p\sim1$ μs, and repetition rate ~10 pulses per s (p.p.s.)), or a doubled Nd : YAG pumped dye laser (pulse energy ~1–5 mJ, $\tau_p\sim10$ ns, and pulse repetition rate ~20 p.p.s.). The laser pulse energy was measured using a Laser Energetics pulsed joule-meter. The OA signal as well as the reference laser level signal sampled by box-car integrators were averaged and ratioed by a NOVA 800 minicomputer. We thus obtained spectra of normalized OA signal $S_\nu=V/E_{inc}$, where V is the OA signal from the PZT transducer and E_{inc} is the incident laser pulse energy, as a function of the dye laser frequency.

The transient acoustical output signal from the transducer (in form of ringing due to the 200 kHz resonant frequency of the

PZT transducer, and the reflections of acoustic waves generated from the condensed liquid) is delayed from the incident laser pulse by a delay, $\tau_D=d/v_a$, where d is the distance between the laser illuminated volume and the OA transducer, and v_a is the acoustic velocity in the condensed liquid. From a measurement of τ_D versus d we have determined the sound velocity in liquid CH_4 ($T=94$ K) to be $v_a=(1{,}455\pm18)$ m s^{-1}. This value is consistent with the currently accepted value[10].

Figure 1 shows the measured spectrum of normalized OA signal from liquid CH_4 at 94 K from 13,300 to 17,800 cm^{-1}. Several clearly recognizable absorption peaks are indicated. Spectral resolution which is typically ~1.5–2 cm^{-1} is much smaller than the observed widths of the absorption features. Note that the only previous measurements of liquid CH_4 in the visible reported[6] the strong peak at ~16,090 cm^{-1} with a signal-to-noise ratio of $\leqslant5$. We see many more absorption features with peak absorptions which are ~30 smaller than that for the 16,090 cm^{-1} band. And even for the weak features the signal-to-noise ratio exceeds 100 for an integration time of ~1.5 s per resolution element of 1.5–2 cm^{-1}. Note also that there are no regions of spectrum where liquid CH_4 absorption drops below ~10^{-4} cm^{-1}. All the observed absorption features show a pronounced asymmetry, the absorption tails being longer on the high frequency side of the peaks.

As reported earlier[7,9], the normalized OA signal, S_ν, can be related to the intrinsic absorption coefficient of the condensed material through the relationship

$$S_\nu=\frac{V}{E_{\rm inc}}=K\beta\frac{v_a}{C_p}\alpha_\nu \qquad (1)$$

where β is the thermal volumetric expansion coefficient, C_p the specific heat at constant pressure, α_ν the absorption coefficient ($\alpha_\nu l\ll l$ where l is the sample path length), and K is a constant that describes the OA conversion efficiency and includes such parameters as the geometry of the OA cell, the acoustic impedance mismatch between the liquid and the transducer, and the sensitivity of the PZT transducer. Thus a knowledge of all the relevant parameters in equation (1) is sufficient to extract the absorption coefficient from the observed normalized OA signal. Procedures such as this have provided an excellent estimate of the absorption coefficient of media at room temperature where a sensitivity $\Sigma=S_\nu/\alpha_\nu$, calibrated for one liquid can be approximated for another of known β, C_p, and ρ. An accurate determination of the sensitivity Σ for a given liquid requires that a suitable dye be incorporated into the liquid medium such that a very small concentration of the dye (small enough so that none of the parameters of the right-hand side of equation (1) other than α_ν are perturbed) produces an absorption which can be measured accurately by conventional optical techniques (and by the OA technique). Unfortunately no data are available for the low temperature condensed gases. For the present study, we have extrapolated our sensitivity measurements from benzene studies[7,8] to obtain absorption coefficient from the measured S_ν for liquid CH_4. For the strong absorption peak at 16,090 cm^{-1}, we thus obtain α $(16{,}090)\approx(3\pm1)\times10^{-3}$ cm^{-1}. This value is in a reasonable agreement with the one which can be deduced from ref. 6.

Table 1 shows the data on observed absorption bands including: (1) the band peak frequencies; (2) bandwidths of peaks which are sufficiently separated to make such a measurement meaningful; (3) band asymmetry parameter defined as the ratio of the half-width at half-height on the high frequency side of peak to that on the low frequency side of the peak; (4) the peak absorption coefficient (subtracting out the broad background absorption in case of weak absorption features); and (5) identifications of the peaks, using Giver's[5] scheme for gaseous methane. We also show in Table 1 relevant data from the gas phase studies of Giver[5].

(1) There is a systematic shift of ~35–50 cm^{-1} of the liquid CH_4 absorption peak positions towards low frequency side when compared with gaseous CH_4 data. This shift is thought to arise from the effect of local environment in liquid CH_4 and is qualitatively in agreement with the data on liquid[8] and gaseous benzene (ref. 11 and R. G. Bray, personal communication). Note that our liquid CH_4 data show well-defined subsidiary peaks/shoulders on the absorption features which are not visible in the gas data of Giver[5].

(2) The observed liquid CH_4 bandwidths vary from ~250 to 350 cm^{-1} and are much wider than those for gaseous CH_4, again in qualitative agreement with liquid/gaseous benzene studies. The higher harmonics in a given series have larger bandwidths.

(3) All the observed liquid CH_4 absorption features in the 5,500–7,500 Å region show pronounced asymmetries with the asymmetry parameter varying from ~1.4 to 2.4. The gaseous CH_4 (ref. 5) data on the other hand show no such asymmetry

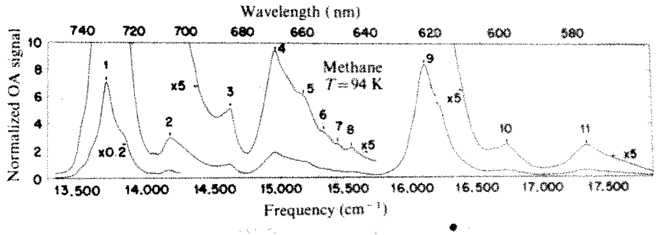

Fig. 1 Normalized OA signal as a function of dye laser frequency. Data including the absolute absorption coefficients for the indicated peaks are summarized in Table 1.

which is again thought to arise from local environment interactions in qualitative agreement with liquid/gaseous benzene studies (refs 8, 11 and R. G. Bray, personal communication) of its harmonic absorption in the visible region. We observe that the asymmetry of the absorption is a general characteristic feature of the absorption profiles of liquids.

(4) From the measured bandshapes one can derive integrated band strength (not done here). The absorption coefficients of the measured peaks vary from $\sim 1\times10^{-4}$ to $\sim 1.6\times10^{-2}$ cm^{-1}. From the signal-to-noise ratio for the smallest peaks (obtained using an integration time of 1.5 s per resolution element of 1.5 cm^{-1}), we conclude that we have the ability to measure absorption features as small as $\sim 10^{-6}$ cm^{-1} for liquids at low temperatures. The trend of the measured absorption coefficient for liquid CH_4 is similar to that for gaseous CH_4, that is the higher the harmonics the smaller the absorption coefficients.

(5) While major peaks have been reasonably well identified as arising from the combinations of harmonics of the four fundamental vibrational frequencies of CH_4, the minor peaks are not yet assigned.

The detailed knowledge about liquid CH_4 absorption spectrum provided here should now allow us to look carefully at the spectra of the outer planets to search for existence of liquid CH_4. (As pointed out by Ramaprasad *et al.*[6], detection of liquid CH_4, in form of an ocean on the planetary surface, is likely to be very difficult because only surface reflection is involved. However, for liquid CH_4 droplets in the planetary atmosphere, the sunlight penetrates and is reflected back from a surface or a cloud layer. Thus detection or setting an upper limit of the droplet fraction of CH_4 is feasible if high resolution high quality astronomical spectroscopic data are available.) Important information is to be gained from the position of the absorption bands as well as from their widths and shapes. As is seen above, these three features are characteristically different for liquid CH_4 from those for gaseous CH_4. For example, the existence of liquid CH_4 (in the form of droplets in the planetary atmosphere) can be deduced from the planetary astronomical absorption data if measurable differences are found in the peaks (positions, shapes, and widths) of the absorption bands (compared to the absorption peaks of gaseous CH_4).

Finally, our demonstration of the usefulness of liquid OA absorption measurement technique to low temperature liquids opens up an entirely new field of study. The ability to measure absorption coefficients as small as 10^{-6} cm^{-1} (an ability which we feel can be improved considerably) at cryogenic temperatures will undoubtedly provide exciting new data on liquids and solids. We have already begun to look at other liquified gases such as ethylene, and ammonia which are also important[12–14] in the atmospheres of the outer planets. We are modifying our OA measurement techniques to go to yet lower temperatures ~4 K to investigate H_2 and HD which are the major constituents[15] of these planets.

We thank Drs L. J. Lanzerotti and J. A. Tyson for helpful comments.

Contact angles associated with thin liquid films in emulsions

M. P. Aronson & H. M. Princen

Lever Brothers Company, Research Division, 45 River Road,
Edgewater, New Jersey 07020

As a result of interaction forces, the tension of a thin liquid film can be lower than the sum of the interfacial tensions of the bulk surfaces bounding the film[1]. To satisfy conditions of mechanical equilibrium, this reduced film tension leads to a macroscopic contact angle between the film and its associated Plateau border[2]. We have observed and report here very high contact angles, in some cases approaching 90°, for aqueous films between oil droplets, stabilized by anionic surfactants in the presence of various electrolytes. The contact angle is found to depend on the nature of the surfactant head group, type and concentration of counter-ion, and temperature. These contact angles have a pronounced effect on the stability, structure and rheology of emulsions.

Consider the thin metastable liquid film and its Plateau border that form when a vertical rectangular glass frame is withdrawn from a surfactant solution (Fig. 1). The tension of the film, γ_f, is related to the normal bulk interfacial tension, γ by[3]

$$\gamma_f = 2\gamma + \Delta F = 2\gamma + \int_{\infty}^{h_e} \pi(h)\,\mathrm{d}h \qquad (1)$$

h is the film thickness, h_e is the equilibrium thickness, π is the 'disjoining pressure', and ΔF is the free energy of interaction per unit area of the film, that is, the reversible work of thinning the film from infinite thickness, where the surfaces do not interact, down to the equilibrium thickness, where attractive and repulsive interaction forces are in balance. [Strictly speaking[3], equation (1) should include a term πh_e. For the extremely thin films (so-called Newton black films) to be discussed in this study, this term is expected to be negligible.]

A mechanical analysis[4] of the region where the film and the Plateau border join indicates that, whenever $\Delta F < 0$, the two bulk surfaces will, on a macroscopic scale, intersect at a sharp angle, 2θ, such that

$$\gamma_f = 2\gamma \cos\theta \qquad (2)$$

It follows from equations (1) and (2) that

$$-\Delta F = 2\gamma(1 - \cos\theta) \qquad (3)$$

One of the many manifestations of a finite contact angle is the spontaneous clumping that occurs when two or more oil drops approach each other in an aqueous surfactant solution (Fig. 2).

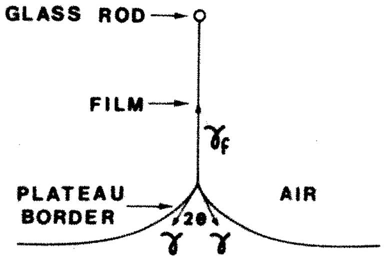

Fig. 1 Film and associated plateau border that are formed when a vertical glass frame is pulled out of a surfactant solution.

0028–0836/80/300370—03$01.00

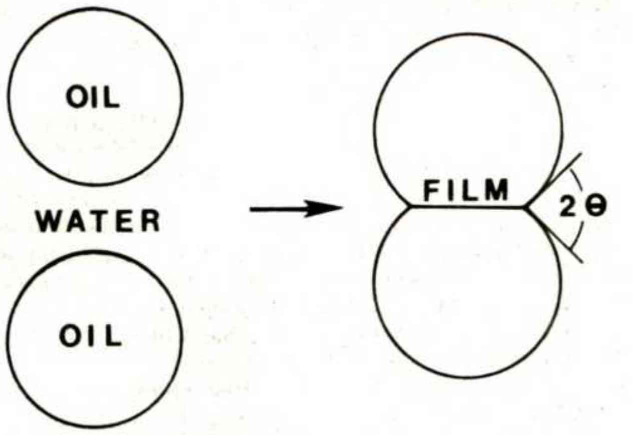

Fig. 2 The spontaneous flocculation of oil droplets when the contact angle, θ, is greater than zero.

When the contact angle is large, the droplets comprising the cluster are highly deformed, while remaining separated by an extremely thin film of intervening liquid of reduced tension.

Appreciable contact angles, as high as 15°, have been observed in aqueous films in air[5–8]. For lipid films in water, contact angles up to 8° have been reported[9,10]. If one assumes that interaction free energies for aqueous films in oil are of about the same magnitude as for aqueous films in air, one would, on the basis of equation (3), expect much larger angles for the former on account of their generally much lower interfacial tension.

Indeed, while studying[11] concentrated oil-in-water emulsions, we have observed very large contact angles, in some cases approaching 90° which would seem to be the theoretical limit. The emulsions were stabilized with anionic surfactants and contained added electrolyte. The contact angle was found to depend strongly on the composition of the aqueous phase (type of surfactant, and concentration and kind of counter-ion), while the nature of the oil phase had a relatively minor influence. We have used two classes of anionic surfactant: sodium alkyl sulphates and sodium alkyl carboxylates (soaps) in the presence of added LiCl, NaCl or KCl. With alkyl sulphates, the contact angle reached at a given electrolyte concentration increases in the order $Li^+ \ll Na^+ < K^+$. With alkyl carboxylates, the order seems to be reversed, although there is some doubt about the position of Li^+ because of the very low solubility of lithium soaps. Similar reversals in the relative effect of the alkali metal ions on properties of alkyl carboxylates and alkyl sulphates have been reported in other areas of colloid and surface chemistry[12]. With Na^+ as the counter-ion, the alkyl carboxylates give rise to much higher contact angles than do the alkyl sulphates. For example, with 0.3 m NaCl and 0.2% surfactant at 25 °C, the contact angles with dodecane are $\simeq 0°$ for SDS and $\simeq 57°$ for sodium oleate. Contact angles were also observed with other *n*-alkanes, as well as with paraffin oil and carbon tetrachloride. The results of this study, still in progress, will be presented elsewhere.

More recently, we have observed that the contact angle varies strongly with temperature. This is not unexpected, as this effect has been reported also for aqueous films in air[8]. Because of the much greater range of contact angles that can be obtained with aqueous films between oil, however, the phenomenon is much more dramatic. An example is given in Fig. 3 that shows dodecane droplets in an aqueous phase containing 0.25% sodium oleate, 0.25% sodium laurate and 0.6 m NaCl. At 25 °C, this system has a contact angle of about 70° which leads to the formation of flocs composed of highly deformed oil droplets. The floc is quite rigid and the individual droplets do not easily roll past each other. Very little water is seen to remain in the Plateau borders in the interior of each floc. Just as in polyhedral foams, these borders are of two types: 'linear' channels where three films meet at angles of 120°, and 'tetrahedral' corner pockets where four linear borders meet at angles of 109.47°. It can be shown[11] that the linear Plateau borders empty out when $\theta \geqslant 30°$ while the tetrahedral pockets do so when $\theta \geqslant 35.26°$.

When the dispersion is heated, the contact angle decreases and the cluster gradually decomposes into increasingly spherical droplets that begin to shift and rearrange (45 °C). Finally, at 60 °C, the contact angle is near 0°, and the floc now appears as a collection of discrete spherical droplets that are mobile. If, at this stage, the dispersion is cooled back to 25 °C, rigid flocs of deformed droplets again appear. They do not, of course, revert to the original configuration because of shifts that have taken place in the first cycle.

The presence of large contact angles can have a pronounced effect on several properties of an emulsion. For example, there is a dramatic increase in the rate and extent of sedimentation or creaming of an emulsion when $\theta > 10°$.

The structure of a concentrated emulsion, such as the cream layer formed on top of an initially dilute emulsion, is also very sensitive to the contact angle[11,13]. When the cream is formed by

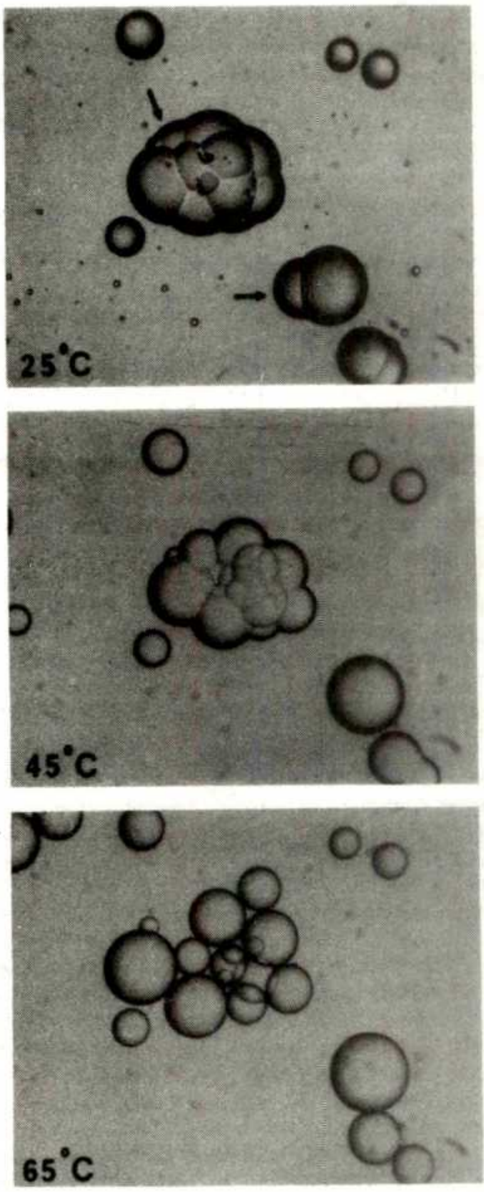

Fig. 3 The effect of temperature on the contact angle in flocs formed when dodecane droplets are dispersed in an aqueous solution of 0.25% sodium oleate, 0.25% sodium laurate and 0.6 M NaCl. The arrows indicate droplets that disappear during the experiment because of coalescence. Magnification, ~×90. An Olympus MG inverted microscope was used and heating was accomplished with a Mettler FP2 programmable hot stage. Contact angle equilibrium was generally achieved in less than 10 min.

sedimentation under gravity, an open network of flocs can form when $\theta \gg 0$. Appreciable amounts of water can be trapped in this network, leading to an expanded cream whose volume fraction of oil is <0.74 (the volume fraction corresponding to closest packing of monodisperse spheres). In this regard, this type of emulsion cream is analogous to the voluminous sediment encountered with a highly unstable colloidal dispersion of solid particles[14]. When such an expanded emulsion cream is compacted by mild centrifugation and then allowed to relax and equilibrate under normal gravity, much of the occluded water can be squeezed out, so that the resulting cream tends to have a final volume fraction of oil significantly greater than 0.74, as predicted by theory for the state of minimum free energy[11,13]. Indeed, using this method, we have prepared stable creams whose volume fraction is as high as 0.94 (ref. 11).

Note that some aspects of this work may have their parallel in biological systems. The cluster shown in Fig. 3 has a close morphological resemblance to a blastula, that is, the aggregate of living cells at the early stage of embryonic development. Of course, in biological systems the liquid phases would be reversed, that is, aqueous drops (cells) would be separated by lipid films (membranes).

We thank Lever Brothers Company for permission to publish this work.

Hydrostatic pressure and long-chain organic molecule diffusion through a polymer matrix

A. R. Rennie & D. Tabor

Department of Physics, University of Cambridge, Madingley Road, Cambridge CB3 OHE, UK

Earlier papers from our laboratory[1–3] have described a sensitive but relatively simple technique using IR spectroscopy to study the diffusion of labelled organic molecules through a polymer matrix. The method showed that the behaviour agreed well with de Gennes[4] model of reptation which assumes that long organic molecules diffuse by the motion of segments consisting of 20 to 30 units in the backbone. We describe here an extension of this work and deal with the effect of hydrostatic pressure on the diffusion of two hydrocarbons (suitably labelled) with backbone units $N = 18$ and 45 through molten low density branched polyethylene at pressures ranging from atmospheric to 1,300 atmospheres. The results show that the diffusion coefficient D decreases as the pressure P is increased. To a close approximation $\log D$ decreases linearly with P implying an apparent activation volume, V. Typical values for $N = 18$, are $V = 55$ Å^3 at 150 °C and 70 Å^3 at 120 °C implying a thermal expansion of the free volume of order 0.5 Å^3 K^{-1}. For $N = 45$, $V = 80$ Å^3 at 120 °C.

The experiments were carried our using ICI Alkathene 11/01 branched polyethylene as the matrix. The diffusants were stearamide ($CH_3(CH_2)_{16}CONH_2$) with 18 backbone atoms and behenyl behenate ($CH_3(CH_2)_{20}COOCH(CH_2)_{20}CH_3$) with 45 units counting the oxygen in the ester linkage. Cylindrical specimens were prepared in the manner described earlier[1] one half containing about 1% diffusant and the other consisting of matrix polymer only. A thin slice cut from the cylinder perpendicular to the join is scanned in an IR microdensitometer tuned to the adsorption frequency of the carbonyl group in the diffusant. Initially the concentration is a step function. As a result of diffusion the profile changes and from the new shape the diffusion coefficient can be calculated.

The diffusion experiments are all carried out above the melting point of the polymer. First, this avoids problems involving different degrees of crystallinity as the molten material at any specified temperature has a reproducible 'morphology'. Second, the diffusion rates are far more rapid than with the solid polymer, an important practical consideration in view of the decrease in D as the pressure is increased. Third, the specimen may be contained in a metal clyinder and compressed by a piston—because it is liquid the pressure is entirely hydrostatic. The force on the piston is applied with dead weights using a converted lever-arm tensile-testing machine and in this way the pressure is maintained constant without the need for elaborate servo-mechanisms. The seals, which slide in the cylinder, are of the Bridgman unsupported area type[5]. The metal cylinder is heated by electrical resistances and thermocouples are inserted at various points near the specimen. Temperature control is reproducible to ±1 °C. After the specimen has been subjected to the required pressure and temperature for a specified time it is solidified rapidly, removed from the containing cylinder and then sliced for examination in the IR microdensitometer.

Figure 1 shows that $\log D$ decreases linearly with P. Assuming a simple Arrhenius relation of the form $D = D_0 \exp(-PV/kT)$ where V is the activation volume for diffusion, k the Boltzmann constant and T the absolute temperature, we obtained the values quoted in Table1.

From Table 1 we first note that the activation volumes are very much smaller than the molecular volumes of the diffusants themselves (400 Å^3 for stearamide, 1,000 Å^3 for behenyl behenate). It is not possible to provide a specific model to explain this. It could be associated with a crankshaft motion involving some 3–4 CH_2 units; or it could relate to a small overall dilation of the matrix to allow passage of the diffusant. However, we also note that the activation volume for the behenyl behenate is only a little larger than for the stearamide although the molecular volume is more than twice as large. This is consistent with the earlier work of Klein and Briscoe[2,3] which

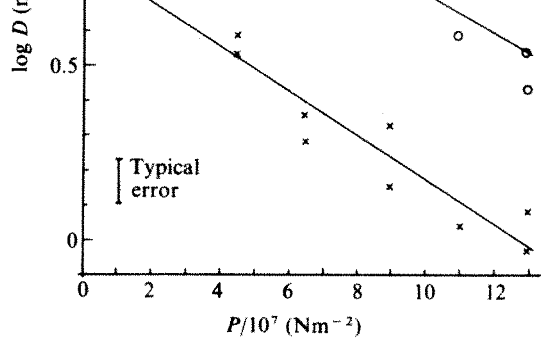

Fig. 1 Plot of $\log D$ against applied hydrostatic pressure, P, for stearamide at 150 °C (+) and 120 °C (○) and behenyl behenate at 120 °C (×).

0028–0836/80/300372—02$01.00

Table 1 Activation volumes, V, for diffusants in molten branched polyethylene

Diffusant	N	Temperature (°C)	V (Å^3)
Stearamide	18	150	55 ± 7
Stearamide	18	120	70 ± 8
Behenyl behenate	45	120	80 ± 8

indicated that however long the diffusant, motion occurs by the movement within individual segments each of which is about 20 carbons in length. Whatever the detailed mechanism it is clear that the diffusant is constrained by the surrounding matrix so that the activation process is easier the larger the available free volume. This accounts for the observation that the activation volume for stearamide decreases from 70 Å^3 at 120 °C to 55 Å^3 at 150 °C. Indeed, we may attribute this decrease to a thermal expansion of the free volume of the order 0.5 Å^3 K^{-1}.

It is interesting to compare these values for V with those deduced from the shear properties of polyethylene in the solid state. Ward[6] and Wilding and Ward[7] quote a value of ~50 Å^3 for bulk shear of linear polyethylene. Although the polymer was largely crystalline and highly oriented the deformation process involves radical disorganization of both the crystalline and the amorphous material in the specimen. Consequently, the mechanisms of motion may not be greatly different from those occurring in the melt. Similarly B. J. Briscoe (personal communication) quotes a value between 100 and 200 Å^3 for the shear of thin films of branched polyethylene. In these experiments the molecular length (and hence N) was many hundreds of times greater than the molecular length of the diffusants used in the present work. This again suggests that the unit involved in shear is a short segment, independent of the overall length of the polymer molecule. We hope to explore this aspect further by carrying out diffusion experiments with diffusants of increasing molecular length. If these data are to be used in the construction of molecular models of diffusion it should be noted once again that the activation volumes are very much smaller than the molecular volume of the segment itself.

Possible ozone reductions and UV changes at the Earth's surface

J. A. Pyle

Department of Atmospheric Physics, Clarendon Laboratory, University of Oxford, Oxford OX1 3BD, UK

R. G. Derwent

Environmental and Medical Sciences Division, AERE Harwell, Oxfordshire OX11 0RA, UK

During recent years there have been suggestions[1-3] that man's activities might reduce the thickness of the atmospheric ozone layer. Reductions in ozone could then give rise to an increase in potentially harmful solar UV radiation at the Earth's surface. Concern has been expressed particularly about the possibility of subsequent increases in skin cancer. Most calculations of ozone reduction have employed one-dimensional (height-only) models and few have calculated the solar radiation reaching the ground. Rather, it has been assumed that, for example, a 1% depletion in ozone is equivalent to a 2% increase in UV-B (the biologically important radiation in the wavelength range 280–320 nm) (refs 4, 5). However, studies using two-dimensional models[6,7] indicate that any change in ozone will not be uniform, but will show significant variations with latitude and season. We show here first, that the commonly accepted idea that a depletion of ozone of a particular figure is equivalent to an UV increase of twice that figure does not hold generally; second, we point out the importance of seasonal and latitudinal variations in ozone changes on the UV radiation reaching the Earth's surface.

Figure 1 shows the latitude–time cross-section of the depletion in total ozone calculated by one of us (J.A.P.) using a two-dimensional model of the atmosphere including detailed photochemistry and simulating a source of chlorofluorocarbons (CFCs). The features of the depletion are similar to a calculation in the model using a much simplified photochemical scheme[6]. Namely, maximum depletions are found in high latitudes where the total ozone is largest; smallest depletions occur in equatorial latitudes where ozone is a minimum throughout the year. Figure 2 shows two calculations, using the depletions found in Fig. 1, of the increase in solar UV radiation at 310 nm at the Earth's surface consequent on the reductions in ozone. The dashed line was obtained using the simple direct beam absorption scheme employed in the two-dimensional model, while the solid line uses the radiation scheme of Green *et al.*[8], which includes the effects of scattering by air molecules and aerosols. It can be concluded immediately from Figs 1 and 2 that the ratio of ozone reduction to UV increase is not constant; the ratio varies with latitude and time. A value of two is perhaps appropriate to mid-latitudes during winter but it is clear that this value cannot be used generally.

It is desirable to know the possible increase in radiation at all wavelengths in the UV-B and ideally these increases should be weighted by the action spectrum for skin cancer. However, as this spectrum is not available we have used that of mild sunburn or erythema[9]. Ideally, we would wish to examine the

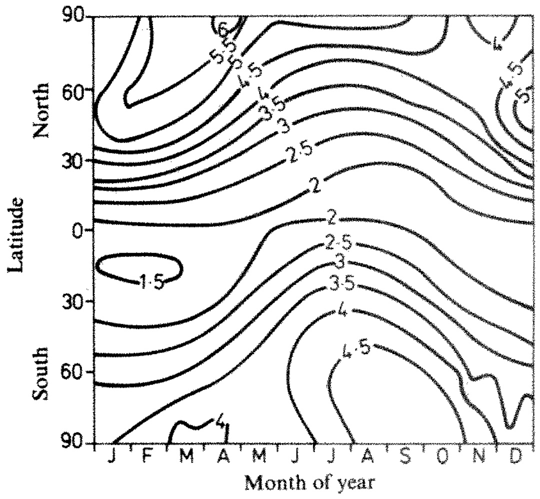

Fig. 1 Latitude–time cross-section of the percentage depletion in the total ozone amount in 1992 using the mean 1973–76 CFC production rates and the Oxford University two-dimensional model.

0028–0836/80/300373—03$01.00

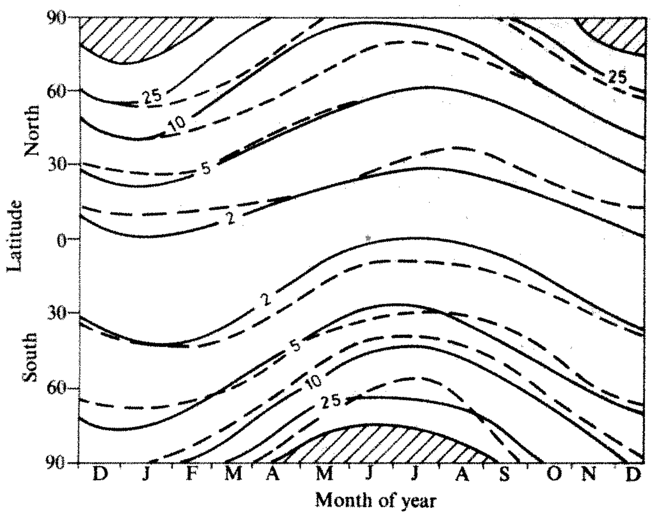

Fig. 2 Percentage change in UV radiation intensity in a narrow wavelength range centred at 310 nm resulting from CFC usage at 1992. Dashed line, calculations using a two-dimensional model; solid line, calculations using a simple UV radiation scheme.

perturbation in erythemally-weighted UV–B dose when the ozone depletion from CFC release reaches its steady state. Because of the many tens to hundreds of years that would be required and because of the detailed horizontal and vertical coverage in the two-dimensional calculations, the cost of running the model to steady state was considered prohibitive. However, the extrapolation of such predictions can be readily achieved by simple scaling up Fig. 1. A steady-state global ozone depletion of 13 ± 3% was selected on the basis of several UK modelling studies[10]. The slight annual increase in ozone depletion apparent in Fig. 1 during 1992, amounts to about a factor of 1.1–1.2. This slight upward drift when extrapolated into steady state introduces errors in the ozone depletion which are small in comparison with the errors in the chosen value itself.

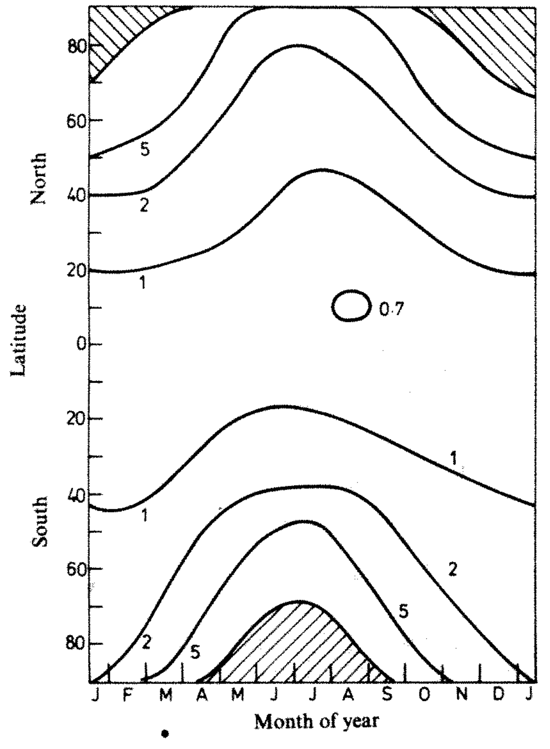

Fig. 3 Ratio of increase in erythemally-weighted UV–B dose to decrease in total ozone amount resulting from CFC usage.

The results shown in Fig. 1 were extrapolated to steady state with respect to CFC release, giving a global ozone depletion of ~13%. The radiation calculations including scattering were then used to compute the increase in the erythemally-weighted UV–B dose at steady state. A global increase of about 12% was found. Figure 3 shows the latitude–time section of the ratio of the percentage increase in UV–B dose to ozone depletion. Only in middle latitudes during winter does the ratio approach a value of 2 and for much of the globe the value is < 1, such that the global ratio, as implied above, is about unity.

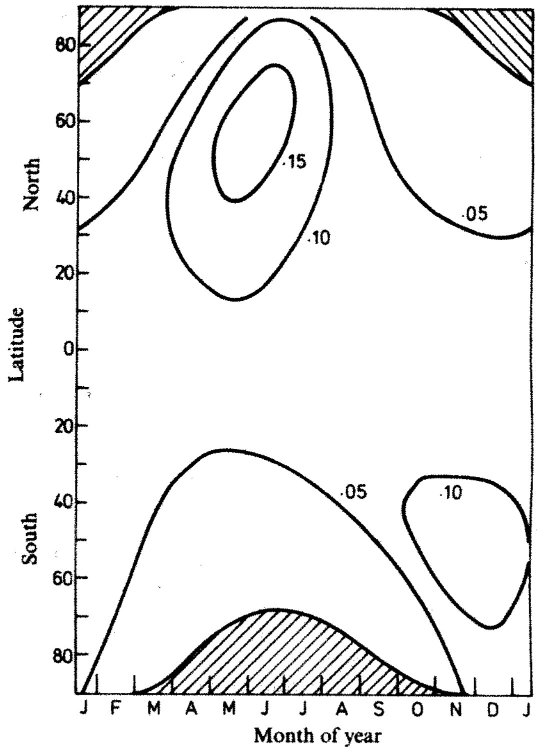

Fig. 4 Ratio of increase in erythemally-weighted UV-B dose from CFC usage to the dose at the Equator.

In high latitudes, the ratio does become larger and the significance of this is interesting. In Fig. 4 the increase in erythemally-weighted UV–B dose at the extrapolated steady state is compared with the dose at the Equator. The larger percentage increases in high latitudes seem to be of little significance when compared with the radiation reaching equatorial latitudes. However, plant and animal life in these high latitude regions coexist with small radiation doses so that we cannot necessarily infer that these changes will have only a small effect.

We conclude that no simple relationship exists between decreased stratospheric ozone and increased surface UV–B dose. The results of radiation calculations in steady-state one-dimensional models for a particular latitude should be treated with caution. Significant variations in the increased dose as a function of latitude and season have been demonstrated here. Inclusions of latitudinal and temporal effects will evidently be important in assessing the biological and botanical effects of possible future ozone depletions.

ELF radio signals in the auroral ionosphere generated by non-linear demodulation of LF and/or MF transmissions

T. Turunen

Geophysical Observatory, Sodankyla, Finland

P. S. Cannon[*] & M. J. Rycroft[†]

Department of Physics, The University, Southampton, UK

We have conducted experiments measuring ELF and VLF radio signals in the afternoon to early morning (local time) between 24 March and 4 April 1979 in Northern Scandinavia. Apart from those of a natural origin (atmospherics, chorus, and so on), we received timing signals, six pips which occurred on the hour UT; the duration of each pip, of frequency 1 kHz ± 0.5 Hz, was 105 ± 8 ms. A spectrogram of these is shown in Fig. 1. We have established that these are not due to non-linear demodulation of strong higher frequency radio signals in any part of the equipment. We consider that they are produced by non-linear demodulation of signals from two or more amplitude modulated transmitters in the USSR operating at 173, 200, 236, 263 and 657 kHz. The demodulation occurs only during enhanced auroral electrojet activity.

The equipment primarily used in this study involved three goniometer ELF/VLF receivers, one located at Sodankyla (Finland), one at Tromsø (Norway) and one at Arjeplog (Sweden). All stations are within the auroral zone. The goniometer system, described in detail by Bullough and Sagredo[1] and Jarvis[2], uses loop antennas, of area 58m^2; the goniometer modulation frequency was 27.5 Hz. Some measurements were made in parallel at Sodankyla using a VLF receiver designed at the Sodankyla Geophysical Observatory. This receiver was fed from a long (500 m) wire antenna. Additionally an ELF receiver (bandwidth 1 Hz–1 kHz), fed by a multiturn loop antenna, was operated during certain periods at Tromsø. Pips were detected by all these independent measuring systems. The ELF/VLF goniometer at Arjeplog was unfortunately disturbed by local interference at 1 kHz; thus recordings made there could not be used for detailed study.

As well as the timing pips, distorted music, distorted speech and station identifiers were occasionally heard. Broadcast band monitoring and subsequent reference to the World Radio and TV Handbook[3] identified the Russian First and Second Programmes on 173, 200, 236, 263 and 657 kHz as being the cause of these signals and, presumably, of the pips; timing signals were being transmitted on at least some of the above mentioned frequencies every time the 1-kHz pips were detected. Some of the stations transmitting these programmes are within 1,500 km of Sodankyla; these are Kaliningrad (173 kHz, 1 MW), Moscow (173 kHz, 500 kW), Syktyvkar (173 kHz, 300 kW), Leningrad (200 kHz, 150 kW), Moscow (200 kHz, 100 kW), Leningrad (236 kHz, 1 MW), Arkhangelsk (236 kHz, 150 kW), Moscow (263 kHz, 2 MW) and Murmansk (657 kHz, 150 kW) (Fig. 2). The field strength of the 173-kHz transmissions was measured by J. Sivusaami (personal communication) at Sodankyla during the daytime on 3 April 1979, and found to be $112\ \mu\text{V m}^{-1}$.

After completing the field experiments, 1 kHz amplitude modulated signals were injected into the goniometer receiving system, using a dummy aerial. Even with signals 52 dB stronger than those measured at 173 kHz, no demodulated output at 1 kHz was noted. Thus we conclude that the receiving system was linear and that the demodulation observed did not take place in the equipment.

The period of the experiment was characterized by two different levels of local geomagnetic activity. From 14 to 21 March, when no pips were recorded, the daily sum of K_{HDZ} indices, measured at the Sodankyla Geophysical Observatory, varied between 2 and 20. From 22 March to 4 April the corresponding values varied between 20 and 45 and, with the exception of 1 April, pips were recorded at least once each day. We conclude that pips were recorded only when the daily magnetic activity was moderately high. The probability of pips occurring is greatest in the local evening sector, at 19 and 20 UT. Only one measurement was available at 18 UT. Inspection of STARE (Scandinavian Twin Auroral Radar Experiment[4]) data and magnetograms from Sodankyla and Kiruna shows that an active auroral zone current system was always nearby during the times of pip occurrence. Additionally, in cases when the source location was possible, this location probably fell within the eastward electrojet.

On six occasions the signal-to-noise ratio was high enough to allow the determination of the azimuthal bearings of the 1-kHz signals both from Sodankyla and Tromsø, enabling the source to be located by goniometer triangulation. On five occasions the sources were approximately the same. Figure 3 shows this location with the worst case envelope of standard errors. The sixth location is also shown with its error diamond. On three more occasions a bearing angle, with 180° ambiguity, was obtained from Sodankyla. These directions are also shown in Fig. 3. They do not coincide with the direction of the five cases having roughly the same source location. The group of five events from the same location occurred at 19 or 20 UT; the sixth location was determined at 22 UT. Two of the directions determined from Sodankyla only are at 19 UT and the other at 21 UT. Two of the measurements belonging to the group of five events of the same source location were measured on the same day.

We summarize the results obtained as follows. During times of active auroral zone currents, and providing that the daily magnetic activity has been relatively high, there is a high probability of the occurrence of pips in Northern Scandinavia. These signals are considered to be due to a demodulation (self-detection) effect (in the lower ionosphere) of certain LF (and MF) AM broadcasting stations transmitting hourly time marks at 1 kHz within the programme schedule of the Russian Internal Service First and/or Second Programmes. The probability of their occurrence is highest around 19 and 20 UT, but a high probability at 18 UT is not ruled out, because of a data gap. At these times the signal-to-noise ratio is sometimes good enough to indicate that the signal source has a favoured location in the ionosphere (shown in Fig. 3) and that this location does not change with time; there are also other possible locations of the source.

Experimental evidence for the demodulation of HF radio signals in the presence of auroral electrojets has been reported by Kapustin *et al.*[5]. Theoretical treatments for the generation of ELF/VLF waves in the auroral ionosphere have been published

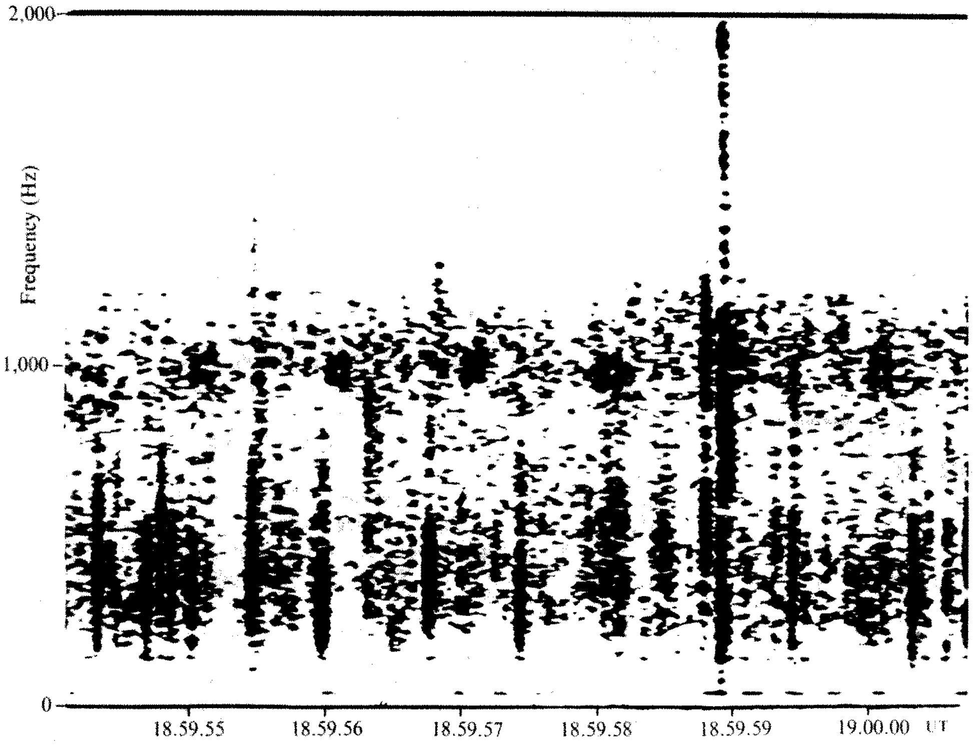

Fig. 1 Spectrogram showing atmospherics and six 1-kHz pips; frequency splitting of the signal, into upper and lower sidebands 55 Hz apart, is due to the goniometer modulation.

by Stubbe and Kopka[6,7] and by Kapustin *et al.*[5], and in the references cited therein. It is proposed there that ELF/VLF radio waves can be generated after heating the lower ionosphere with a strong HF wave having amplitude modulation at ELF/VLF. The modulation causes periodic changes in electron temperature which cause corresponding changes in the Hall and Pedersen conductivities. As a consequence, an a.c. component, at the frequency of the periodic heating, is formed in the auroral electrojet, which radiates a wave at the heating frequency. Stubbe and Kopka[6,7] consider the case when a limited area of auroral ionosphere is heated by a vertical narrow beam radio transmission at HF which can penetrate both the D and E layers in most conditions. This also applies to the experimental arrangements of Kapustin *et al.*[5].

We believe that we have found a basically similar phenomenon, but caused by obliquely propagating amplitude modulated LF and/or MF transmissions acting in the lower portion of the auroral D-layer. In the case of one transmitting station, maxima of the heating effect are located at any instant at positions where the maxima of the modulation of the direct wave and waves after experiencing several sky and ground reflections are essentially in phase with each other. When the same programme is transmitted from two stations an interference pattern is formed, with maxima in the heating power moving along roughly hyperbolic trajectories in space. The positions of these trajectories depend on the modulation frequency. Non-linear demodulation occurs only in regions where the appropriate ionospheric conditions are satisfied.

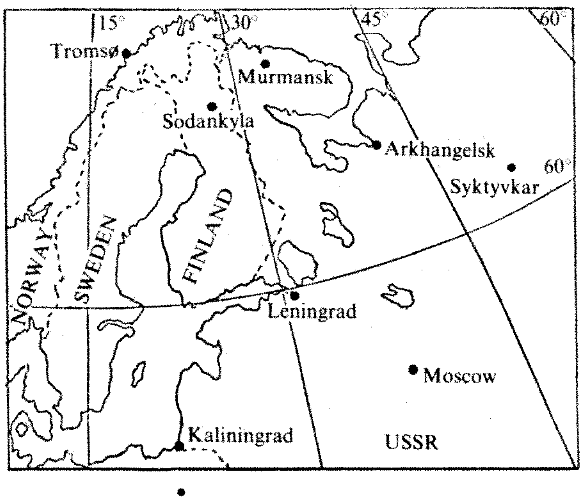

Fig. 2 Mercator projection of Scandinavia and North Western USSR, showing Soviet high power LF and MF broadcast stations within 1,500 km of Sodankyla, on 173, 200, 236, 263 and 657 kHz.

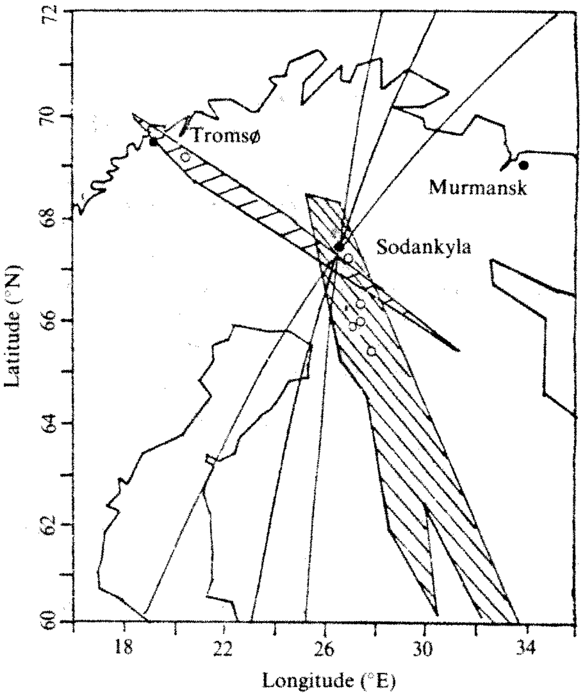

Fig. 3 Cartesian projection of Northern Scandinavia showing the positions (○) of the sources in the ionosphere of the 1-kHz pips, with the worst case error envelopes (hatched area). Additionally, three bearings with 180° ambiguity and a typical error of ±6°, are shown from Sodankyla.

In the case of three stations there are a few particular areas, which remain fixed, where the crests of the modulated waveforms occur and where the periodic heating maximizes. For four or more stations, the extra stations may, depending on their locations and the phases of modulation of their transmitted signals, contribute to the phenomenon.

We consider that at 1 kHz a proper phasing of the signals from at least three stations is obtained in the area in which we have located five sources. We then explain our discovery that pips occur only when the daily magnetic activity is above a certain threshold by this preferred area lying in the electrojet. On quiet days the main current system lies at higher latitudes beyond the particular area mentioned. The distortion of music or speech occurs because sources at different modulating frequencies have different fixed locations; not all of these may lie in areas suitable for ELF/VLF wave generation. This gives rise to a complicated and spectrally varying weighting of the signal. Other such areas may also be invoked to explain the sixth location shown in Fig. 3 and the three signals, observed only at Sodankyla, which had quite different propagation directions.

We thank our colleagues who took part in the present observational programme, and also members of the Measuring Station of the Finnish Broadcasting Company for measurements of various LF and MF transmitter field strengths.

The pear-shaped section of the Earth

D. G. King-Hele*, C. J. Brookes† & G. E. Cook*

* Royal Aircraft Establishment, Farnborough, Hants GU14 6TD, UK
† University of Aston, Gosta Green, Birmingham B4 7ET, UK

The Earth's gravitational field, and hence the shape of the Earth's sea-level surface, the geoid, can be determined from analysis of the motion of artificial satellites in orbit about the Earth. The method is particularly powerful in revealing the longitude-averaged meridional profile of the geoid, that is, an average slice through the poles, which from its north–south asymmetry is often called 'pear-shaped'. We now report an improved determination of this profile, which should be accurate to about 50 cm at latitudes up to 86°, and replaces our previous evaluation[1,2].

The Earth's gravitational potential may be expressed as the sum of (1) an infinite series of zonal harmonics independent of longitude, and (2) a double infinite series of tesseral harmonics, dependent on both latitude and longitude. Here we are only concerned with (1), and we express the longitude-averaged potential at an exterior point distant r from the Earth's centre at geocentric latitude ϕ in the standard form[3]

$$\bar{U} = \frac{\mu}{r}\left\{1 - \sum_{l=2}^{\infty} J_l \left(\frac{R}{r}\right)^l P_l(\sin\phi)\right\} \qquad (1)$$

where μ is the gravitational constant for the Earth, 398,600 km^3 s^{-2}, R is the equatorial radius, 6,378.14 km, and $P_l(\sin\phi)$ is the Legendre polynomial of degree l and argument $\sin\phi$. The J_l are constant coefficients: $J_2, J_4, J_6, \ldots$ express the effects of harmonics symmetrical about the Equator; J_3, J_5, $J_7, \ldots$ express the effects of north–south asymmetry, and it is these odd zonal harmonics that determine the pear-shape tendency of the Earth.

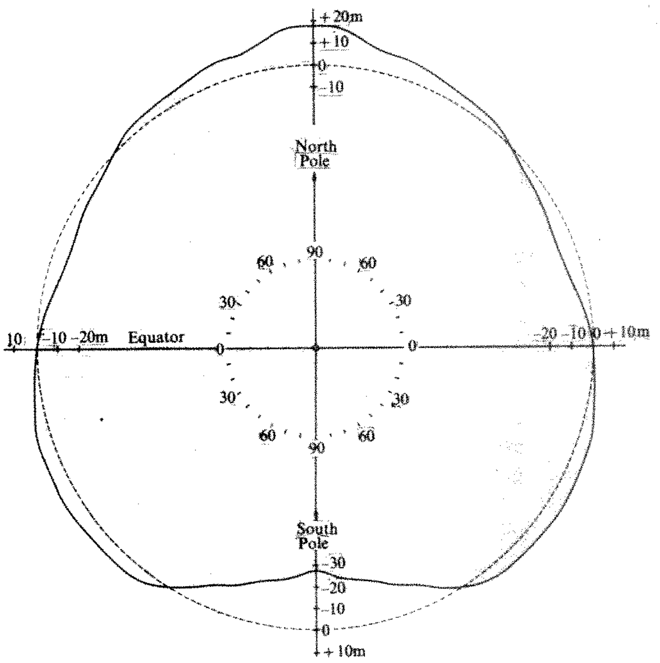

Fig. 1 Height of the meridional geoid section (solid line) relative to a spheroid of flattening 1/298.25 (dashed line) as given by our nine-coefficient set of odd harmonics and GEM 10B even harmonics.

A major effect of the odd zonal harmonics on satellite orbits is to alter the distance of perigee from the Earth's centre: although the north–south asymmetry of the Earth only amounts to about 40 m, it produces an oscillation several kilometres in amplitude. We have evaluated sets of odd zonal harmonics by analysing such oscillations in 28 satellite orbits, from near-equatorial to polar. Previously there was a lack of accurate orbits at inclinations near 63.4°, where the oscillation becomes very large. So two suitable satellites, Cosmos 248 and Cosmos 373 at inclinations 62.2° and 62.9°, have been specially observed optically for more than five years by the Hewitt camera at Malvern, the kinetheodolite at the South African Astronomical Observatory, and visual observers in Britain and elsewhere. The orbits of these satellites were determined from about 5,000 observations[4,5], and were used to evaluate the amplitudes of the oscillations in perigee distance, which amounted to 58.7 ± 0.2 km for Cosmos 373.

The methods for evaluating J_3, J_5, $J_7, \ldots$ were basically similar to those previously used, but with significant improvements in the theory. More than 500 solutions were computed, and the following nine-coefficient set is selected as the best[6]:

$$\begin{array}{lll}
10^9 J_3 = -2{,}530 \pm 4 & 10^9 J_9 = -90 \pm 7 & 10^9 J_{15} = -20 \pm 15 \\
J_5 = -245 \pm 5 & J_{11} = 159 \pm 9 & J_{17} = -236 \pm 14 \\
J_7 = -336 \pm 6 & J_{13} = -158 \pm 15 & J_{19} = -27 \pm 19
\end{array}$$

This set of values has standard deviations about 40% smaller than in the previous eight-coefficient set[2], and differs from the previous values by less than the sums of their standard deviations.

Figure 1 shows the profile of the longitude-averaged meridional section as given by this set of odd zonal harmonics and the even harmonics of the Goddard Earth Model 10B (ref. 7). The heights shown in the diagram are relative to a spheroid of flattening 1/298.25, which is drawn as a broken line. With the new profile, sea level at the north pole is 17.84 m above the spheroid, and sea level at the south pole is 27.23 m below the spheroid. So the 'pear-shape asymmetry', the north polar minus the south polar radius, is 45.1 m, compared with 44.7 m from the previous solution.

We have also derived 8- and 14-coefficient solutions as alternatives, but they give almost identical results, with differences of less than 30 cm in geoid height up to 86° latitude.

Comparison with the corresponding geoid profile from the most recent comprehensive gravity field[7], GEM 10B, which has a completely independent set of odd zonal harmonics, shows differences of less than 80 cm up to latitudes of 85°, the average difference being about 25 cm. The effect of changing the even harmonics from those of GEM 10B to the most recent set derived at the Smithsonian Astrophysical Observatory shows an average difference of only 20 cm. For these and other reasons, we suggest that the profile of Fig. 1 should be accurate to 50 cm up to latitudes of 86°. Over the remaining 0.2% of the Earth's surface very near the poles, the errors may be larger, possibly up to 1.5 m: basically, this increased error arises because there is so little of the Earth's mass at these latitudes.

Although the longitude-averaged geoid profiles agree well, the predicted amplitudes of the oscillations in perigee distance do not: at certain inclinations, the amplitudes given by our zonal harmonics differ from those given by GEM 10B by up to 350 m, even if the singularity near 63.4° inclination is excluded. So further improvements in the values of the zonal harmonics, utilizing satellites in chosen orbits specially observed, will be needed if orbital models capable of centimetric accuracy, to match centimetric laser observations, are ever to be developed.

West Antarctic ice sheet fluctuations in the Antarctic Peninsula area

D. E. Sugden & C. M. Clapperton

Department of Geography, University of Aberdeen,
Aberdeen AB9 2UF, UK

The West Antarctic ice sheet is believed to be inherently unstable because much of it is grounded below sea level[1–4]. It has been suggested that the ice sheet has withdrawn from its late Wisconsin maximum position, grounded at the edge of the continental shelf, and is now undergoing collapse as a delayed response to the warming and sea-level rise of the Holocene[5], and that the ice sheet is likely to collapse shortly in response to rising CO$_2$ levels in the atmosphere[6]. We present here some geomorphological evidence from Alexander Island and the Antarctic Peninsula which does not agree with either hypothesis. Rather, following deglaciation from the Wisconsin maximum, there was less ice than at present around 8,000 yr ago. The ice shelf in George VI Sound has built up subsequently.

Alexander Island is a mountainous block of country approximately 450 km from north to south and 300 km from east to west. Jagged mountains rise to altitudes exceeding 3,000 m in the north of the island but more subdued tracts of dissected plateau 250–800 m altitude are more characteristic of the south and east. These topographical contrasts partly reflect the island's geology for, whereas the spectacular Elgar Mountains of the north are composed of plutonic rocks, the bulk of the island's plateau scenery in the south and east coincides with extensive areas of sedimentary strata, particularly shales, sandstones, volcanoclastics and conglomerates[7–9]. The adjacent part of the Antarctic Peninsula, similarly aligned from north to south, is 200 km across and includes mountains rising to 3,000 m. As on Alexander Island, the land is more extensively buried by ice fields towards the south. The Peninsula is geologically distinct from Alexander Island in that the bulk of it is composed of plutonic and volcanic rocks and a variety of gneisses, granites and lavas predominate[10]. It is believed that block faulting has separated the two land areas resulting in the trench of George VI Sound which is over 20 km wide, and 500 km long.

The Peninsula is covered by a northward extension of one of the three main ice domes comprising the West Antarctic ice sheet and from its axis the ice drains westwards and eastwards into ice shelves. The western ice shelf, 100–500 m thick, flows westwards across George VI Sound and abuts the east coast of Alexander Island where it is depositing a conspicuous moraine. This ice shelf terminates at either end of the Sound in environmental conditions where summer temperatures rise to within a few degrees of 0 °C. As such the ice shelf in George VI Sound is in a marginal environment for its survival[11]. Alexander Island itself supports an ice cap and ice fields which discharge outwards to each coast. Outlet glaciers flowing into George VI Sound ice shelf are quickly dominated by the more powerful ice flow from the Peninsula and are almost immediately deflected northwards and southwards.

Evidence of past glacial maximum conditions points to increased ice thicknesses on both Alexander Island and the Antarctic Peninsula, with both areas acting as independent centres of outflow. On eastern Alexander Island the evidence is in the form of glacial trough alignment, the direction and position of striations on plateau surfaces and interfluves, and erratic fans which can be traced from distinctive bedrock outcrops. Examples of these features in the Ablation Point area show how flow was consistently eastwards towards George VI Sound (Fig. 2). Compatible with this reconstruction is the absence of Peninsula erratics on the eastern plateaux of Alexander Island; although Peninsula-derived granites and gneisses are clearly identifiable in the moraine flanking the present ice shelf in George VI Sound, none were found above an altitude of 85 m. On Plateau surfaces in the Batterbee Mountains of the Peninsula across from Alexander Island the flow of a former ice cover was westwards into the Sound and then northwards parallel with the Sound. Clear evidence for this comes from roches moutonnées, striations, sub-glacial meltwater channels and the slope of high-level lateral moraines which cross the plateau at 400–670 m altitude (Fig. 3).

Previous reconstructions of maximum ice conditions in the late Wisconsin for this part of Antarctica show the ice flowing from the Peninsula axis across Alexander Island to the edge of the continental shelf on its west side[5,12]. The field evidence from eastern Alexander Island indicates ice-flow directions directly opposite to those implied by these previous reconstructions and implies that the ice masses were thinner, consisting of separate domes that were based on Alexander Island and on the Peninsula and becoming confluent in George VI Sound.

Some indication of the age of the last maximum glaciation was obtained from a shelly till deposit found on a spur 3 km north of Two Step Cliffs and lying between 94 and 114 m above the present ice shelf. The shells consist of fragments of *Hiatella solida*. They lie in a till with striated clasts and a typical glacial matrix (mean ϕ 0.21, sorting 4.05, skewness 0.39, kurtosis 0.82). Analysis of the lithology of the clasts and of the magnetic susceptibility of the matrix suggests the till is derived from sedimentary rocks characteristic of Alexander Island and is quite different to the Peninsula-derived ice shelf moraines in the vicinity originating on igneous rocks. The outer fraction of the shells gave a radiocarbon age of 32,160 ± 360 yr and the inner fraction 30,600 ± 660 yr (SSR 1499). That such an old radiocarbon age is likely to be a minimum was confirmed by the results of amino acid analysis on three separate shells which yielded total D/L ratios of 0.169, 0.113 and 0.147 (AAL 1297).

0028–0836/80/300378—04$01.00

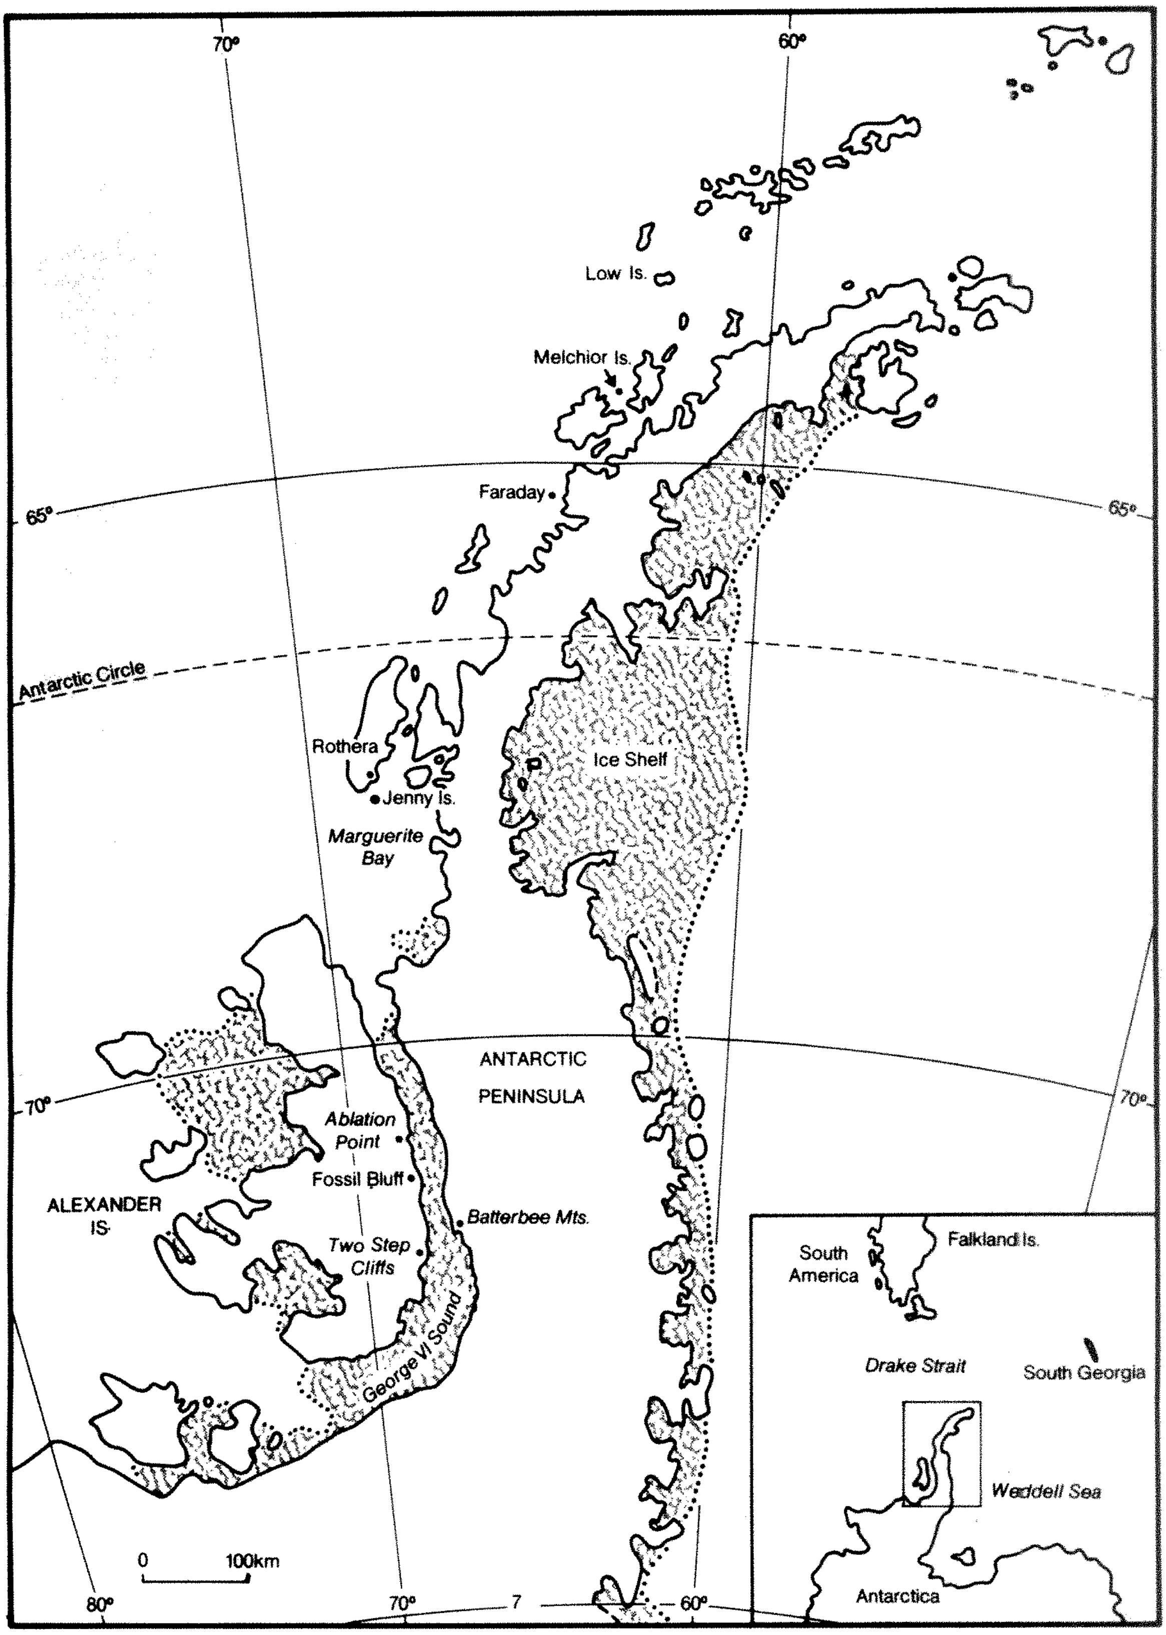

Fig. 1 The Alexander Island–Antarctic Peninsula area of West Antarctica.

We cannot place accurate absolute dates on these values without knowing the precise thermal history of the shells since their death. Nevertheless, a reconstruction of the most likely thermal history (in seawater or beneath a warm-based glacier) produces an age which is compatible with that of the last interglacial (G. H. Miller, personal communication). We can go even further and suggest that at the time of their growth the Sound was free of an ice shelf. The basis of this suggestion is the discovery from the J9 drill hole through 420 m of the Ross Ice Shelf, 430 km from the open sea, that no living infauna existed and that the sediments contained no animal traces or bioturbations[13]. As George VI Sound Ice Shelf is 300 m thick over 200 km distant from the open sea in the vicinity of Two Step Cliffs, it is reasonable to suggest that shells may be unable to thrive beneath its canopy and must, therefore, reflect open conditions in the Sound.

The most likely explanation of the shelly till is that it was formed by an enlarged ice sheet grounded in George VI Sound and just impinging on Alexander Island on the promontory north of Two Step Cliffs. In such a case the dates imply that the ice cover was substantially thicker in the Wisconsin than at present. In the absence of any alternative moraine limits it seems reasonable to attribute the maximum reconstruction described earlier to this Wisconsin advance.

Evidence of the Holocene history of the ice shelf comes from the moraine which flanks the ice shelf where it abuts onto Alexander Island. The moraine has two components. One is a landward ridge 5–30 m high which apparently contains no ice. The other is immediately adjacent and forms one to three ice-cored ridges. The crests of all the ridges are lower than the overall surface of the ice shelf. At Two Step Cliffs barnacles *Bathylasma corolliforme* (Hoek) were found in the landward of the two ridges. The presence of striated clasts and mechanical analysis of the matrix confirm that the deposit is till but with signs of water activity (mean ϕ 2.09, sorting 4.19, skewness −0.02, kurtosis 0.96). Radiocarbon dating of the outer fraction of the barnacles produced an age of 6,930±60 and the inner fraction 7,200±50 (SRR-1500). If one allows for a correction factor of ~750 yr for the ^{14}C deficiency in Antarctic waters based on radiocarbon dates on modern shells in the Antarctic Peninsula area[14,15] then the adjusted dates come out as 7,700 and 7,950 radiocarbon yr BP. This Holocene age is fully consistent with the results of amino acid analysis which revealed total D/L ratios of 0.028 and 0.01 (AAL 1298). The position and age of the barnacles implies that they were growing in George VI Sound around 8,000 yr ago and that subsequently they have been incorporated in the ice shelf moraine. There are two possible implications pertinent to the Holocene history of the ice shelf. The most likely is that the barnacles were growing in an ice-free Sound ~8,000 yr ago and the ice shelf has built up subsequently. The other less likely possibility is that the

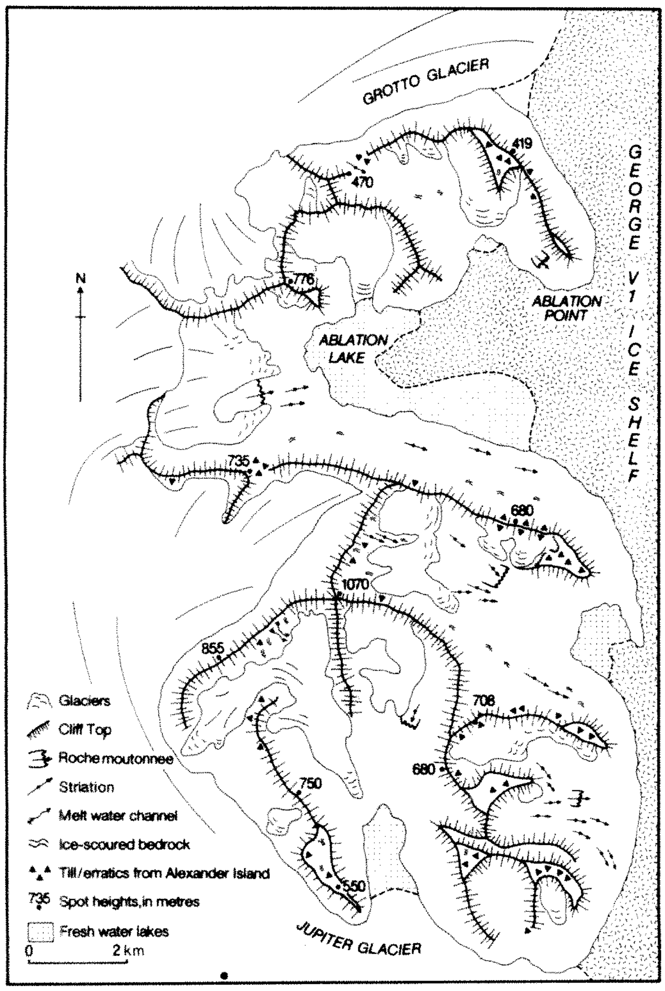

Fig. 2 Evidence of former ice movement from west to east across the Ablation Point area.

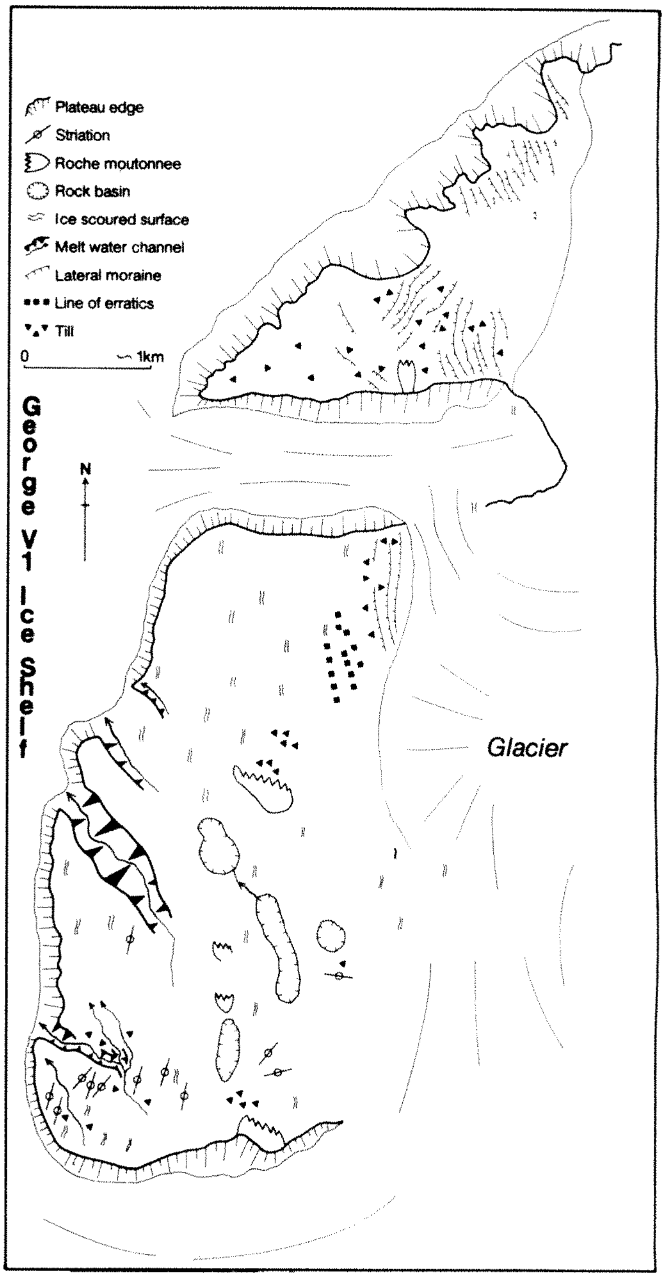

Fig. 3 Evidence of former ice movements sub-parallel to George VI Sound in the Batterbee Mountains area.

barnacles were growing beneath the ice shelf; in this case the implication is that the ice shelf has not been materially thicker than at present for ~8,000 yr (although it is possible that it has been thinner and less extensive).

These results of investigations in the Alexander Island and Antarctic Peninsula area yield five conclusions relevant to the history of the West Antarctic ice sheet.

(1) During the last maximum glaciation separate ice domes were centred over both Alexander Island and the Peninsula. This represents an ice thickness less than that predicted on theoretical grounds in the CLIMAP reconstructions[12].

(2) Amino acid analyses on shells suggest that the last maximum was achieved in the Wisconsin and followed an interval when the Sound may have been free of ice, perhaps during the last interglacial.

(3) George VI Ice Shelf, one of the most sensitive to environmental change in West Antarctica, has apparently reformed in the last 8,000 radiocarbon yr following a period of warmer conditions when the Sound was ice-free.

(4) Ice sheet fluctuations in this part of West Antarctica, especially the signs of a warmer period ~8,000 yr ago, seem to be in phase with world environmental changes as reflected for example by deep sea cores[16] and recent ice cores[17].

(5) With regard to the hypotheses concerning the possible instability of the West Antarctic ice sheet, one can conclude that in this sector: the ice in the last maximum was thinner than previously supposed and that there is no sign of progressive ice sheet collapse; rather there seems to have been an expansion in the last 8,000 yr as George VI ice shelf reformed; the West Antarctic ice sheet is able to survive without the presence of George VI ice shelf; so long as the ice shelf survives, then there is no need to fear imminent West Antarctic ice sheet collapse due to climatic warming as proposed by Mercer.

We thank NERC for financial support, the British Antarctic Survey for logistic support, Drs G. Oliver and W. Newman for identifying the shells, Dr D. Harkness for radiocarbon dating, Dr J. T. Andrews for amino acid analysis and Professor F. Oldfield for magnetic susceptibility measurements.

Shelly microfossils near the Precambrian–Cambrian boundary, Mackenzie Mountains, northwestern Canada

S. Conway Morris

Department of Earth Sciences, Open University, Milton Keynes
MK7 6AA, UK

W. H. Fritz

Geological Survey of Canada, 601 Booth Street, Ottawa, Ontario
K1A 0E8, Canada

Our understanding of early metazoan evolution is being revolutionized by recent discoveries of pre-trilobite faunas. A fascinating aspect of this evolution is the appearance and development of metazoan skeletal parts near the Precambrian–Cambrian boundary. Fossils of these parts are best known from the lowermost stage (Tommotian) of the Cambrian in Siberia which contain archaeocyathids and small shelly fossils, the latter commonly of phosphatic composition[1–3]. Although the sudden, in terms of geological time, appearance of metazoan hard parts near the boundary is recognized as an outstanding evolutionary event, none of the proposals given to explain the 'Cambrian explosion' (see refs 4–6) has been widely accepted. Additional information from areas outside Siberia is now needed to broaden our knowledge on early Metazoa, and to assist a geological team, the Precambrian–Cambrian Boundary Working Group of the International Union of the Geological Sciences, that is locating, defining and correlating the Precambrian–Cambrian boundary on a world-wide basis. Here we report the discovery of a small fauna of microfossils near the boundary in the Mackenzie Mountains. New forms are present and a known species is used for correlation with the classic Precambrian–Cambrian sections in Siberia and successions elsewhere.

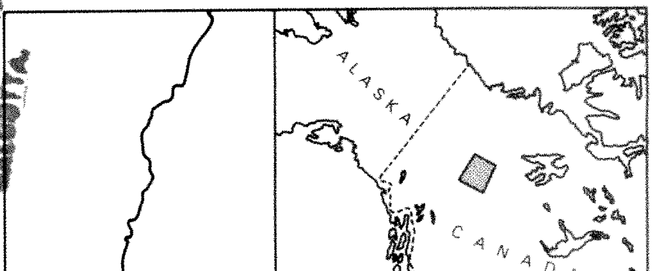

Fig. 1 Map locating sections 35, that contains shelly microfossils at GSC locality 94597, and 33. Section 35 is located between lat. 63°22·5′, long. 128°38.75′ (base of section) and lat. 63°22′, long. 128°35.75′ (top of section).

A sample from the Mackenzie Mountains (Geological Survey of Canada (GSC) locality 94597) collected by one of us (W.H.F.) yielded shelly microfossils after 660 g of limestone was digested in dilute acetic acid ~10%). The sample is from stratigraphic section 35 (ref. 7), located between the Keele and Natla Rivers, Northwest Territories (Fig. 1). Note that the sample came from a horizon 3,065 feet (934 m) stratigraphically below the next youngest fossil locality (GSC locality 94599) (Fig. 2) which is located in the Sekwi Formation[7,8] and yields cf. *Parafallotaspis grata* Fritz, the oldest described trilobite species from North America. GSC locality 95497 is in the middle of a 135 foot (41.4 m) thick limestone unit that has been correlated with map Unit 11 (ref. 7), an informal stratigraphic unit recognized by Blusson[9] a short distance to the east. In addition to the microfossils documented here, stromatolites and burrows were noted[7] at GSC locality 94597. These latter fossils, together with the light colour of the limestone, suggest the sampled limestone was deposited in shallow water.

The following microfossils were obtained: (1) A single specimen of *Protohertzina* cf. *P. anabarica* Missarzhevsky[10] (Fig. 3*a*–*c*). Both ends are broken, but the specimen is otherwise well preserved. *P. anabarica* is the genotype and four other species have been described[10–12]. The genus belongs to a group of phosphatic fossils known as protoconodonts that may form one

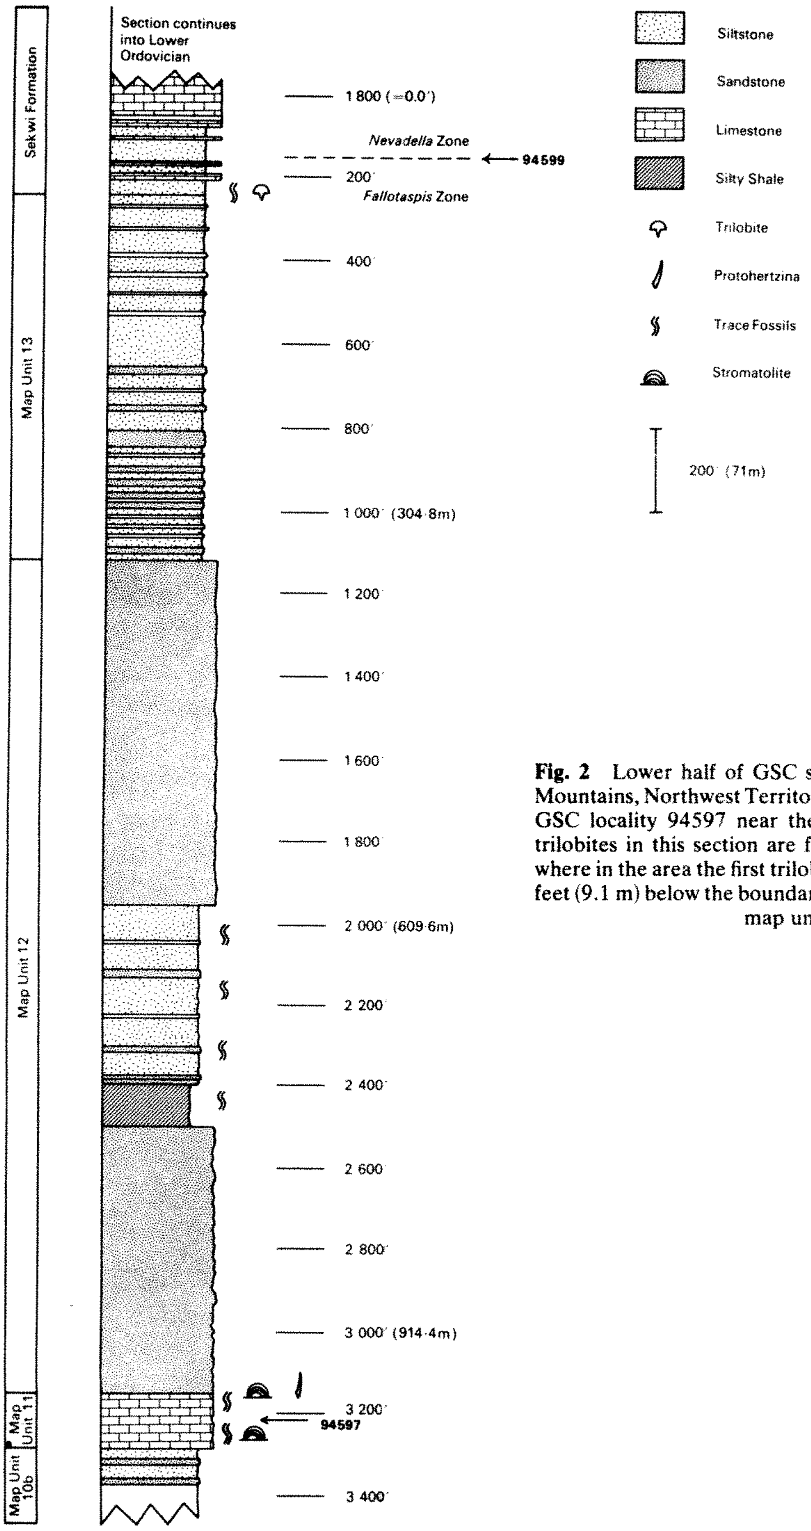

Fig. 2 Lower half of GSC stratigraphic section 35, Mackenzie Mountains, Northwest Territories. The shelly microfossils are from GSC locality 94597 near the base of the section. The earliest trilobites in this section are from GSC locality 94599, but elsewhere in the area the first trilobites occur slightly lower at about 30 feet (9.1 m) below the boundary between the Sekwi Formation and map unit 13 (ref. 8).

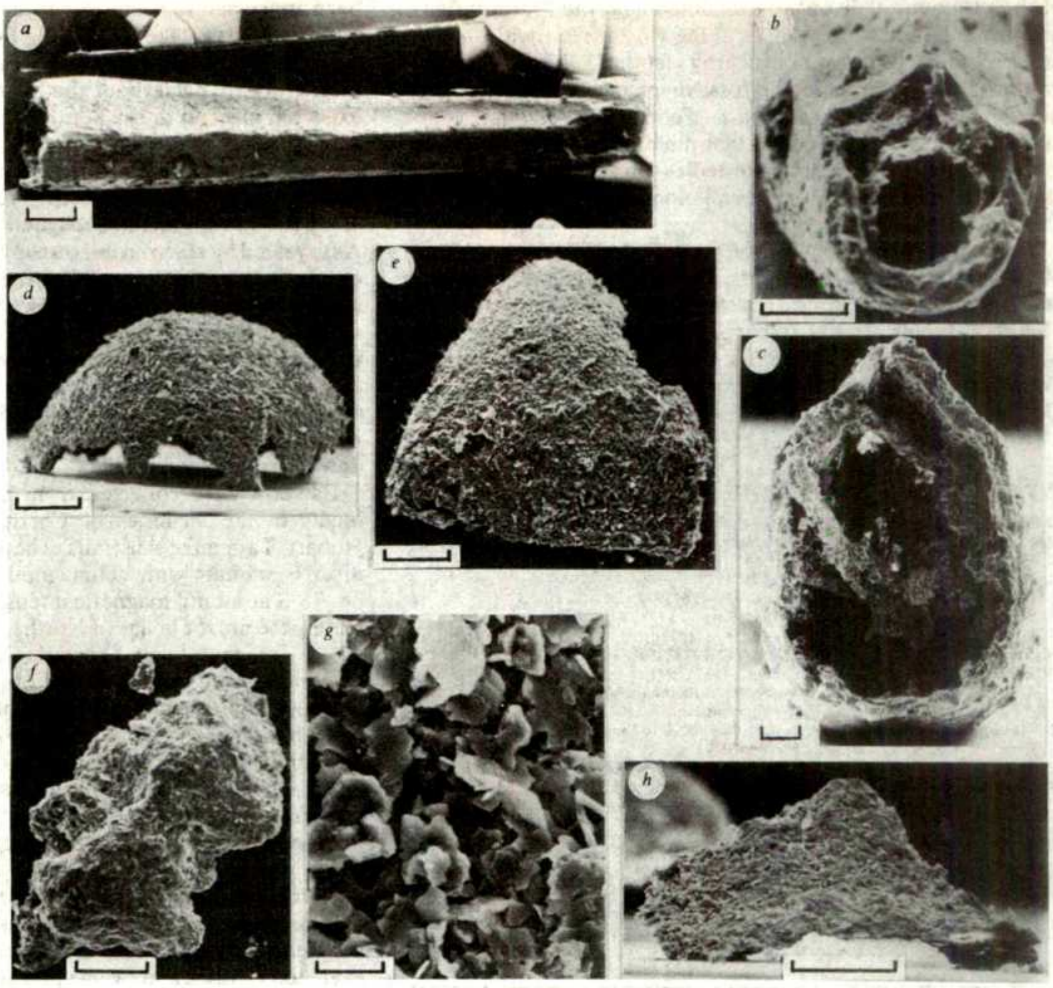

Fig. 3 Scanning electron micrographs of gold–palladium coated microfossils from GSC locality 94597. Each specimen is given a type number for storage in the National Type Fossil Collection, Geological Survey of Canada, Ottawa. *a–c*, *Protohertzina* cf. *anabarica* (GSC 45338). *a*, Posterior view; *b*, transverse section of distal end; *c*, transverse section of proximal end. *d–e*, Silicified concavo–convex microfossils of uncertain systematic position. *d*, Side view of GSC 45339; *e*, top view of GSC 45340. *f–h*, Microfossils, composed of agglutinated clay plates, possibly of foraminifer affinities; *f*, top view of GSC 45341; *g*, detail of exterior surface of GSC 45342 showing clay plates; *h*, side view of GSC 45343. Scale bars, 20 μm (*g*); 100 μm (*b*, *c*); 200 μm (*a*, *d*, *e*, *f*, *h*).

end of an evolutionary series leading to the true or eucondonts[4]. (2) Approximately 12 fossils composed of agglutinated platy grains, apparently of a clay mineral (Fig. 3*g*). The fossils are roughly orthoconical and in basal outline are irregularly oval (Fig. 3*f*, *h*). Several phyla have representatives with agglutinated tests, but the small size of these fossils prompts comparison with protistans and in particular the Foraminifera. The Lower Cambrian *Platysolenites* and *Spirosolenites*, regarded as the earliest agglutinated foraminifers, have a tubular form that is elongate in *Platysolenites* and coiled in *Spirosolenites*[13,14]. The agglutinated foraminifer *Iridia*, which belongs to the primitive suborder Allogromiina[15] has an irregularly hemispherical test, although with pseudochitinous base. As such a base is most unlikely to be fossilized, a comparison between the extant *Iridia* and these fossil forms may be valid (no intimate systematic relationship is at present claimed), and individuals of the latter may have lived adpressed to the substrate with pseudopodia extending from the margins. (3) About 200 silicified fossils with a pronounced concavo–convex shape (Fig. 3*d*, *e*). The degree of convexity varies, but hemispherical types predominate. In basal outline the specimens are usually slightly oval, but more elongate configurations are not uncommon. The lack of diagnostic shape or surface ornamentation precludes any useful speculation on their zoological affinites. This assemblage may well contain several different taxa. Use of very dilute acid (~1%) during rock digestion may produce more complete specimens.

Protohertzina anabarica has been recorded from the Siberian Platform (Anabar Shield) and Kazakhstan (Malij Karatau Ridge)[10]. In the north-west region of the Anabar Shield *P. anabarica* ranges through the latest Precambrian (?) Nemakit-Daldyn (= Manykay) Horizon[10], and in Kazakhstan it occurs in equivalent strata[16]. The Nemakit–Daldyn Horizon, which has been correlated with the upper beds of the Yudoma Suite in the classic Aldan River sections (refs 1, 2 and Rozanov in ref. 17), has a sparse shelly fauna which in addition to protoconodonts includes the worm tubes *Paleolina* and *Anabarites trisulcatus* (ref. 1 and Savitsky in ref. 17). A richer shelly fauna of Tommotian aspect has, however, been discovered close to the top of the Horizon near the type locality for *P. anabarica*[10] on the Kotujkan River in the Anabar Shield[18]. Current Soviet usage[1,2] generally places the Precambrian–Cambrian boundary at or very close to the first appearance of this richer fauna. Microfossils identified as *P. anabarica* have also been reported from the upper part (Huangshandong, Zhongyicun and Siaowaitoushan members; the latter two formerly comprised the Meischucun Formation) of the Tongying Formation[12,19] which is regarded as equivalent to the Tommotian of Siberia.

The presence of *P.* cf. *anabarica* in map unit 11 suggests that it is probably equivalent to part of the Nemakit–Daldyn Horizon or the lowermost Tommotian. Thus, according to current Soviet definition, the unit is close to the Precambrian–Cambrian boundary. If this correlation is correct the equivalents of the Tommotian Stage probably lie within map unit 12 and perhaps 13 (Fig. 2). The possibility remains that *P.* cf. *anabarica* has a higher stratigraphic range in the Mackenzie Mountains, but the great stratigraphic sequence (3,065 feet, 934 m) between *P.* cf. *anabarica* and the lowest Cambrian trilobites indicates otherwise.

Additional samples from the Mackenzie Mountains and elsewhere in the North American Cordillera are being processed, but the paucity of carbonate beds near the Precambrian–Cambrian boundary means that recovery of further microfossils may be limited. Recovery of other microfossils, such as acritarchs, through the use of stronger acids on clastic rocks has only begun and has so far met with limited success. Trace fossils in section 35 and nearby sections[7] should be studied for evidence of the pronounced diversification noted near the Precambrian–Cambrian boundary elsewhere in the world (see review in ref. 20). Preliminary field work at nearby section 33 (Fig. 1) provides grounds for optimism that this fossil diversification also exists in the Mackenzie Mountains (M. Fedonkin, personal communication). It is to be hoped that the diversification events in trace and shelly fossils can be tested against each other thereby improving intercontinental correlation of the Precambrian–Cambrian boundary.

We thank S. Bengtson, J. W. Cowie, G. S. Nowland and S. C. Matthews for helpful comments, J. Taylor, J. Hill, D. Newling and R. Carlton for technical assistance and P. Hammond and A. Mahoney typing. Initial research by S.C.M. was undertaken whilst a Research Fellow of St John's College, Cambridge. W.H.F. publishes with the permission of the Director of the Geological Survey of Canada.

South-seeking magnetotactic bacteria in the Southern Hemisphere

R. P. Blakemore*, R. B. Frankel† & Ad. J. Kalmijn‡

* Department of Microbiology, University of New Hampshire, Durham, New Hampshire 03824

Several species of aquatic bacteria which orient in the Earth's magnetic field and swim along magnetic field lines in a preferred direction (magnetotaxis) have been observed in marine and freshwater sediments of the Northern Hemisphere[1,2]. Their orientation is due to one or more intracytoplasmic chains of single-domain magnetite particles[3]. These linearly arranged particles impart a net magnetic dipole moment to the bacterium, parallel to the axis of motility. Northern Hemisphere magnetotactic bacteria with unidirectional motility swim consistently in the direction of the magnetic field, that is, to the geomagnetic North[1,2,4]. This implies that their magnetic dipole is systematically orientated with the North-seeking pole forward. The magnetic polarity can be reversed by single, magnetic pulses of high field strength (1–2 μs, 300–600 G), and these bacteria then swim along magnetic field lines to the South[5]. Due to the inclination of the Earth's magnetic field, magnetotactic bacteria which swim to the North in the Northern Hemisphere are directed downward at an angle increasing with latitude. It has been suggested that this downward-directed motion confers a biological advantage by guiding the bacteria, when dislodged, back to the sediments[1]. On the basis of this hypothesis, magnetotactic bacteria of the Southern Hemisphere would be expected to swim to the South to reach the bottom. We report here several morphological types of magnetotactic bacteria present in sediments of the Southern Hemisphere. These bacteria indeed swim consistently to the South, hence downward along the Earth's inclined magnetic field lines, as hypothesized. As revealed by electron microscopy, they contain internal chains of electron-opaque particles similar to those observed in magnetotactic bacteria from the Northern Hemisphere. Like their Northern Hemisphere counterparts, their magnetic polarity can be permanently reversed and they cannot be demagnetized. We also report on Northern Hemisphere magnetotactic bacteria incubated in Southern Hemisphere magnetic conditions, confirming the biological relevance of downward directed motility.

Bacteria were collected from marine and freshwater sediments in the vicinities of Christchurch, New Zealand, and Hobart, Tasmania, Australia. These locales offered ecologically diverse habitats with geomagnetic characteristics (inclination 68–73°S at a total magnetic intensity of 0.59–0.63 G) approximately the mirror image of Northern Hemisphere environments where magnetotactic bacteria are found. Magnetotactic responses were recorded by optically monitoring bacterial motion in uniform magnetic fields of 0.2–2 G, provided by a pair of Helmholtz coils mounted to either side of a Zeiss OPMI 1 operation microscope (magnification ×83.2; working distance, 10 cm). The Helmholtz-coil axis was aligned with the horizontal component of the Earth's magnetic field; the polarity of the imposed field was selected by a toggle switch. The coils and the dark-field illuminator were battery operated. In the coil system, both freshwater and marine bacteria migrated along magnetic field lines in the direction opposite to that indicated by a magnetic compass needle. On reversal of the field, the organisms executed U-turns and swam opposite to the initial direction. The rates of migration were comparable to those observed in Northern Hemisphere bacteria. Thus, the magnetotactic responses of Southern Hemisphere bacteria are similar to those of the Northern Hemisphere species, except for their magnetically opposite direction of migration (South-seeking magnetotactic bacteria have also been observed in Victoria, Australia[6]).

Transmission electron microscopy of bacteria magnetotactically separated from sediments was carried out at the University of Canterbury, Christchurch, New Zealand, using a Hitachi HS-7S electron microscope operating at 50 kV. Samples were placed on parlodion-coated, carbon-reinforced, 300-mesh copper grids, and were lightly stained with uranyl acetate. Magnetic cells of various morphological types were observed to contain one or two chains of intracytoplasmic electron-opaque particles which vary in size and shape with cell type (Fig. 1). Thus, Southern Hemisphere magnetotactic bacteria also possess magnetosomes[7], the characteristic morphological feature of all magnetotactic bacteria examined thus far.

To establish the ferromagnetic nature of their orientation mechanism, bacteria were subjected to alternating 50-Hz magnetic fields over 1,000 G, produced by a small hand-held magnetic tape degausser (Tandy Corporation). Northern Hemisphere and Southern Hemisphere magnetotactic bacteria were examined in separate water drops on a microscope slide before and after exposure to the alternating magnetic field. On exposure, the degausser was slowly moved away from the water drops to obtain the field decay required for demagnetization. Whereas before exposure all the cells in these samples swam exclusively either to the North or to the South, after exposure each sample contained approximately equal numbers of North- and South-seeking cells. Magnetic reversals were also effected by approaching individual bacteria at the water–air interface with a sharp, magnetized needle. These observations indicate that bacteria from both hemispheres physically function as single-domain magnetic dipoles, in agreement with previous

0028–0836/80/300384—02$01.00

remagnetization studies using strong magnetic pulses of short duration[5].

In experiments carried out in Massachusetts, sediment samples containing North-seeking bacteria from New England were placed in an experimental chamber in which the vertical component of the local Earth's magnetic field was inverted, reproducing conditions in the Southern Hemisphere. Control samples were placed in a similar chamber with a field of normal inclination. The polarities of cells from the samples were determined periodically for several weeks, that is, over many generations. Whereas all samples contained almost exclusively North-seeking cells at the beginning of the experiment, with time the number of North-seeking cells in the experimental chamber decreased dramatically, and South-seeking bacteria gradually predominated. In the control samples no such changes occurred. Thus, downward-inclined fields select for North-seeking bacteria whereas upward-inclined fields select for South-seeking cells. This demonstrates that the vertical component of the Earth's magnetic field is the relevant parameter determining the predominant cell polarity.

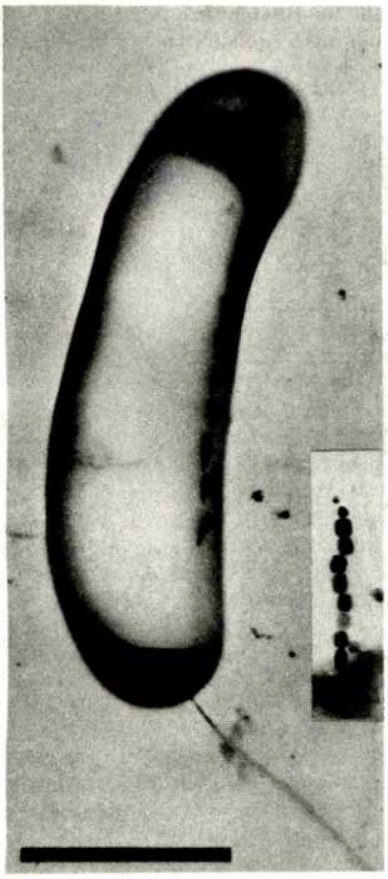

Fig. 1 Electron micrograph of a magnetotactic bacterium separated magnetically from freshwater sediments of New Zealand and stained with uranyl acetate. Inset shows one of two chains of particles found in a freshwater magnetotactic coccus of New Zealand. Both photographs are presented at the same magnification (scale bar = $1\ \mu m$). Whereas the particles shown in the inset are similar to those found in Northern Hemisphere magnetotactic bacteria, those in the rod-shaped species have a novel shape.

In conclusion, the prevalence of South-seeking magnetotactic bacteria in Southern Hemisphere sediments and in samples held in similar magnetic conditions in the Northern Hemisphere verifies the hypothesis that downward-directed motion is advantageous for and upward-directed motion detrimental to the survival of these magnetotactic bacteria with unidirectional motility. Magnetotaxis is a reliable means of keeping these microorganisms in or near the bottom sediments. As particles in the micrometre size range with densities close to 1.0 tend to remain suspended in water, gravity is virtually inconsequential in determining the vertical distribution of the bacteria.

The Earth's magnetic field provides a global orientation cue to which various organisms are known to respond. Only recently have detection mechanisms based on electromagnetic induction[8] and ferromagnetic alignment[5,9] been explained. In the bacteria, nature has shown the biological feasibility of synthesizing a highly organized ferromagnetic structure equivalent to a magnetic compass needle.

We thank Nancy Blakemore for her participation in the expedition to New Zealand and Tasmania, Australia, Drs T. Cole, L. Greenfield and W. D. Parkinson for hospitality and co-operation, M. Ingerfeld for assistance with electron microscopy, and H. Stram, D. Lobel, J. Perc, V. Kalmijn and T. Dourdeville for valuable contributions to this work. This work was supported by a research grant from the National Geographic Society, and the Office of Naval Research. Laetoli Pliocene hominid footprints and bipedalism

M. H. Day

Department of Anatomy, St Thomas's Hospital Medical School,
London SE1 7EH, UK

E. H. Wickens

Department of Photogrammetry and Surveying, University College
London, Gower Street, London WC1 EGBT, UK

The ability to stand upright and walk on two legs is widely recognized as a crucial hominid adaptation that had profound effects on the course of human evolution. The relief of the upper limb from the task of supporting the trunk in locomotion would have permitted the efficient carriage of food, infants and later tools and weapons. Any or all of these activities could, it is believed, have improved the differential survival of early hominids. Precisely when upright stance and bipedal gait were first acquired within the hominid evolutionary line is not known, and so the discovery of apparently bipedal footprints of Pliocene age at site G, Laetoli, Tanzania is important in itself[1,2]. A study of the footprints, reported here, has shown that when these hominids walked, they transmitted their body weight and the forces of propulsion to the ground in a manner very similar to that of modern man.

Most of the evidence for early hominid upright posture and bipedal gait has been deduced from the anatomy of fossil hominid lower limb and pelvic bones from several African sites, including Sterkfontein and Swartkrans in the Republic of South Africa, Olduvai Gorge in Tanzania, Koobi Fora (formerly East Rudolf) in Kenya and the Afar site in Ethiopia[3–11]. Opinions have varied as to the degree of adaptation to bipedalism that the

0028–0836/80/300385—03$01.00

study of these fossil remains has disclosed[12-17]. The dates recorded for the sites where fossil hominid lower limb and pelvic bones have been found span from about 1.5 to 3.0 Myr BP, so that the discovery of what are believed to be bipedal footprints in 1978 and 1979 in a tuff dated at 3.6–3.75 Myr BP has added nearly 0.75 Myr to the known antiquity of bipedalism.

The fossil footprints of three individuals were made in a fine grained volcanic ash that subsequently became damp, perhaps after rain, and consolidated into a tuff retaining the imprints, often in considerable detail.

Because footprints made during walking reflect the way in which weight and propulsive forces are transmitted to the ground, we have compared the fossil footprints with those of modern man made experimentally on ground of similar consistency. Modern human footprints were made by walking over wet sand (grade 25/52, that is 0.30–0.6-mm grain size) in the laboratory so that clear impressions were made and retained for stereophotography. The instrument used was an Officene-Galileo stereometric camera on a 560-mm base, and the stereo images produced were contoured at 2-mm intervals on a Thompson–Watts Mk 2 plotting instrument. This technique—photogrammetry—is widely used by surveyors and map-makers as a precision method of determining surface form. The experimental footprint contour diagrams (Fig. 1) show the various depths that resulted from the differing pressures exerted on the ground in walking; the darker the colour, the deeper the impression. Similar diagrams were prepared from stereophotographs of replicas of three fossil footprints from two individuals (Figs 2, 3).

The remarkable similarities between the modern human footprint contour patterns and those of the fossil hominids can be seen at a glance. In more detail, heel and ball impressions are clear and transfer of weight and force progresses from heel to ball on the outer side of the foot outlining a medial arch. The heel and ball impressions are deep and surrounded by an irregular figure-of-eight pattern in each case. The ball impressions have oblique principal axes that run anteromedially towards the base of the great toe, where the impressions are especially deep, and lead on to the great toe impression itself as it digs into the soft ground during walking.

The similarity of the contour patterns of the three fossil footprints to the modern human examples is striking confirmation of the bipedal nature of the gait of the Laetoli Site G hominids already claimed from the footfall sequence[1,2]. The pattern of weight and force transference through the foot, well known in modern man[18], also seems to be very similar in the

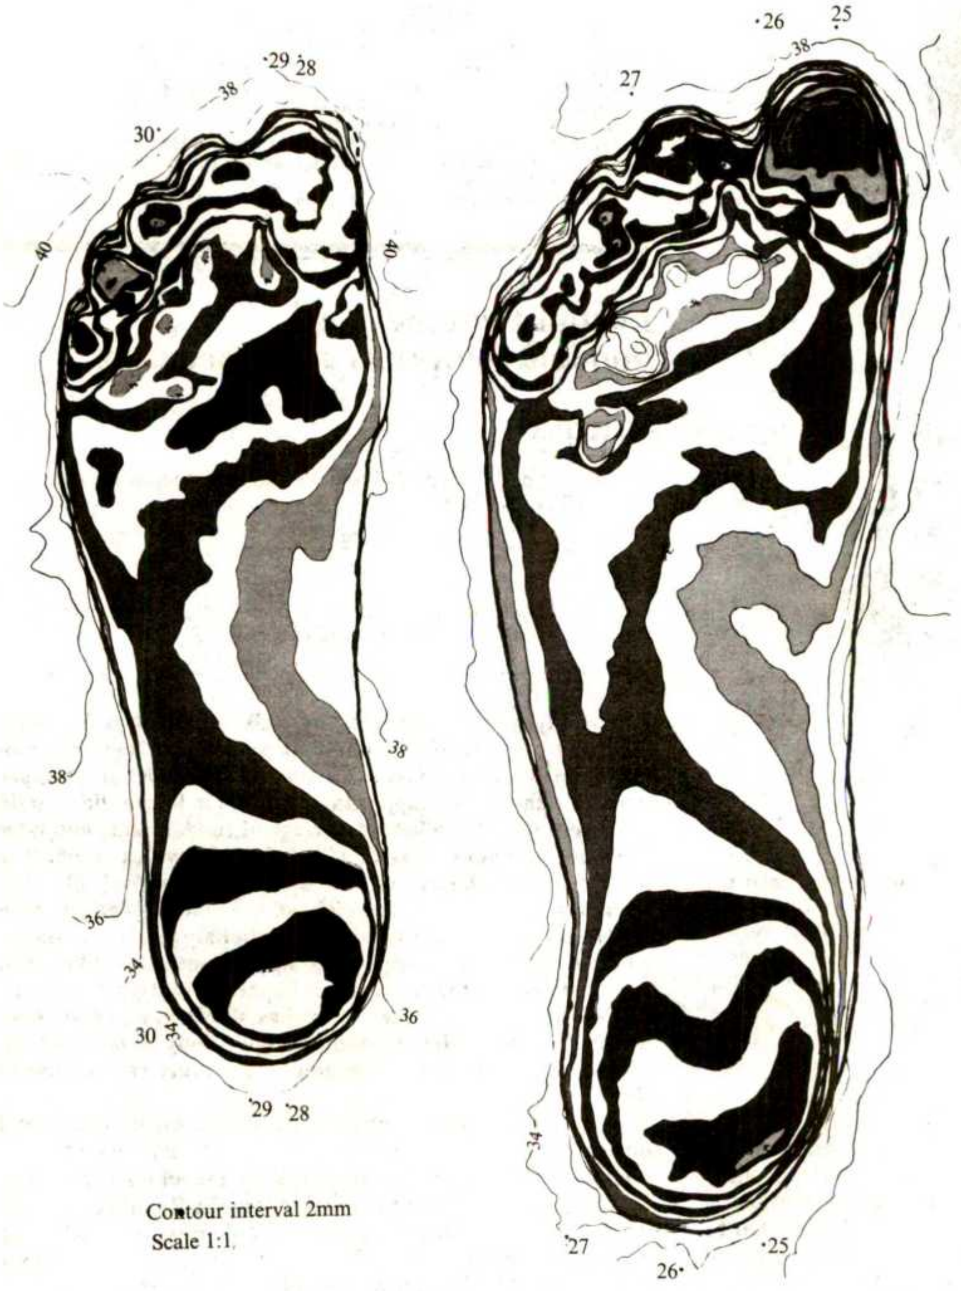

Fig. 1 Modern human female (*a*) and male (*b*) soft ground walking footprints. Contoured at 2-mm intervals.

fossil footprints and indicates that even at this early stage of hominid evolution bipedalism had reached an advanced and specialized stage. Ironically these fossil hominid footprints from Laetoli provide locomotor evidence without a single adult fossil hominid limb bone being known from the site. Nonetheless Pliocene hominid footprints, and their comparison with experimental modern human equivalents, may well prove to be more convincing evidence of early hominid bipedalism than osteological or morphometric analysis of fossil bones.

We thank Dr Mary Leakey for the opportunity to examine the Laetoli footprints; Mr A. A. Mturi, Director of Antiquities, Tanzania, Mr A. J. N. Mgina, Ngorongoro Conservation Authority, for help and cooperation; the Research Endowments Committee at St Thomas's Hospital for support, and colleagues in the Department of Photogrammetry and Surveying, University College London.

Environmental preference induced experimentally in ants (Hymenoptera: Formicidae)

Pierre Jaisson

Equipe de Recherche Associée au CNRS no. 885, Laboratoire d'Ethologie et Sociobiologie, Université Paris-Nord, Avenue J.B. Clément, 93430 Villetaneuse, France

In ants, early experience seems to influence the development of aggression[1,2] and the recognition of cocoons[3–6], but there has been no investigation of such influences on the ants' relationship with their habitat. There are, however, many descriptions of the use of plants as nests (*Azteca*[7], *Colobopsis*[8], *Oecophylla*[9] and *Pseudomyrmex*[10], for example), while habitat selection based on early experience is known among some vertebrates, principally amphibians[11–13], birds[14] and mammals[15]. In this context, my hypothesis is that the preference of an ant for a plant can be induced on the basis of previous entrainment to a plant stimulus. Using ants of the sub-family Formicidae, *Camponotus vagus* Scop. and *Formica polyctena* Först., I have demonstrated that early experience can induce an environmental preference and may explain specific associations that can be found in the wild between ants and plants.

C. vagus and *F. polyctena* seem to have close affinities with plants. The former lives inside wood, while the latter builds nests of twigs or pine needles. The two species are common in France, and colonies were collected either in Provence (near Vaison-la-Romaine, Vaucluse) in the case of *C. vagus*, or the Rambouillet forest (Yvelines). Laboratory colonies were established using very young ants which all emerged on the same day and which were placed in a glass tube (22 × 2 cm) with a source of water at the closed end, providing the necessary humidity; an envelope of black card obscured the light.

Colonies comprised 25–45 individuals, depending on the number of ants eclosing weekly. Three 5-cm sprigs of thyme (*Thymus vulgaris* L.) were placed near the water reservoir in the experimental colonies. Control colonies had no thyme. Sprigs were replenished each week during the training period which lasted 30 days for *C. vagus* and 21 days for *F. polyctena*. Food consisted of honey and water. All colonies were then transferred to tubes without thyme for 24 h; then, anaesthetized with carbon dioxide, each colony was put into a plastic box equidistant from two lateral horizontal plastic tubes fixed into the sides, one of which was randomly chosen to contain thyme (to avoid any effect of laterality).

Each tube was a potential nest. The apparatus was illuminated isotropically, with white light, so that the interior of each tube (covered by an envelope of black card) was relatively dark. On recovery from anaesthesia, the ants, avoiding the light, explored the box and finally chose the shade in one of the tubes. On the following day the ants in each tube were counted. This choice test was applied to 15 control and 9 experimental colonies of *C. vagus*, and 9 control and 13 experimental colonies of *F. polyctena*. The few ants remaining in the box were also counted but not included in the determination of colony preference. This preference was evaluated as the difference between the number of ants that chose the nest with thyme and the number that chose the nest without thyme.

Table 1 shows that all colonies of *C. vagus* trained to the thyme stimulus chose the tube containing thyme. Conversely, all but one of those familiarized to an environment without thyme preferred the tube without thyme. But even this colony, although found in the tube that had contained thyme at the beginning of the test, moved all the sprigs into the plastic box. Nevertheless, I decided that this colony had chosen the thyme side. In fact, the two tubes were empty when the count was made.

Table 1 Behaviour of young *C. vagus* and *F. polyctena*

		N	*T*+	*T*−	*d*
C. vagus	Experimental colonies	9	171	41	9
	Control colonies	15	72	330	1
F. polyctena	Experimental colonies	13	348	33	11
	Control colonies	9	89	181	2

Experimental colonies comprised 25–30 workers, and control colonies 30 workers for *C. vagus*; experimental and control colonies comprised 25–45 workers for *F. polyctena*. *N*, number of colonies; *T*+, ants that preferred the tube with thyme for all colonies; *T*−, ants that preferred the tube without thyme; *d*, colonies in which *T*+ > *T*−.

I used non-parametric statistical analysis: at the colony level, the χ^2 total correlation is highly significant ($\chi^2 = 16.5$; $P < 0.01$). This analysis was applied to all the colonies to test the nul hypothesis of a randomized distribution of the colonies between two possibilities (preference for thyme/preference for empty tube). The same test applied only to each group as a whole (experimental or control) confirms my first observations: in both cases the probability that the results represent a randomized distribution of the colonies during the choice test is less than 0.01. Thus the preference of the experimental group for the nest containing thyme is significant ($\chi^2 = 8.8$), as is that of the control group for the empty nest ($\chi^2 = 11.3$).

Wilcoxon's test gave the same results, but more precisely than χ^2. It enabled me to classify the colonies on the basis of the difference between the number of ants in the colony that preferred the tube with thyme and the number in the colony that preferred the empty tube. In other words, it enabled me to associate the qualitative and quantitative aspects of the preference (the tables show only the total group values).

In terms of the number of ants involved (namely their individual preference), χ^2, either total or calculated for each of the two groups, is highly significant, regardless of the fact that the colonies were artificially set up. However, there is a need for caution because each ant's choice between the two artificial nests is not standard: each new entry into a tube may be qualitatively different from the preceding entry.

The same applies to *F. polyctena*, as Table 1 shows, although after choosing the tube containing thyme, the two control colonies did not expel the sprigs. The same statistical treatment shows again that the behaviour of the colonies as a whole was heterogeneous ($\chi^2 = 6.19$; $P < 0.02$) and the experimental colonies had a significant preference for the tube containing thyme ($\chi^2 = 6.23$; $P < 0.02$). But the same test applied to control colonies gives a non-significant value ($\chi^2 = 1.77$). Wilcoxon's test does not improve the precision (only significant for the experimental group). However, the comparison of individual ant preference for the tube without thyme in the controls becomes significant ($\chi^2 = 31.3$; $P < 0.01$); nevertheless, it should be remembered that treatment of the individual results increases the information but modifies somewhat the significance of the choice test.

Thus, the behaviour of these two species differed according to previous experience: the experimental colonies, trained to thyme, chose the tube containing it, while the control colonies preferred the tube without thyme. However, these results were more clear-cut for *C. vagus*.

To test the possible importance of age, I examined environmental preference in older ants, collected from nests in the same localities as before. These experiments were carried out at the end of the season, when I could form only seven

0028-0836/80/300388—02$01.00

colonies of *C. vagus* and five of *F. polyctena*, to which the same training period and bioassay was applied. Table 2 shows, first, that adult ants reared in the presence of thyme suffered heavy mortality: 48.6% for *C. vagus* and 56.6% for *F. polyctena* (compared with 9.8% and 5.8% for the young ants). It seems to be deleterious for naive adult ants to be exposed to this plant, for which they have a spontaneous aversion (as known already in insects[16]). The aversion was revealed by the distribution of the workers, especially at the beginning of the training period: most of them remained close to the sprigs, rather than within the thyme as the young workers had done.

In the choice test, statistical analysis revealed responses much less clear than for the young ants. Preference for the empty tube seemed to be clear-cut for *C. vagus* ($\chi^2 = 5.14$; $0.05 > P > 0.01$), but not significant for *F. polyctena* ($\chi^2 = 5.26$; $0.05 > P > 0.01$).

Adult ants trained to the thyme always seemed to prefer a tube without thyme, even if this preference (in particular for *F. polyctena*) appeared less pronounced than for control colonies. Although the high mortality of the adults exposed to thyme affected the number of individuals, the sensitivity of the young workers seemed to be greater and their age more favourable for the establishment of an environmental preference.

The behaviour of workers in the presence of thyme varied according to age. Mature ants avoided contact with the plant more often than not, while the young ants entered the sprigs. This difference may enable the latter to develop an active preference for thyme on the basis of its presence during the neonatal period.

Table 2 Behaviour of mature *C. vagus* and *F. polyctena*

	N	*T+*	*T−*	*d*
C. vagus	7	11	115	0
F. polyctena	5	28	48	2

In each case there were 35 worker ants.

There have been reports of avoidance conditioning in mature ants for the odour of peppermint (used as a conditional stimulus)[17,18]. But the preference reported here could resemble more the olfactory conditioning discovered by Thorpe and Jones[19], as in two species of *Drosophila*[20,21], which if reared in a culture medium scented with peppermint oil, later showed a positive response to that odour. However, that phenomenon, which is difficult to interpret[22], develops only when peppermint is presented simultaneously with food during training[23]. Conversely, in my experiments food was presented very briefly at the nest entrance, away from the thyme.

I suggest that the induction of the preference for thyme in young ants is due to either passive familiarization or an association between favourable environmental factors (for example darkness and/or humidity in my experiments) and the odour of the plant. The repulsive nature of plant odour for young ants has not been established, and their sensory receptors might increase progressively in sensitivity as the ants develop, as shown for the phytophagous larva of *Manduca sexta* reared on a plant that it normally finds unacceptable[24]. A mechanism of this type, but independent of feeding, may contribute to the development of relationships of the sort involving the ants *Azteca* or *Pseudomyrmex*, which live exclusively on the plants *Cecropia* or *Acacia*, respectively.

Orientation bias of cat retinal ganglion cells

W. R. Levick & L. N. Thibos

Department of Physiology, John Curtin School of Medical Research, Canberra, Australia 2601

Kuffler[1] described the receptive fields of cat retinal ganglion cells as having a concentric arrangement. This has usually been taken to mean that they are approximately circular in form (see, for example, ref. 2). Hammond[3] tested the circularity of the centre component of receptive fields by plotting a contour of isosensitivity to a small flashed spot. He concluded that centres were often elliptical (average ratio of major to minor axis 1.23) and that more than 50% of the recorded cells had the major axis oriented within ±20° of the horizontal. Such data are important for discussions[4] of the neurophysiological basis of the 'oblique effect' (reduced visibility for periodic grating patterns when oriented away from the vertical or horizontal) observed in psychophysical experiments on humans because subcortical units are often assumed to be orientationally unbiased. Orientation selectivity is a prominent attribute of visual cortical neurones[5] so analysis has usually emphasized the distribution of orientation selectivity at that level[6–8]. The results presented here redirect attention to the retinal level since they reveal a previously unsuspected systematic relation between orientation bias of ganglion cells and their location relative to the area centralis.

Experiments were conducted on adult cats anaesthetized for surgical procedures with 1–2% Fluothane and maintained during data collection on a 70:28·5:1·5 mixture of nitrous oxide, oxygen and carbon dioxide, usually supplemented by intermittently administered urethane (about 0.6 g per day). Eye movements were controlled by continuous infusion of gallamine (5 mg per kg per h) and tubocurarine (0.7 mg per kg per h). The paralysis necessitated artificial ventilation. Extracellular recordings were made from ganglion cells with a tungsten-in-glass electrode[9] passed through a cannula penetrating the globe so as to leave the natural optical system undisturbed. Because optical quality of the retinal image may influence results special precautions were taken as follows. Corneal refraction was modified with a plastic contact lens of spherical form and zero power. The resulting ocular refraction was measured with a Hartinger refractionometer. The point of passage of the axis of the instrument through the dilated natural pupil (1% atropine drops) was adjusted so as to minimize astigmatism. An artificial pupil (3 mm diameter) was centred on this axis and close (about 1 mm) to the contact lens. The combination of spherical and cylindrical lenses indicated by the refractionometer was placed next to the pupil and further measurements were made to confirm the emmetropic state.

The stimulus was a sine wave grating (contrast 0.5, mean luminance 82 cd m^{-2}) drifting slowly (2 bars per s passing a given point) across the receptive field. The pattern was generated as a raster on the face of a cathode ray tube (Tektronix 608) which

0028–0836/80/300389—02$01.00

was centred on each receptive field in turn by means of a gimbal mounting. The orientation of the bars of the grating was controlled by a Dove prism also carried on the gimbal. The visual subtense of the pattern through the prism was about 20°. The screen was focussed at optical infinity with a +4 dioptre lens placed close to the prism between screen and prism. A computer (Hewlett Packard 2100) controlled both the production of the raster and the measurement of trains of impulses constituting the responses of a ganglion cell. The instant when a particular phase of each cycle of the grating passed the centre of the screen provided the synchronization for accumulating usually 100 cycles of response as a 'peri-stimulus time histogram' (PSTH).

As the spatial frequency of a grating was increased over the range 0.03–8 cycles per degree, modulation of a ganglion cell's discharge first increased to a maximum, then decreased. By working near the high-frequency limit for a modulated reponse from each ganglion cell it was easy to find instances where response modulation was strongly influenced by grating orientation. The orientations yielding maximum and minimum modulation were generally 90° apart. Two obvious examples are shown in Fig. 1. A convenient measure of response is the amplitude of the first harmonic component obtained by Fourier analysis of the PSTH. In the examples of Fig. 1 the ratio of maximum to minimum response was 3.2 for unit 1 and 10.7 for unit 2. In a sample of 250 units from five cats the distribution of the ratio ranged from 1.0 to 18.7 with the median at 1.86. By extrapolating the relations between response and spatial frequency to determine the spatial frequency at zero response ('cutoff frequency') for best and worst orientations, the behaviour may also be expressed as a ratio of cutoff spatial frequencies. Ratios of up to 1.6 have been encountered. Clearly the orientation dependence is a definite effect. However, the dependence was insignificant in 30% of the cells tested and this may explain why it was not reported previously[2].

In several animals where data were collected from many ganglion cells in a local patch of retina, it became evident that there was a clustering of best orientations. Patches from various locations had different best orientations. The central tendency of best orientations seemed to be consistently parallel to the line joining the patch to the area centralis. The uncertainties of combining diverse data from various animals influenced us to examine a substantial number of ganglion cells in a single preparation. A sequence of recordings was made along an approximately circular trajectory completely encircling the area centralis. Each unit was assessed as in Fig. 1 and the best orientation recorded as that yielding the maximum modulated response. The position of the centre of each receptive field was transferred to a fundus photograph with the aid of three independent assessments: (1) direct ophthalmoscopic visualization of the electrode tip relative to the pattern of retinal blood vessels; (2) hand mapping of receptive field centres on a frontal tangent screen; (3) noting azimuth and elevation readings on the gimbal carrying the centred cathode ray tube. The photograph was also marked with the centre of the area centralis estimated from the peak of ganglion cell density in the cresyl violet stained whole-mount of the retina and correlation of the blood vessel pattern in whole-mount and photograph.

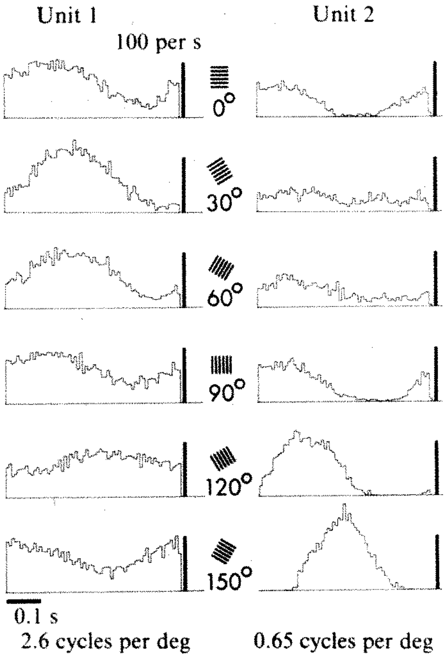

Fig. 1 Peristimulus time histograms (8 ms bin width) of responses to a sinusoidal grating (contrast 0.5) at various orientations (indicated schematically down centre column) drifting at a constant rate (2 c.p.s.) across the receptive field of two ganglion cells: left, on-centre brisk-sustained type; right, on-centre brisk-transient. Same vertical scale (solid bar at right of each, 100 impulses per s) for all PSTHs. Spatial frequencies indicated at bottom are just below the highest resolvable by each unit. The preferred orientations were judged to be 30°, 150° respectively. The positions of the cells relative to the area centralis are indicated (1, 2) in Fig. 2.

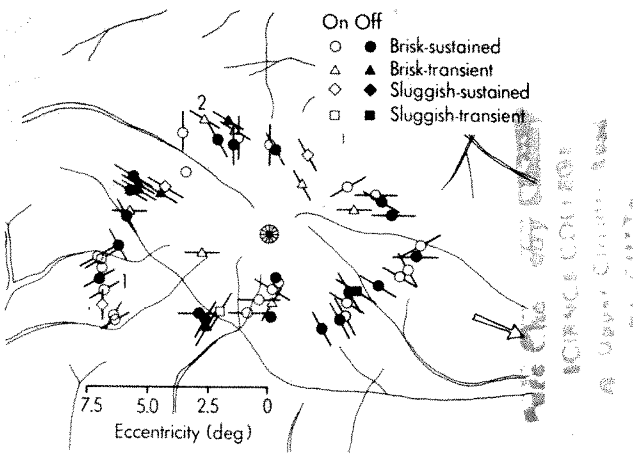

Fig. 2 Preferred grating orientation in relation to retinal location. Positions of receptive fields are indicated by symbols (keyed to unit class, top right) on a tracing of a fundus photograph showing pattern of blood vessels and centre of area centralis (spoked wheel symbol). A line through a symbol indicates the preferred orientation of that unit (no line–no orientation bias). The two units of Fig. 1 are distinguished: 1, 2. The arrow points along the line from area centralis to optic disk.

The result is displayed in Fig. 2 which is a tracing of the fundus photograph. Out of 57 units examined, 52 showed definite orientation bias. Their positions and best orientations are indicated. It is evident in a statistical sense that orientation bias was systematically related to retinal locus. A similar result was obtained in another experiment of the same design. The effect was observed in all classes of concentrically organized ganglion cells[10].

A particular point of interest in these results is that they indicate retinal regions where the information sent to the brain is biased in favour of obliquely oriented gratings. As far as we are aware, eccentric regions along oblique meridians have not been systematically explored in human psychophysical experiments.

Voltage clamp discloses slow inward current in hippocampal burst-firing neurones

Daniel Johnston & John J. Hablitz

Hippocampal pyramidal cells, among the most-studied cortical neurones, display several interesting properties. In particular, intracellular recordings in both *in vivo*[1] and *in vitro*[2] preparations have shown that the pyramidal neurones of the CA3 region of the hippocampus have, in addition to the more conventional single spike, the capacity to generate spontaneous bursts of action potentials (APs). The burst-firing patterns have been well documented, but their underlying electrophysiological mechanisms are not completely understood. The bursts seem to be an intrinsic response of individual neurones and can be triggered by weak orthodromic stimulation or by direct depolarization of the somatic membrane. In molluscan and spinal systems, voltage-clamp techniques have revealed slow, voltage-sensitive, inward currents underlying this type of firing behaviour[3–7]. The use of these voltage-clamp techniques to study this phenomenon in hippocampal neurones has previously been precluded by the small size of the neurones and by the difficulty of recording from them in intact preparations. However, the development of methodology for voltage-clamping with a single microelectrode (SEC)[8] and for the maintenance of hippocampal slices *in vitro*[9] has made it possible for us to examine the membrane currents in these CA3 neurones. We report here a slow inward current in CA3 neurones and suggest that it is carried by calcium ions.

Experiments were carried out on hippocampal slices from guinea pigs weighing 300–700 g. Slices 400–600 μm thick were cut transverse to the longitudinal axis of the hippocampus and maintained *in vitro*, using standard techniques[9,10]. Intracellular recordings were obtained from CA3 neurones, using 3 M KCl- or 2 M CsCl-filled micropipettes (30–50 MΩ). Electrodes were selected carefully for current-passing capability and for rapid decay of tip potentials following cessation of current.

The circuit used for voltage clamping is based on that of Wilson and Goldner[8,11]. The technique uses a single microelectrode and rapid switching (3,000 Hz) between voltage-recording and current-passing modes. The membrane potential is sampled after the potential across the microelectrode has decayed and just before return to the current-passing mode. The sampled potential is fed into a standard voltage-clamp circuit and determines the amplitude of the next current pulse. For excursions of approximately ±30 mV from rest, a steady potential could be reached within 2 ms.

A standard voltage-clamp protocol was used, whereby step depolarizing commands were given to the cell while the current response was monitored. Figure 1*a* shows the response of a CA3 neurone, bathed in saline containing 1 μg ml^{-1} tetrodotoxin (TTX), to 300-ms commands. At small depolarizations, only the leakage current is seen; at larger depolarizations, a slow, inward-going current develops and peaks in about 50–100 ms. Either the inward-going current decays during the command, or an outward current develops and reverses the inward-going trend. The total current–voltage (I–V) relationship of this cell in

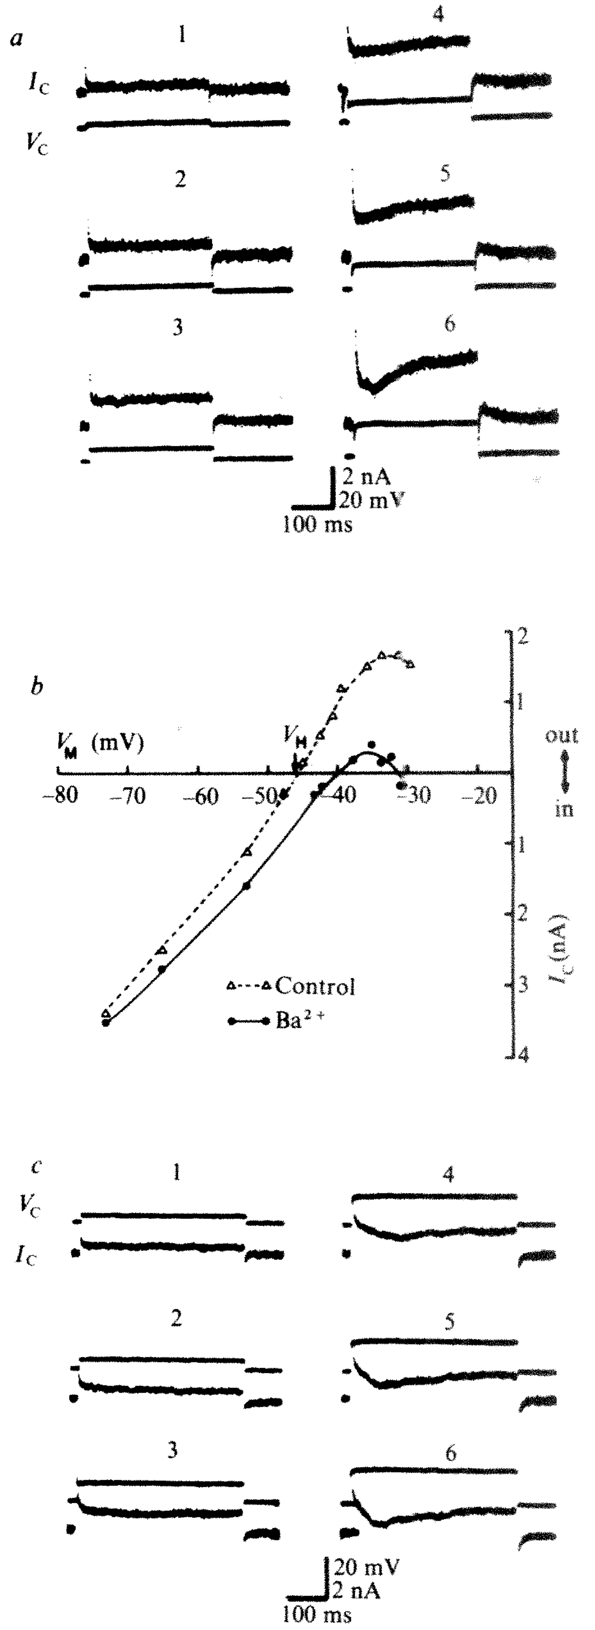

Fig. 1 Voltage-clamp data from a CA3 neurone in the presence of 1 μg ml^{-1} TTX. *a*, A series of depolarizing commands is given to the cell. Frames 1–3 show primarily leakage current. In frames 4–6, an inward-going current develops that peaks in 50–100 ms. I_c, clamp current; V_c, command potential. (See 1*b* for value of holding current.) *b*, I–V curve from same cell before and after applying a drop of 15 mM Ba^{2+}. Current is measured as the peak of the inward-going phase. V_M, membrane potential under voltage clamp; V_H, holding potential. After application of Ba^{2+}, the I–V curve becomes net inward at about −30 mV. *c*, Depolarizing clamp commands after applying Ba^{2+}.

0028-0836/80/300391—03$01.00

normal saline plus TTX is shown in Fig. 1*b*; the current is measured with respect to zero at the peak of the inward-going phase. A similar inward-going current has been observed in well over 50 CA3 neurones. In Fig. 1*c*, current from depolarizing commands is shown from the same cell after applying a drop of 15 mM Ba^{2+} from a coarse extracellular micropipette. It is clear that after the application of Ba^{2+} the total membrane current is less outward at all potentials, membrane current becomes net inward at about −40 mV (Fig. 1*b*), and the inward-going current is more prominent during the depolarizing commands (Fig. 1*c*). Since it is likely that the depolarizing commands activate both an outward K^+ current and a TTX-insensitive inward current simultaneously, and as Ba^{2+} has been shown, in several preparations, to block K^+ currents[12,13] as well as to substitute for Ca^{2+} as the charge carrier through Ca^{2+} channels[14,15], further manipulations were necessary to separate the inward and outward currents.

Internally applied caesium (Cs^+) has been shown to block outward K^+ currents in a variety of systems[16], and we used Cs^+ loading to reduce the K^+ contamination of the inward current in CA3 neurones. Neurones were impaled with micropipettes containing 2 M CsCl, and Cs^+ was iontophoresed for 1–10 min using 200–400-ms pulses at 2 Hz. Cs^+ injection typically increased the passive input resistance two- or threefold and seemed to block K^+ currents, as judged by: (1) the increased duration of the APs; (2) the decreased leakage conductance; and (3) the decreased outward current observed in voltage clamp. Moreover, the passive input resistance, as measured under current clamp, showed little decrease with depolarization up to about −40 mV, suggesting a substantial reduction in delayed rectification. Figure 2 shows an *I–V* relationship from a Cs^+-injected neurone in which Na^+ currents had previously been blocked by TTX. In this cell, the total membrane current was inward over the entire voltage range up to −10 mV, the limit to which we could clamp the cell reliably; a clear region of negative slope conductance in the range of −45 to −20 mV is demonstrated.

To test for the ionic sensitivity of this slow inward current, Co^{2+}, a potent inhibitor of Ca^{2+} inward currents in a variety of preparations[14,15], was applied to CA3 neurones. Figure 3*a* shows data from another Cs^+-injected CA3 neurone in a TTX-treated slice. Although in this cell the holding current is outward at the holding potential of −40 mV (Fig. 3*b*), the depolarizing commands activate a persistent inward-going current (see Fig. 3*a*, 3 and 4) that becomes net inward at about −25 mV. Hyperpolarizing commands from −40 mV show little leakage current (Fig. 3*a*, 1 and 2). A drop of 10 mM Co^{2+} was applied to this cell via a coarse extracellular micropipette. Figure 3*c* shows that following this application, the current response to step commands is quite different. No inward-going current is activated by

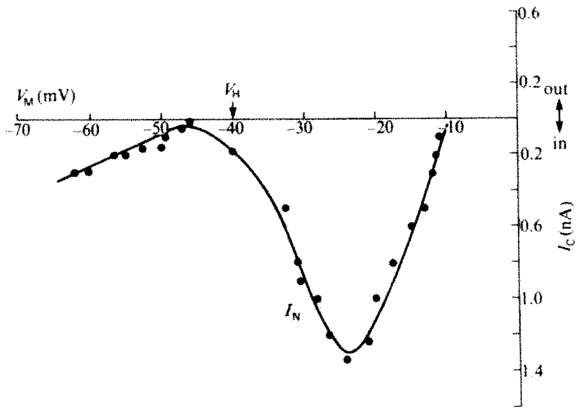

Fig. 2 *I–V* curve of a CA3 neurone, injected with Cs^+. The cell was treated with 1 μg ml^{-1} TTX, and Cs^+ was injected via the intracellular microelectrode. Total current is inward at all potentials. A prominent region of negative slope conductance is seen after Cs^+ loading.

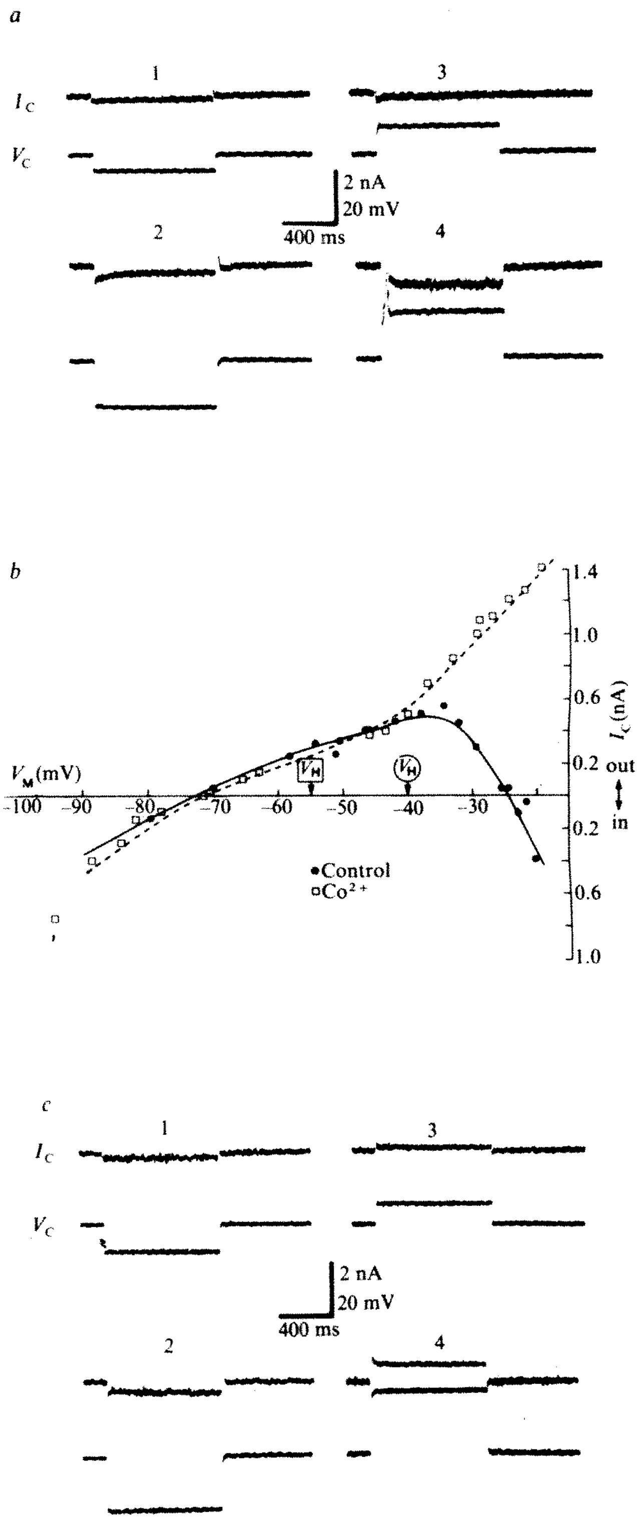

Fig. 3 Effects of Co^{2+} on a CA3 neurone. *a*, Voltage-clamp commands to another Cs^+-loaded cell exposed to 1 μg ml^{-1} TTX. Frames 1 and 2 show hyperpolarizing commands and the small leakage current. Frames 3 and 4 show depolarizing commands that activate an inward-going current that shows little or no decay during the command. (See *b* for value of holding current.) *b*, *I–V* curve before and after applying a drop of 10 mM Co^{2+}. The region of negative slope conductance is absent after Co^{2+}. Although a more negative holding potential was used after Co^{2+}, the depolarizing commands used reach well into the previous region of negative slope conductance, and no inward-going current is observed. This impalement was lost before measurements at the previous holding potential could be made. *c*, Voltage-clamp commands after application of Co^{2+}. The inward-going current is no longer present during the depolarizing commands.

depolarization, and the *I–V* curve shown in Fig. 3*b* displays no region of negative slope conductance. These data suggest that a slow, voltage-dependent, inward current is present in these cells, probably carried by Ca^{2+} ions. However, a TTX-resistant Na^+ current, which is affected by Ba^{2+} and Co^{2+} in the above manner, cannot be excluded. Although Cs^+ injection substantially reduced the outward-current contribution to the total membrane current, it did not block it completely. During large depolarizing commands (for example >20 mV from the holding potential), an outward current, possibly a Ca^{2+}-dependent K^+ current, developed. This latter current apparently was less sensitive to Cs^+ injection and contaminated our inward current measurements.

We appreciate the difficulties associated with attempting to voltage clamp neurones whose geometry is as complex as that of the hippocampal pyramids. However, an analysis of the cable properties of CA3 neurones suggests that their total electrotonic length is less than one space constant[11]. A twofold increase in input resistance as a result of Cs^+ injection theoretically would reduce the electrotonic length by a factor of $1/(2^{1/2})$, improving spatial control of voltage. Given such an electronic structure and twice the average membrane time constant of 23.6 ms (ref. 11), equation (32) of Rall[17] predicts a time constant of decay of about 7 ms for the passive current transient following a step change in potential at the soma. Empirically, we have found that this decay is complete in less than 7 ms.

After Cs^+ injection, the persistent inward current exerts almost complete control over the membrane potential in unclamped conditions. Small applied currents move the membrane potential rapidly into and out of the region of negative slope resistance (approximately −50 to −10 mV). This sensitivity to small potential changes suggests that the slow inward current is generated electrically near the recording site and is therefore amenable to voltage-clamp study.

When not voltage clamped, all of the neurones illustrated displayed spontaneous bursting behaviour after Ba^{2+} application or Cs^+ injection, even in the presence of TTX. The bursts consisted of one or more regenerative events, presumably Ca^{2+} spikes, triggered by slow depolarizations of the membrane potential. The voltage-clamp data and the behaviour of the unclamped cell are therefore in agreement.

Although the SEC is not capable of resolving currents underlying the action potential, we believe that it is more than adequate for resolution of the currents described here. This slow inward current in CA3 neurones is similar to the slowly inactivating inward current shown to be responsible for endogenous bursting in molluscan and spinal neurones[3–6], which suggests that the burst tendencies of CA3 neurones may arise from similar mechanisms. The results of the experiments with Cs^+ injection indicate that K^+ currents may be important in modifying the effect of an inward Ca^{2+} current. As in molluscan neurones[18], several K^+ currents undoubtedly exist and may control different aspects of bursting.

Circadian clock in *Limulus* brain increases response and decreases noise of retinal photoreceptors

E. Kaplan* & R. B. Barlow Jr†

Marine Biological Laboratory, Woods Hole,
Massachusetts 02543

The sensitivity and structure of ommatidia in the *Limulus* lateral eye exhibit circadian rhythms[1–3]. The cyclic changes are mediated by the activity of efferent optic nerve fibres[1] that originate in the brain and terminate in the retina[4,5]. We report here that the effects of the efferent input to the retina are detectable in single photoreceptor cells. At night the efferent input decreases photoreceptor noise (discrete waves of the membrane potential in darkness) and increases the photoreceptor response to light (amplitude of the receptor potential).

The receptor potential is a fundamental component in the process of visual excitation. It is believed to be formed in *Limulus* photoreceptors by the summation of discrete waves of membrane potential[6]. The statistical behaviour of the waves in light is consistent with the notion that they are triggered by single photon absorptions[7,8]. Discrete waves occurring in the dark are thought to result from thermal events in the excitatory process[9,10]. We found that the efferent input to the retina at night reduces the frequency of discrete waves occurring in the dark without reducing the efficacy of light to initiate them. Apparently the circadian clock can affect early steps in the process of visual excitation. The action of the clock suggests the existence of separate pathways for the spontaneous and light-evoked excitation of photoreceptor cells.

Figure 1 shows records of the membrane potential of a single, dark-adapted photoreceptor (retinular cell) *in situ*. On the day of this experiment an animal was taken from a natural light–dark environment in the early afternoon and fastened to a rigid platform in a seawater aquarium located in a light-proof cage. We removed a small section of cornea from one lateral eye and inserted a glass microelectrode into the exposed patch of retina. We impaled a single retinular cell in the late afternoon and optically isolated the ommatidium containing the cell with a light pipe aligned in contact with the cornea[11]. The cage was then closed to dark adapt the animal. Details of the technique have been described elsewhere[12]. The membrane potential of the retinular cell was recorded continuously from 6 to 10 p.m. We chose this particular period because the results of previous experiments indicated that efferent fibres in the optic nerve trunk become active about the time of sunset (~7 p.m.) and exert their maximal effects on the retina in the late evening hours (~10 p.m.)[1]. Each trace in Fig. 1 shows the membrane potential recorded from the cell in darkness for 20 s and in response to a 5-s flash of constant light intensity.

At 6 p.m. numerous discrete waves of membrane potential occurred in the dark, and the response to the test flash was small. As the evening progressed, the discrete waves occurring in the dark decreased in frequency and those in the light increased. At 10 p.m. no waves occurred in the dark, whereas numerous ones summated to produce the light response. It seems that at night the photoreceptor 'noise' decreased and response increased.

Figure 2 shows that pulses of current delivered to the optic nerve during the day mimic the effects recorded from photoreceptor cells at night. The intracellular data in Fig. 2 were recorded from a single dark-adapted retinular cell. For an additional measure of photoreceptor sensitivity we also recorded the electroretinogram (ERG) from the eye using a surface

corneal electrode[1]. The intracellular recording at 2.30 p.m. is characteristic of the day-time state of the retina, that is, it contains many discrete waves in the dark and a relatively small response to light. Note that these features are also contained in the 6 p.m. record of Fig. 1. At 2.32 p.m. periodic episodes of current pulses were delivered to the distal end of the cut optic nerve to simulate endogenous efferent activity[1]. The effect of the nerve shock was to reduce the frequency of discrete waves in the dark and elevate the amplitude of both the receptor potential and ERG. Maximal response amplitudes were recorded after about 2 h of nerve shock (4.30 p.m.) at which time the current pulses were turned off. Subsequently, the receptor potential and ERG decreased in amplitude and discrete waves reappeared in the dark.

In Fig. 2 simulation of efferent optic nerve activity during the day produced night-time characteristics in the photoreceptor recordings; compare the 4.30 p.m. record with the 10 p.m. record in Fig. 1. Cessation of current pulses to the cut optic nerve at night led to the return of the day-time characteristics; compare the 8.30 p.m. record with the 6 p.m. record in Fig. 1.

The results reported here for single photoreceptor cells parallel those recorded from single optic nerve fibres *in situ*[1]. In both cases the time of day when the light-evoked response is elevated and spontaneous activity is depressed corresponds to the period of endogenous efferent activity. Also, in both cases, cutting the optic nerve abolished the circadian changes. Finally, shocking the cut optic nerve during the day produced the physiological effects characteristic of the night-time state of the retina. We therefore conclude that the reduction in noise and increase in response of the photoreceptor in Fig. 1 were mediated by the endogenous activity of efferent optic nerve fibres.

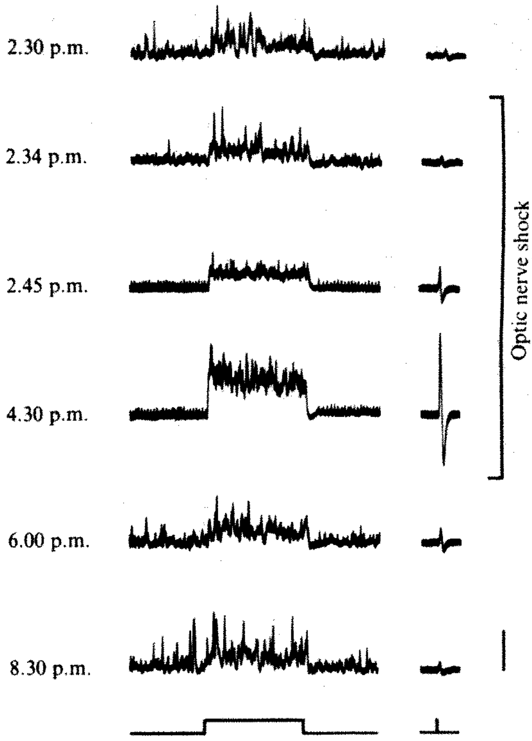

Fig. 2 Effect of optic nerve shock on visual responses of the *Limulus* lateral eye. On the left are intracellular records of a dark-adapted photoreceptor cell recorded with a glass microelectrode in response to 4-s flashes of constant intensity. On the right are electroretinograms (ERGs) recorded with a corneal electrode in response to 100-ms flashes. Before impaling the retinular cell, the optic nerve was exposed, sectioned and its distal end placed in a suction electrode. The 2.30 p.m. records are characteristic of the dark-adapted day-time state of the retina: small responses to light and frequent occurrence of discrete waves in the dark. At 2.32 p.m., current pulses were delivered to the cut nerve at the rate of 4 s^{-1} for 30 s every minute. This shock regime was chosen to simulate the maximum level of endogenous efferent activity recorded at night from the proximal end of cut optic nerves in other preparations. The effect of nerve shock was to elevate the responses to light and reduce the 'noise' in the dark. The increased response amplitudes correspond to about a 20-fold increase in visual sensitivity. The small spikes occurring in the dark are believed to originate in the second-order eccentric cells. They are often observed in experiments in which efferent activity is simulated by nerve shock but not when it is generated by the circadian clock as in Fig. 1. After the optic nerve shock was turned off at 4.30 p.m., the characteristics of the recorded responses returned to the day-time state and remained there until the cell was lost at 8.45 p.m. Cutting the optic nerve blocked the transmission of endogenous efferent activity to the retina at night and thus eliminated circadian changes of the type shown in Fig. 1. Duration of each intracellular record is 10 s. Scale bar, 10 mV for the intracellular data and 50 μV for the ERG records.

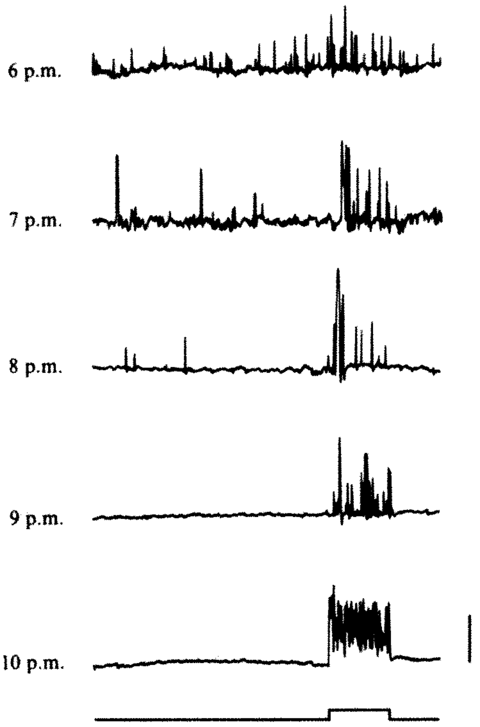

Fig. 1 Intracellular records from a retinular cell of the *Limulus* lateral eye *in situ*. The cell was impaled in the late afternoon with a glass microelectrode without disrupting the blood supply to the eye. At 5 p.m. the cage was closed to dark adapt the animal. The only light stimuli reaching the animal during the next 5 h (5 to 10 p.m.) were the 5-s test flashes (bottom trace) delivered by a light pipe isolated on the ommatidium containing the recorded retinular cell. In each trace a 20-s recording of the cell membrane potential in the dark precedes the response to the test flash. Based on the results of previous experiments, we estimate that the transmission of efferent optic nerve impulses to the retina from the circadian clock in the brain began between 6 and 7 p.m. By 9 p.m. efferent input seems to have abolished the occurrence of discrete waves in the dark and increased the response to the test flash. The recording was lost shortly after the 10 p.m. test. Cell resting potential was 50 mV. Scale bar, 10 mV. The intracellular recordings for this study were carried out with freshly collected crabs at the Marine Biological Laboratory, Woods Hole, Massachusetts.

The night-time increase in the amplitude of the photoreceptor response in Fig. 1 can be largely attributed to an increase in the number of photons caught by the retinular cells. Circadian changes in the morphology of the retinular cells and surrounding pigment cells maximally expose the photosensitive rhabdom to incident light collected by the corneal lenses[3].

The night-time reduction in photoreceptor noise cannot be attributed to any known cellular mechanism. The spontaneously occurring discrete waves in retinal cells seem to result from the thermal isomerization of single rhodopsin molecules, whereas the light-evoked waves result from the photo-isomerization of rhodopsin[9,10]. This seems to be a general property of photoreceptors[13,14]. If the spontaneous fluctuations in membrane potential are in fact initiated by thermal events, by what mechanism does the circadian input to the retina abolish the effects of thermal energy without influencing those initiated by light? Perhaps part of the chain of events triggered by light is separate from that initiated by thermal energy, and only the latter part is influenced by the efferent input to the retina. Whatever the answer, neural signals from the circadian clock seem to act at a stage preceding the excitatory conductance change in the photoreceptor membrane.

Our intracellular recordings did not reveal any additional information on the nature of the mechanisms that mediate the effects of the circadian clock. For example, no consistent changes in either the potential or the resistance of the photoreceptor membrane were detected. Long-term recordings of the type shown in Figs 1 and 2 are generally associated with a slight but steady increase in resistance as monitored by current pulses passed through the recording electrode. Such drifts in resistance are independent of the time of day and probably result from a gradual clogging of the microelectrode. Neither membrane potential nor resistance reflect the activity of efferent optic nerve fibres.

The elevated night-time sensitivity of the retina may partially compensate for diurnal changes in ambient illumination. The circadian rhythm of sensitivity corresponds reasonably well to that of the animal's locomotor behaviour[15]. Interestingly, the period of elevated sensitivity also corresponds to the time the animals congregate in shallow water to mate (C. M. Cavanaugh, unpublished observations).

In sum, the efferent input from a circadian clock enhances retinal sensitivity at night by increasing the quantum catch and decreasing the spontaneous activity of the retinular cells. The efferent input thereby increases the signal-to-noise ratio of the photoreceptor response. The efferent input seems to act at an early stage in the process of visual excitation.

Light-induced calcium fluxes from outer segment layer of vertebrate retinas

S. Yoshikami, J. S. George & W. A. Hagins

Laboratory of Chemical Physics, NIAMDD, National Institutes of Health, Bethesda, Maryland 20205

Light affects the membrane potential of a vertebrate retinal rod or cone cell by transiently reducing its 'dark current', an inward flow of Na^+ through the plasma membrane covering the light-absorbing outer segment[1,2]. In rods most photons are absorbed by photopigment molecules in intracellular disk membranes that are physically separate from the plasma membrane[2–5]. Photochemical events in the disks probably control the Na^+ conductance of the plasma membrane through a chain of events that ultimately change the level of a diffusable substance in the cytoplasm of the outer segment. By combining reversibly with Na^+ carriers or channels in the plasma membrane, this 'internal transmitter' substance would modulate the dark current and thus the rod's membrane potential[6]. There is evidence that the internal transmitter is free Ca^{2+} (refs 7–10). Ca^{2+} buffer EGTA has a desensitizing effect on rods, consistent with a free cytoplasmic Ca^{2+} concentration of about 1 μM in darkness and release of 500–1,000 additional calcium ions for each absorbed photon[10]. However, there is insufficient proof that Ca^{2+} is released into the cytoplasm of rod outer segments by light and removed again in darkness. Reports that light reduces the total Ca^{2+} in outer segments have varied widely in their details[11–15]. Small amounts of Ca^{2+}, ~1 mol per mol of photoisomerized rhodopsin, are released by strongly illuminated isolated rod disks[16], but this is not enough to explain the large size of single photon responses[10,17]. We have studied net movements of Ca^{2+} in the receptor layer of albino rat retinas during the responses of the rods to light with the aim of detecting release of internal Ca^{2+} by a rise in its extrusion into the interstitial space.

Microelectrodes sensitive to free Ca^{2+} were made as described previously[18]. The siliconed tips were 2–3 μm in diameter and were filled for a length of 250 μm with *O*-nitrophenyl octyl ether containing 10% Na tetraphenylborate and 10% of the Ca^{2+} selective synthetic ionophore, ETH 1001 (Orion)[19]. The remainder of the electrode contained 0.1 M $CaCl_2$. Electrode resistances were 1–3,000 MΩ. the microelectrodes responded to step changes in Ca^{2+} activity from 0.5 to 5 mM with potential changes having an exponential rise of 130 ± 10 ms. Over the range of free $[Ca^{2+}]$, a_{Ca}, from 10^{-7} to 10^{-2} M, the Ca electrode potential V_{Ca} followed the equation

$$V_{Ca} = V_o + M \log_{10}(a_{Ca} + a_o) \qquad (1)$$

where V_o is a constant dependent on the solutions in the Ca and reference electrodes and M is 31 ± 1 mV per decade change in a_{Ca} at 37 °C. The apparent basal Ca activity due to electrode permeability to other ions, $a_o < 5 \times 10^{-8}$ M. Changes in *p*H of 1.5 unit on a background of 70 μM Ca^{2+} produced electrode potential changes of <20 μV. The electrodes were insensitive to changes in Mg^{2+}, Na^+, and K^+ (ref. 19).

The Ca electrode potential was referred to one of a pair of Ringer-filled micropipettes mounted in a cluster with it (shown in Fig. 1*a*). The entire assembly could be thrust under direct vision by IR microscopy[1] into the upturned receptor surface of an isolated retina so that the external voltage gradient V_d due to the dark current could be monitored with the change in potential of the Ca^{2+} electrode. As shown in Fig. 1*a*, electrode B and the Ca electrode were placed at the same depth in the retina so that the Ca signal was not mixed with light-induced changes in V_d.

Isolated rat retinas were prepared as previously described[1,2]. They were mounted in a chamber in a stream of physiological solution that passed parallel to the outer segment layer in laminar flow. The fluid velocity 50 μm above the rod tips was ~100 μm s^{-1}. An arrangement of valves allowed the fluid composition to be changed in 5 s. When more rapid changes in fluid composition were needed, a continuous jet of the desired fluid from a pipette in the bath was quickly lowered so as to sweep over the retina near the electrodes.

0028–0836/80/300395—04$01.00

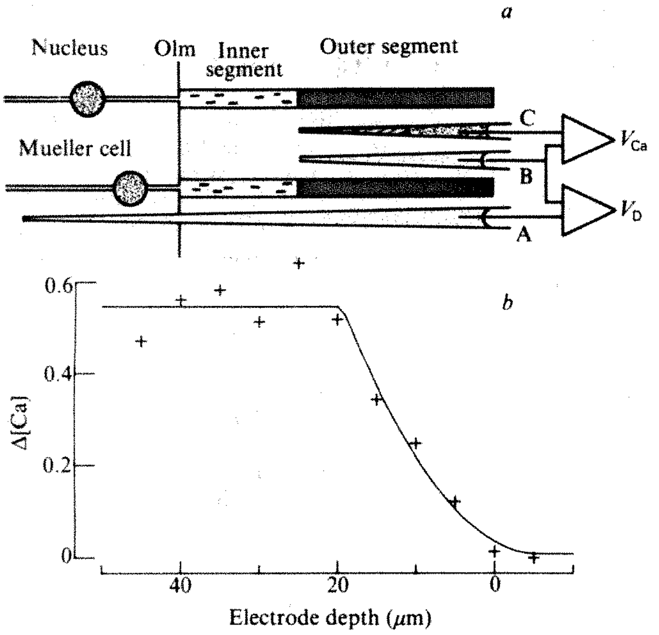

Fig. 1 Spatial distribution of the light-induced transient increase in interstitial [Ca^{2+}] with depth of the Ca-sensing electrode in the receptor layer. *a*, Diagram of the structure of the receptor layer to scale indicated at the bottom of *b*. Electrodes placed as shown in the interstitial spaces between the rods. *b*, Amplitude of the Ca^{2+} against depth. Each point is the mean area under the first 800 ms of the Ca transient obtained by averaging 16 flash responses. Curve: amplitude distribution to be expected from a source of Ca^{2+} limited to the outer segment layer of the retina. The assembly of three electrodes was moved in steps through the receptor layer. Stimuli: 2 μs, 560 nm, 110 photons absorbed per rod per flash. Ambient free [Ca^{2+}] 10 μM in a Ringers of composition similar to that of Fig. 2*a*.

Light causes a transient increase in the Ca^{2+} activity in the interstitial space of the outer segment layer. Figure 2*a* shows the effect of a 560-nm flash yielding 110 photons absorbed per rod on V_d recorded between electrodes A and B at depths of 75 and 25 μm from the rod tips and changes in the Ca^{2+} activity seen by the Ca electrode at 25 μm. The flash immediately shut down the dark current for about 1 s after which V_d returned to its initial level with a small overshoot. This waveform is characteristic of rat rods in the 70 μM unbuffered Ca^{2+} of the Ringer used. The Ca electrode showed a transient increase in a_{Ca} followed by a longer lasting decrease to slightly below the level before the flash. Although V_{Ca} was logarithmic in Ca^{2+} activity (equation (1)), the changes seen were so small relative to the background a_{Ca} that the relationship between ΔV_{Ca} and Δa_{Ca} was nearly linear. The time integral of the Ca^{2+} transient (smooth line) was nearly zero over the duration of the record. The rise in Ca^{2+} was ~1.2 μM at its peak just after the minimum in V_d.

If the Ringer was augmented with 10 mM Ca^{2+} buffer, nitrilotriacetic acid (NTA), and the Ca^{2+} and Mg^{2+} activities carefully adjusted to those of the control, the light-induced change in V_d was unaffected, but the Ca^{2+} transient was greatly reduced (Fig. 2*b*). This effect of NTA could not be attributed to its action as a buffer for H^+ or Mg^{2+}: there was 10 mM of the *p*H buffer HEPES present in both cases, and NTA is a weak Mg^{2+} buffer at the concentration used (500 μM Mg^{2+}). Thus the responses of the Ca electrode were probably due to changes in interstitial a_{Ca}.

With a fixed 10-μM free Ca^{2+} concentration in the Ringer and a stimulus of 80 photons absorbed per rod per flash, the size and shape of the Ca transient varied with electrode depth in the retina. Figure 1*b* shows data from Ca transients recorded at 5-μm intervals beginning 5 μm above the tips of the outer segments and extending inward to a depth of 45 μm. The points were computed from the time integrals of the responses 800 ms after the flashes. This time was near the peaks of the transients themselves. Small Ca transients could usually be seen even when the electrode was 25 μm above the retinal surface. These were much slower than the intraretinal ones and were caused by clouds of Ca^{2+}, released from distant retinal areas, drifting past the Ca electrode. In the space between the rods, the transients grew rapidly in size with increasing electrode depth in the region between the rod tips and the inner–outer segment junction at 25 μm depth. As the Ca electrode was advanced further, the transients remained at constant size or decreased slightly. In the dark, there was no detectable gradient of a_{Ca} in the extracellular space. Thus the Ca transients must indicate increased efflux and not a light-induced fall in a steady dark influx.

Viewed as a problem in one-dimensional diffusion of Ca^{2+} from sources in the receptor layer to sinks there and in the flowing Ringer stream, the concentration *c* of Ca^{2+} should follow the differential equation

$$\frac{\partial c}{\partial t} - D\frac{\partial^2 c}{\partial x^2} = F(x, t) \qquad (2)$$

where *D* is the diffusion coefficient of Ca^{2+} in the interstitial space perpendicular to the retinal surface and *F*(*x*, *t*) is the distribution of Ca^{2+} sources and sinks on the receptor cells. In

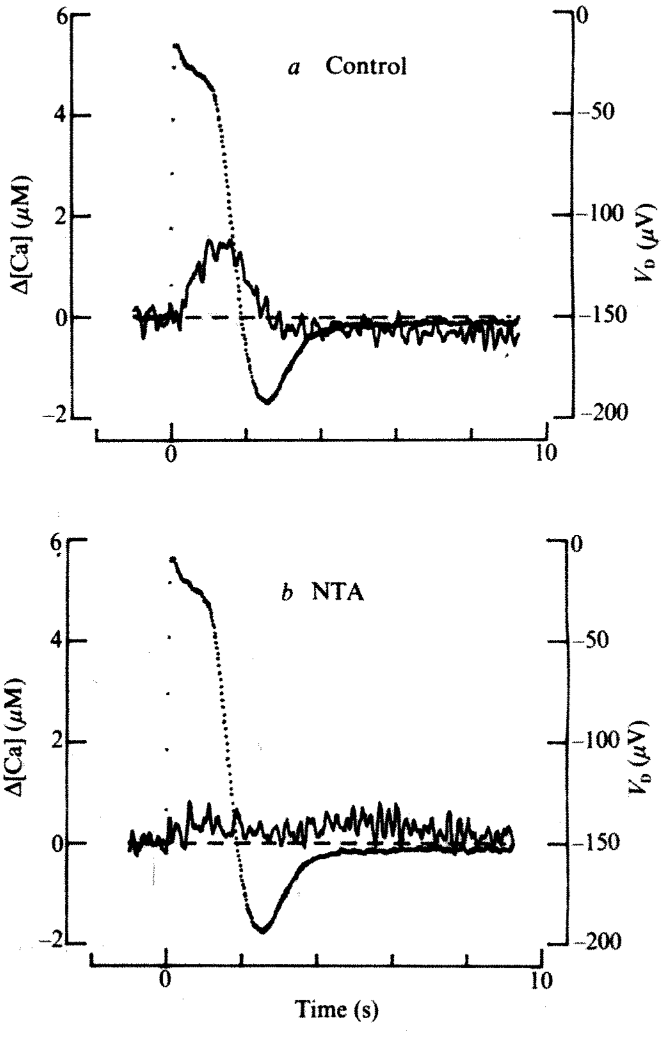

Fig. 2 Changes in interstitial dark voltage gradient V_d and free [Ca^{2+}] in the rod layer of an albino rat retina. Voltage-recording and Ca-recording electrodes placed as shown in Fig. 1*a*. Stimuli: 2 μs flashes of wavelength 540–580 nm that resulted in 110 photons absorbed per rod per flash. Dotted curves: changes in V_d. Continuous noisy curves: interstitial free [Ca^{2+}]. Dashes: drawn at signal levels seen just before flashes. Each curve is the mean of 16 responses. *a*, Control Ringer containing 136 mM NaCl, 0.5 mM $MgCl_2$, 2.7 mM KCl, 0.5 mM NaH_2PO_4, 11 mM glucose, 10 mM HEPES, and $CaCl_2$ added until the Ca electrode indicated a free [Ca^{2+}] of 70 μM. *p*H 7.14. *b*, Bathing Ringers same as control except that 10 mM nitrilotriacetic acid (NTA) was added and excess Ca^{2+} and Mg^{2+} were added by titration to achieve the same free metal concentrations as in *a*. The buffering effect of the NTA was negligible for H^+ and Mg^{2+} but reduced the concentration elevating effect of added Ca^{2+} to <10% of that of the control Ringers.

principle the two partial derivatives could be measured directly with electrode arrays and F computed as Ca^{2+} current sources and sinks[1], but the noise in the present data makes this procedure inaccurate. However, if the Ca transients are sampled at their peaks as in Fig. 1*b*, $\partial c/\partial t$ is negligible and equation (2) becomes an ordinary differential equation linking $c(x)$ with the Ca^{2+} source distribution $F(x)$. In Fig. 1 $c(x)$ is computed from equation (2) for a hypothetical distribution $F(x)$ (solid line) where the source is a uniform zone covering the entire length of the outer segments. No flow of Ca^{2+} is assumed to occur at the outer limiting membrane at $x = 45$ μm.

The data fit the hypothetical source distribution closely when its amplitude is properly scaled. In the outer segment layer, the transients grow in size roughly as the square of the electrode depth and not linearly as would be expected for Ca sources concentrated at the inner segments or more deeply. Unlike the computed curve, however, the data suggest some loss of Ca^{2+} towards the deeper retinal layers. The slight shift of the measured Ca source distribution (Fig. 1*b*) relative to the retinal elements of Fig. 1*a* is due to the 5-μm uncertainty in electrode position. Most of the Ca^{2+} arises in the region of the rod outer segments.

The internal a_{Ca} of rat rod outer segments is ~1 μM (ref. 10), and that of the external medium is much higher. Thus rods, like other eukaryotic cells, must regulate their internal Ca^{2+} with membrane pumps that exchange Ca^{2+} for Na^+ (refs 20, 21) or extrude Ca^{2+} via nucleotide phosphatases in the plasma membrane[22,23]. Is the light-induced Ca^{2+} efflux caused by a rise in the cytoplasmic a_{Ca} or by a light-stimulated increase in the activity of some Ca^{2+} extrusion mechanism? The results shown in Fig. 3 suggest the first mechanism perhaps augmented by the second through light-induced rod hyperpolarization.

If the NaCl in the bath is replaced with the depolarizing salt, potassium isethionate, the large V_d response shown in Fig. 3*a* (right) is completely abolished, but the interstitial increase in a_{Ca}, while slower and four times smaller, persists (Fig. 3*b*). Replacing the Na^+ in the medium with choline ions produces a similar result even though the rod membrane potentials should be hyperpolarized to near K^+ equilibrium potential in this solution. Since the residual Na^+ in both choline and K isethionate Ringers was less than 10 μM, it is unlikely that Na : K exchange causes the Ca^{2+} efflux in these solutions.

Can light still produce a Ca^{2+} efflux when plasma membrane calcium pumps are partly shunted by a divalent metal ionophore? If the rods are exposed to X-537A, the dark current and the V_d responses are greatly reduced at external $a_{Ca} > 10^{-5}$ M (ref. 8), but the light-induced rise in interstitial a_{Ca} remains large (Fig. 3*d*). Reducing the ambient a_{Ca} to 10 μM increases the dark current and V_d, but the Ca signal decreases slightly. Since X-537A increases the permeability of the plasma membrane to Ca^{2+}, it is likely that the increased Ca^{2+} efflux follows mainly from an increase in cytoplasmic a_{Ca}. Because the external $[Ca^{2+}]$ is greater than that in the cytoplasm even in the presence of X-537A, however, the Ca extrusion machinery must link the presumed light-induced rise in internal Ca^{2+} to that seen extracellularly, making it larger and faster.

If intracellular Ca^{2+} release causes the dark current shutdown, the kinetics of Ca^{2+} efflux should closely track the V_d waveform. To compare the kinetics of the two processes, the observed waveform of the transient increase in interstitial a_{Ca} must be transformed mathematically to allow for the finite volume v of the interstitial space (l cm^{-2}) and for the loss of Ca^{2+} by diffusion into the flowing Ringers. Neglecting the small unstirred layer at the retinal surface and solving equation (2) for the condition of no flow at the outer limiting membrane (OLM) (Fig. 1*a*) and for a uniform Ca^{2+} source distributed along the outer segments that instantaneously dumps Q mol cm^{-2} into the interstitial space yields a transient increase in a_{Ca} at 25 μm depth in the receptor layer that is close to a truncated exponential of the form

$$c(25, t) = 0.5\, c(25, 0) \exp(-t/\tau) \qquad (3)$$

where $c(25, 0) = Q/v$ and $\tau = 4l^2/\pi^2 D$ (ref. 24, equation 3.4.5, p. 101). Here l is the distance from the rod tips to the OLM. For this special position of the Ca electrode, the total outflux $J(t)$ from the entire length of outer segments thus is represented approximately by

$$2v\left(\frac{dc}{dt} + \frac{c}{\tau}\right) = J(t) \qquad (4)$$

For the receptor layer of the rat retina, measurements from electron micrographs yield $v = 650$ nl cm^{-2}. τ, Computed from a measured D for Ca^{2+} of 1.1×10^{-5} cm^2 s^{-1} in the rod interstices (W. A. H. and S. Y., unpublished) is 650 ms. Using these two experimental parameters and forming the sum on the left-hand

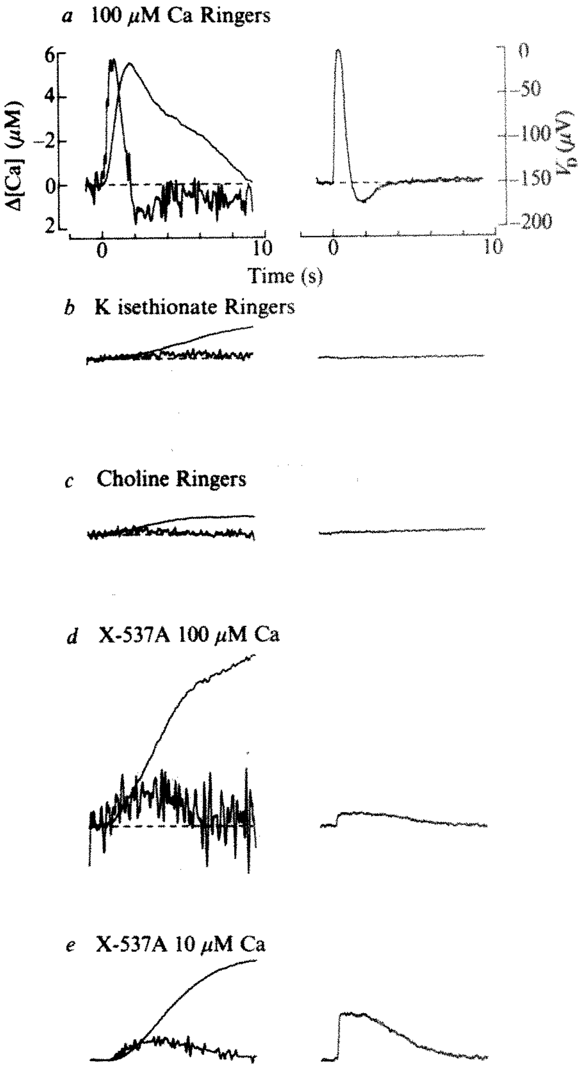

Fig. 3 Changes in dark voltage gradient V_d (right column) and extracellular free $[Ca^{2+}]$ (left column) in the rod layer of the rat retina in solutions of various compositions. Stimuli as in Fig. 2, electrode positions as in Fig. 1*a*. Temperature, 37 °C. *a*, Control. As in Fig. 2 but Ca^{2+} added to give *p*Ca 4.0. Mean of four responses. *b*, NaCl and KCl replaced with 140 mM K isethionate, *p*Ca 4.0. Mean of 96 responses at 15-s intervals. V_d response suppressed by the depolarizing solution, but there was a distinct light-induced increase in interstitial $[Ca^{2+}]$ as shown by its time integral (smooth line in left column). The total Ca^{2+} appearing was 25% of that in the control solution. *c*, NaCl replaced with 140 mM choline chloride. This solution should hyperpolarize the rod membrane potentials but suppress the dark current. As in *b*, the V_d response disappeared but there was a measurable Ca^{2+} release from the rod layer. *p*Ca 4.0. Mean of 96 responses. *d*, 10 μM of the divalent cation ionophore, X-537A was added to control Ringers at *p*Ca 4.0. The dark current and V_d were greatly reduced, but there was a large light-induced release of Ca^{2+} from the rod layer. Mean of eight responses. The large spikes in the Ca responses were electrical interference from the bath heater. 200 photons per rod . *e*, Same retina as in *d* but ambient free $[Ca^{2+}]$ reduced to 10 μM. Dark current and V_d response immediately increased, but Ca release was slightly reduced. Mean of eight responses. 200 photons per rod.

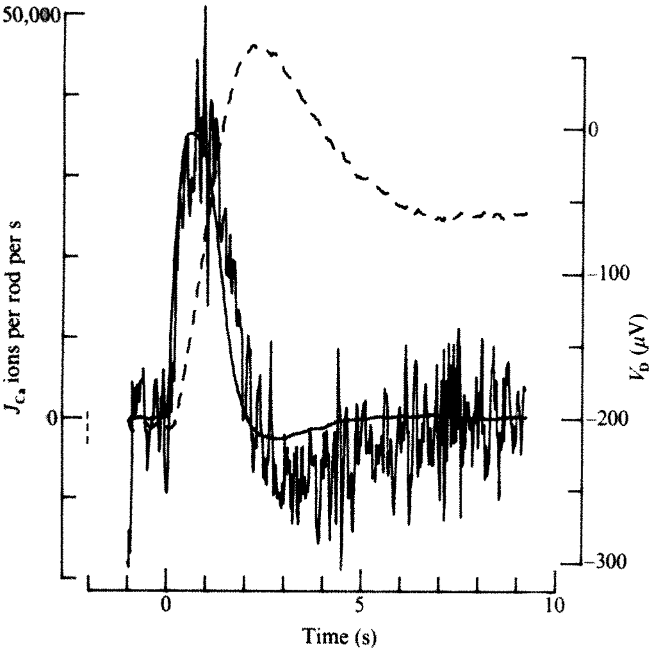

Fig. 4 Time courses of the light-induced Ca^{2+} flux from the rod layer compared with the light-induced reduction in V_d. Stimuli as in Fig. 2. Smooth line: V_d response convolved with an exponential response function of time-constant 130 ms to simulate the time-lag of the Ca electrode. Noisy curve: Ca^{2+} flux from the rods computed from equation 4. Dashes: time integral of Ca^{2+} flux in units of ions per rod on the left-hand scale. Mean of four responses to flashes of energy 110 photons absorbed per rod. The time course of the Ca efflux and the change in V_d are similar. Apparently about half of the Ca^{2+} released within 2 s of the flash is reaccumulated by the rod layer.

side of equation (4) by numerical differentiation of the experimental Ca transient yields the noisy curve in Fig. 4.

The Ca flux can now be directly compared with the waveform of the V_d response if the latter is first convolved with a truncated exponential with a 130-ms time constant to simulate the response lag of the Ca electrode. The result is a smooth line, shown in Fig. 4. The two waveforms are nearly identical, the duration of the Ca efflux being slightly longer and its peak not more than 100 ms later than the transformed V_d response.

The Ca^{2+} flux is large and biphasic. As much as half of the 45,000 ions leaving the outer segments in the first 2 s after the flash are apparently reabsorbed in the next 7 s (Fig. 4, dashed line). Since each rod absorbed 110 photons per flash, about 400 Ca^{2+} ions must have been extruded per photon response. If Ca^{2+} is the internal excitatory transmitter, the total Ca release must have been at least twice as large, because only cytoplasmic Ca^{2+} should reduce the Na^+ permeability of the plasma membrane. The observed release would only increase the cytoplasmic $[Ca^{2+}]$ by about 3 μM, a small fraction of the total Ca^{2+} in rod outer segments[14,25]. But if a steady 25-s light stimulus of intensity 9,500 photons per rod per s is used instead of a flash, the Ca^{2+} outflux is sustained for the entire period of illumination and amounts to about 100 $\mu mol\,l^{-1}$ of rod water. The light-sensitive Ca store is therefore large.

The light-induced Ca^{2+} effluxes seen here are fast enough, large enough, and of the spatial distribution to be expected from the Ca hypothesis. Moreover, the observed fast exchange of Ca^{2+} across the plasma membrane of rod outer segments explains the great sensitivity of the dark current to the $[Ca^{2+}]$ in the external medium. It remains to link the Ca^{2+} fluxes to enzymatic events in the disk membranes, such as the hydrolysis of GTP[26–29] and of cyclic GMP[30], and the binding of GDP[29]. *Note added in proof*: Since this paper was submitted, a preliminary account has appeared in *Fedn Proc.* **39,** 2066 (1980) and similar conclusions are reached by use of surface calcium electrodes by G. H. Gold and J. Korenbrot, *Fedn Proc.* **39,** 1814 (1980).

Co-infection by lactic dehydrogenase virus and C-type retrovirus elicits neurological disease

Larry R. Pease & William H. Murphy

Department of Microbiology and Immunology, The University of Michigan Medical School, Ann Arbor, Michigan 48109

Intraperitoneal injection of neuropathogenic strains of lactic dehydrogenase virus (LDV)[1–3] causes a histologically distinctive[4] fatal paralytic disease characterized by an inflammatory destruction of motor neurones in the brain stem and cord in C58 mice aged over 9 months. To elicit the disease in the naturally susceptible C58 strain requires an age-associated[5] or X-ray induced[6] loss of immunological competence[5], LDV infection[1–3] and genetic susceptibility[1,6]. Genetic studies[1,7] of the common inbred mouse strains showed that susceptibility to the disease was not linked to the major histocompatibility complex but correlated with the FV-1^n allele, susceptibility to spontaneous leukaemia, and infection by neuropathogenic strains of LDV[1–3]. These observations suggested that neuropathogenic strains of LDV elicit the disease only in those strains of mice that carry multiple copies of N-tropic C-type retroviruses in their genomes[8,9] and that are permissive for retrovirus replication. Presumably the expression of these viral genomes (high titres of virus in tissues correlating with age[9]) is the important factor. Here we present genetic evidence to support this hypothesis and briefly discuss the possible implications.

In Table 1 the mice in group 1 were selected to test whether there was a correlation between susceptibility to the disease, the number of copies of N-tropic C-type retroviruses in their genomes[8,9], their haplotype and their FV-1 genotype. The FV-1^b allele[10] dominantly restricts N-tropic C-type retrovirus replication. All of the strains (*a–e*) that were FV-1^n and are known to contain multiple copies of N-tropic C-type retroviruses in their genomes[8,9] were susceptible. The data for the congeneic AKR strains are of interest because they show that

Tab! 1 Susceptibility of inbred mice to paralytic disease

Group		Inbred strains*		FV-1 type	Genomic copies of C-type retroviruses	Incidence of paralysis† age (months) 6	9	12
	a		k	n	Many		10/10	15/15
			k	n	Many		13/20	
			b	n	Many	0/17		5/6
			k	n	Many			16/16
			u	n	Many			6/11
			k	b	Many		0/24	
			k	n	Few	0/8		0/12
			d	n	Few	0/13		0/14
			b	b	Few		0/13	
			b	b	Few	0/19		0/10
		/Boy	b	n	Few		0/12	
			k	b	Few	0/18		
	a	/wm × C3H/HeJ	k/k	n/n		2/8	7/12	
	b	C58/wm × DBA/2J	k/d	n/n		2/8	5/8	
2	*c*	C58/wm × B10	k/b	n/b		0/26		0/10
	d	C58/wm × B10.BR	k/k	n/b		0/20		0/14
	e	C58/wm × BALB/cWm	k/d	n/b		0/11		0/19
Backcross progeny								
	a	(C58 × B10) × B10	k/b or b/b	n/b or b/b		0/43		
3	*b*	C58 × (C58 × B10)	k/k or k/b	n/n or n/b		18/53		6/12
	c	(C58 × B10) × C58	k/k or k/b	n/n or n/b		1/93		1/20

* In group 1, strains *a–c* are considered to have a 'high' incidence of leukaemia ranging from 40 to 90% depending on the colony. Strains *d* and *e* have a 'moderate' incidence of leukaemia ranging from 20 to 40%. The remaining mice listed have a 'low' incidence of spontaneous leukaemia (usually < 5%)[16]. AKR-H-2^b/Boy is congeneic to AKR/Boy and is H–2^b rather than H–2^k. AKR-FV-1^b/Boy is congeneic to AKR/Boy but is FV-1^b rather than FV-1^n. B6/Boy is a subline of C57BL/6 and is FV-1^b. The congeneic line B6-FV-1^n/Boy is FV-1^n. The C58/wm and BALB/cWm mice are our stock inbred lines. The following abbreviations were used: C58 for C58/wm, B10 for C57BL/10Sn, and B10.BR for B10.BR/SgSn. In Groups 2 and 3 the female is listed first for each breeding set; mice were 2–5 months old when mated.

† Mice received 550R of whole body X-ray irradiation 24 h before the intraperitoneal injection of LDV (10^7–10^8 infectious doses) derived from either line I*b* cells or from a stock prepared from the plasma of infected BALB/cWm mice[2]. The plasma stocks of LDV cause the same clinical and histopathological effects as line I*b* derived virus[2]. After infection, mice were held for 30 days and scored for the incidence of paralysis. Paralysed and disease-free mice (3–6 per group) were killed and the diagnosis of paralysis or its absence confirmed histologically as described previously[4]. The sex of mice did not affect their susceptibility in any of the test groups.

when H–2^b was substituted for H–2^k, mice were still susceptible (compare *c* with *b*). When FV-1^b was substituted for FV-1^n, mice were resistant (compare *f* with *b*). The mice in groups *g* and *h* were representative of strains that carry few copies of retroviruses in their genomes but are permissive (FV-1^n) for retrovirus replication. None contracted the disease. The strains in groups *i* and *j* contain few copies of retroviruses in their genomes, are not permissive (FV-1$^{b/b}$) for N-tropic C-type retrovirus replication, and were not susceptible. Introduction of the FV-1^n allele in place of FV-1^b (compare *k* with *i*) or H–2^k in place of H–2^b (compare *l* with *j*), did not confer susceptibility. These results confirmed our findings[1,7] that susceptibility or resistance was not H–2 linked and indicated that mice had to carry multiple copies of N-tropic C-type retroviruses in their genomes and be permissive for retrovirus replication to be susceptible.

The mice in group 2 were used to test whether mice presumed to be genetically susceptible, but containing too few copies of N-tropic C-type retroviruses in their genomes (mice in *g* and *h*, Group 1), would manifest paralytic LDV infection if they became infected by the appropriate C-type retrovirus. Thus, 'genetically susceptible' male mice 'deficient' in virus (C3H/HeJ and DBA/2J) were bred to C58 females. The assumption was that the C58 mothers would transmit virus to the newborn F$_1$ progeny either chromosomally or by the milk. Table 1 shows that the F$_1$ hybrids derived from the 'potentially susceptible strains' (groups *a* and *b*) were susceptible. The corresponding genetically resistant (FV-1$^{n/b}$) hybrids were not (groups *c–e*) even when the H–2^k haplotype (group *d*) was substituted for H–2^b (group *c*).

In group 3, test-cross progeny were tested to determine whether resistance segregated in accordance with the hypothesis that the FV-1^b allele determined resistance. The data show that all of the backcross progeny in control group *a*, which in principle inherited an FV-1^b allele, were resistant. In theory, 50% of the test-cross progeny in group *b* should have been FV-1$^{n/n}$ and susceptible if they were infected by an N-tropic C-type retrovirus by their mothers. The results confirmed this expectation with a somewhat lower incidence of disease (34%) in the incompletely susceptible 6-month-old indicator C58 mice[1,6,7]. Moreover, when backcross progeny were nursed on resistant (C58 × B10) mothers (group *c*) there was a strong maternal effect. Such an effect would be consistent with the failure to transmit virus to the progeny by the milk[11], or the transmission of antibody to the progeny by the milk, thereby protecting them from C-type retrovirus infection. Other mechanisms of conferring maternal resistance are not ruled out by the data[11].

If one accepts the genetic data at their face value they support the hypothesis that dual infection by LDV and N-tropic C-type retrovirus(es) was required to elicit a specific paralytic motor neurone disease in genetically susceptible mice. Expression of N-tropic C-type retrovirus genomes in FV-1$^{n/n}$ mice seemed to be an important factor in the susceptible strains. The paradox is that neither LDV[12] or the common C-type retroviruses are frankly cytopathic to cells either *in vitro* or *in vivo*. Although Gardner *et al.*[13] and McCarter *et al.*[14] have reported the occurrence of neuropathogenic C-type viruses in mice, LDV has not been evaluated as an essential contributory factor in such virus stocks. However, these investigators also have not claimed tha neurone destruction is a direct cytopathic response to vira infection. The striking feature of the model we describe is tha two viruses that are ubiquitous in mice, and that ordinarily d not cause overt disease, seem to act together to elicit a specif disease syndrome in a genetically susceptible host. The findings are of interest because they direct attention to ho unrelated viruses may interact together at the cellular lev provide an additional way to characterize phenotypically LD and mouse leukaemia virus strains, and may provide an additional insight to the complex interactions between viruses and their hosts in the slow viral infections of the nervous system[15].

This work was supported by funds from the Institute of Gerontology of the University of Michigan and by USPHS grant S07-RR-05383. All the 'Boy' mouse strains were from Dr Edward Boyse. The mice with a J designation and B10 and B10.BR lines were from Jackson Memorial Laboratory.

S100 protein is present in cultured human malignant melanomas

Richard Gaynor, Reiko Irie, Donald Morton & Harvey R. Herschman

Division of Hematology-Oncology, Department of Medicine; Division of Oncology, Department of Surgery; Department of Biological Chemistry and Laboratory of Nuclear Medicine and Radiation Biology, Center for the Health Sciences; University of California, Los Angeles 90024

S100 protein, so called because of its solubility in 100% saturated ammonium sulphate[1], is an acidic cytoplasmic protein specific for the nervous system[2,3]. It is localized primarily to glial elements of the brain, Schwann cells in the peripheral nervous system and satellite cells in sympathetic ganglia[4,5]. This brain-specific protein shows a close immunological relationship among a wide variety of vertebrates, as measured by a quantitative complement fixation technique[6]. Although strict serological conservation and tissue localization have been maintained among different species, no function for S100 protein has been determined. However, the appearance of S100 protein in brain is correlated with maturation of the nervous system in both rat and man[7,8]. Previous *in vitro* studies on the production and regulation of S100 protein in the C6 cell line derived from a rat astrocytoma indicated that cell contact and cessation of division induced S100 protein[9]. Neuroblastoma cell lines lack this protein[10,11] although it is found in other astrocyte cell lines. We are unaware of any reports of cell lines, other than those of glial origin, which produce S100 protein. Melanocytes are derived from neuroectodermal elements, and this common origin of glial cells and melanocytes prompted us to study whether S100 protein might be present in cell lines from human malignant melanomas. We now report the presence of S100 protein in five f seven continuous cell lines of human malignant melanoma.

All lines used in our studies were derived from metastatic elanomas, and were maintained in culture for 12–20 passages. Most lines have been characterized previously[12,13]. After the elanoma cells in tissue culture flasks were confluent, the cells ere collected and homogenized. The soluble protein was assayed by quantitative complement fixation for S100 protein, using rabbit antisera to bovine S100. Complement fixation curves for extracts of human brain and one of the melanoma cell lines are shown in Fig. 1. Five of seven cell lines from human melanomas were found to have S100 protein (Table 1). In two of the lines (lines 19 and 12) the amount of S100 protein exceeded that present in human brain medulla. Lymphocyte cell lines of the two patients from which M14 and M29 were derived were negative for S100, as were HeLa cells and a human sarcoma cell line. Cells from line M14 were injected into a nude mouse; the tumour resulting after 30 days had 2.2 μg of S100 per g of tumour. Of the lines studied, only M12 and M19 were melano-

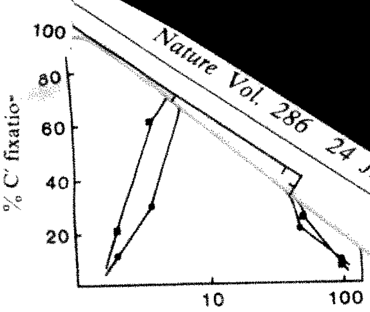

Fig. 1 Complement (C') fixation curves of S100 for human brain medulla (●) and M29 cell line (■). M29 cell line extract was prepared as described in Table 1 legend. The brain sample was homogenized with Tris buffer, 2 ml per g tissue, and spun at 40,000*g* for 10 min before S100 determination. Quantitative complement fixation using an 8,000-fold dilution of antiserum was carried out on extracts of M29 and human brain medulla.

Table 1 S100 protein values for melanoma cell lines and other tissues

Specimen	μg S100 per mg soluble protein
Melanoma cell lines	
M12	6.2
M14	1.0
M15	1.9
M19	30.0
M21	ND
M24	ND
M29	3.5
Other cells and tissues	
C6 rat glial cells	2.6
Brain cerebrum (human)	2.3
Brain medulla (human)	5.6
HeLa cells	ND
Sarcoma cell line (human)	ND
Lymphocyte cell lines	
L14	ND
L29	ND

Cell lines were cultured in 75-cm^2 culture flasks using RPMI 1640 medium with 20% fetal calf serum and maintained in 5% CO_2. Confluent cells were washed twice with phosphate-buffered saline (NaCl, 8 g l^{-1}; KCl, 0.2 g l^{-1}; $MgCl_2 \cdot 6H_2O$, 0.1 g l^{-1}; $Na_2HPO_4 \cdot 7H_2O$, 2.16 g l^{-1}) and once with complement fixation buffer (0.0 M trisma base, 0.14 M NaCl, 0.5 mM $MgSO_4$, 0.15 mM $CaCl_2$, 0.1% bovine serum albumin). Cells were collected by scraping into complement fixation buffer, homogenized and spun at 40,000*g* for 10 min. Quantitative complement fixation was carried out using a 6,000-fold dilution of antiserum as described by Levine[17]. S100 was quantified as described by Zuckerman *et al.*[18]. The serological specificity of our antiserum has previously been demonstrated by double diffusion in agar and by quantitative complement fixation analysis using soluble protein extracts of a variety of tissues as antigens[17,18]. Purified bovine S100 was used as a standard to quantify the amount of S100 present in the soluble portion of each specimen. ND, Not detectable.

8–0836/80/300400—02$01.00

tic. Line M19 cells are the source with the greatest specific activity of S100 protein so far reported.

The serological cross-reactivity of S100 protein is strongly conserved in different species[6]. To show that the S100 protein present in human brain was immunologically identical to that present in human melanoma, we examined the serological cross-reactivity, as measured by complement fixation. The ratio of antisera required to give the same percentage of complement fixation at equivalence for heterologous compared with homologous antigens provides a quantitative measure of cross-reactivity defined as the 'index of dissimilarity' (refs 14, 15). The maximal complement fixation values for brain extracts and extracts from melanoma cell lines at three dilutions of antiserum were plotted against the log of the antiserum concentration (Fig. 2). The superimposable lines for the brain and melanoma samples indicate immunological identity for the S100 protein from these two sources (that is, an 'index of dissimilarity' of 1.0).

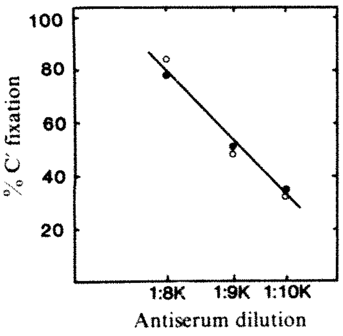

Fig. 2 Cross-reactivity of brain and melanoma cell line S100 protein. Maximal complement (C′) fixation values for brain extract (●) and melanoma (○) line M29 extract at these dilutions of antisera [1/8,000 (1 : 8 K), 1/9,000 (1 : 9 K), 1/10,000 (1 : 10 K)] are plotted against the log of the antiserum concentration. The superimposable lines for both samples indicate immunological identity for the S100 protein from these two sources.

We do not know whether S100 protein accumulation is a function only of malignant melanocytes or of all melanocytes. S100 protein does not accumulate in human skin (our unpublished observations); however, this may reflect the low density of melanocytes normally present. Malignant melanoma cell lines have previously been shown to possess receptors for nerve growth factor[16]. Either nerve growth factor receptors or S100 protein may serve as a tumour-associated marker for malignant melanoma.

Cultured human lymphocytes of the IM-9 line have specific binding sites for ^{125}I-insulin that have been characterized in detail[1,2]. When the hormone–cell interaction was studied by quantitative electron microscopic (EM) autoradiography, it was shown that initial binding was to the plasma membrane and that at 37 °C a small fraction of the ligand was internalized by the cell[3,4]. The internalized ligand was found preferentially localized in lysosomes in the Golgi region of the cell[5]. It is well known that di- or multivalent ligands redistribute in the plane of the membrane before internalization[6]. We now report that following initial binding the univalent ligand insulin also undergoes a polar redistribution ('capping') before internalization.

Cultured human lymphocytes have a polarity that can be distinguished in appropriately taken photomicrographs of thin sections of these cells (Fig. 1). The Golgi pole was arbitrarily assigned to half the cell and the opposite pole was assigned to the other half as indicated in Fig. 1.

In this study we have assumed that initial receptor binding is most accurately reflected at low temperature and at early times of incubation. When 0.2 nM ^{125}I-insulin was incubated at 15 °C for 2 min and the hormone–cell interaction examined by EM autoradiography, grains became distributed on the plasma membrane of the cell in a statistically indistinguishable fashion (Table 1). We interpret this to mean that insulin receptors or groups of receptors are initially distributed at each pole of the cell with equal frequency.

Table 1 Distribution of autoradiographic grains on the surface of IM-9 lymphocytes during incubation with 0.2 nM ^{125}I-insulin

	2 min, 15 °C	90 min, 15 °C	2 min, 37 °C	60 min, 37 °C
Golgi pole	53%	58%	72%	73%
Opposite pole	47%	42%	28%*	27%*

Number of grains analysed = 2 min, 15 °C: 148; 90 min, 15 °C: 154; 2 min, 37 °C: 140; 60 min, 37 °C: 164.

* As determined by the χ^2 test these grain distributions are significantly different ($P < 0.005$) from the grain distribution found after 2 min of incubation at 15 °C.

We next investigated whether this was true for insulin at physiological concentrations. Labelled insulin was, therefore, incubated with cultured lymphocytes for a longer period of time at 15 °C and 37 °C. By 90 min at 15 °C there was no statistically significant difference between the percentage of grains associated with each pole of the cell (Table 1). By contrast, by 2 min of incubation at 37 °C there was a preferential association of the ligand with the Golgi pole of the cell and the same distribution of the labelled material was apparent after 60 min of incubation (Table 1, Fig. 2). We have found that although the affinity of insulin for its receptor is decreased with increasing temperature, there is no change in the total number of receptors when the incubation temperature is raised from 15 to 37 °C (unpublished observations). We interpret the present data to mean that, although insulin initially binds with equal frequency to either

0028-0836/80/300401—03$01.00

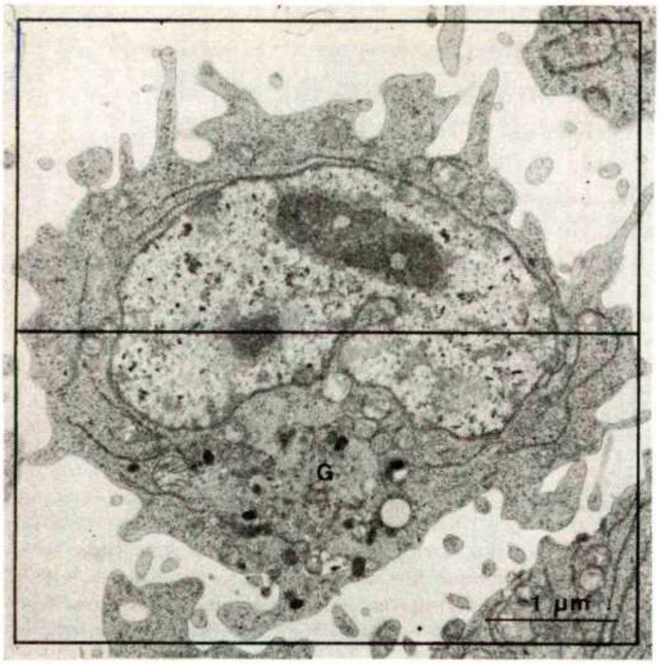

Fig. 1 The method used to determine the two plasma membrane segments of the lymphocytes for evaluation of ^{125}I-insulin redistribution (examples of lymphocytes with autoradiographic grains are shown in refs 3, 5, Figs 2, 6, respectively). Typically, the lymphocyte has an eccentric, indentated nucleus. The Golgi area (G) lies close to the indentation of the nucleus. A square divided in two equal rectangles by an horizontal line was superimposed on each cell so that the Golgi area fitted approximately the centre of one of the rectangles. The plasma membrane segment contained within that rectangle was considered as the 'Golgi pole' of the membrane; the number of autoradiographic grains present within ±250 nm of the plasma membrane in each rectangle was then recorded separately. Approximately 100 cells showing the typical morphology illustrated were evaluated in each experimental condition. Lymphocytes were incubated with 0.2 nM ^{125}I-insulin at 15 and 37 °C as described elsewhere[3,5]. At each time point selected cells were fixed with 4% phosphate-buffered (*p*H 7.4) glutaraldehyde, dehydrated, embedded in Epon and thinly sectioned. High-resolution autoradiography of the thin sections was carried out using Ilford L4 emulsion and Microdol-X developer after 3–5 weeks' exposure time[3,5].

pole of the cell, at 37 °C there is a rapid redistribution of the ligand in the plane of the membrane.

It has previously been shown in human fibroblasts that some ligands initially bind preferentially to specialized regions of the membrane known as coated pits[7–11]. The lymphocyte differs from the fibroblast in that the coated regions of the plasma membrane are much less marked with respect to the size of the coated segment and coat development. Although this factor must be taken into account in the analysis of our data, we find no initial preferential localization of labelled insulin to coated segments of the membrane after 2 min of incubation at either 15 or 37 °C. These data are similar to our findings of insulin binding in isolated hepatocytes, to those of Billheimer *et al.* for low-density lipoprotein (LDL) binding in circulating monocytes and to those of Haigler *et al.* studying epidermal growth factor (EGF) binding in A-431 epithelioid carcinoma cells[12–14], but may not rule out a participation of coated segments of the membrane in internalization of the labelled material.

Table 2 Relationship of autoradiographic grains to coated regions of the plasma membrane

	2 min, 15 °C	2 min, 37 °C
Total no. of grains examined	252	292
No. of grains associated with coated invaginations	5 (2%)	6 (2.1%)

The criteria for selection were: (1) the grain centre was ±250 nm from the plasma membrane, and (2) the plane of the section was appropriate for a clear identification of the plasma membrane. A grain was considered associated with a coated invagination if its centre was closer than 250 nm from a coated invagination. These methods are identical to those previously used for analysis of binding of ^{125}I-EGF and ^{125}I-LDL to cultured fibroblasts[9,10].

Schlessinger *et al.*[15] have shown in cultured mouse fibroblasts that, at high concentration, insulin conjugated to lactalbumin–fluorescein undergoes patching before internalization. Whether a similar process occurs in our cultured lymphocytes cannot be determined from these studies. The redistribution of insulin in the plane of the membrane to the Golgi pole of the cultured human lymphocytes seems more closely analogous to the phenomenon of capping. Taken with the data of Schlessinger *et al.*[15], the present results suggest that insulin binding to the cell surface induces a patch–cap formation similar to that described for di- or multivalent ligands[6]. In this respect, it is interesting that the capping of ^{125}I-insulin on the cell surface is qualitatively and, most importantly, quantitatively identical to that observed for a unique immunoglobulin (anti-insulin receptor antibody) which binds specifically to the insulin receptor[16], and which was isolated from a patient with a severe insulin resistance.

Fig. 2 IM-9 lymphocytes incubated for 60 min at 37 °C with 0.2 nM ^{125}I-insulin. Autoradiographic grains (encircled) are concentrated in the region of the cell characterized by numerous microvilli and membrane infoldings (uropod). This region corresponds to the Golgi pole of the lymphocyte.

If one assumes that at physiological concentrations insulin behaves as a univalent ligand, it is then clear that bivalency of the ligand is unnecessary either for mobility in the plane of the membrane or for internalization. However, whether the ligand induces some form of aggregation or cross-linking of its receptor remains unknown.

Finally, we have proposed that endocytosis may be the major mechanism by which polypeptide hormone receptors are lost from the cell surface[5]. Micro-aggregation, lateral mobility and internalization of the hormone and its specific receptor in the plane of the membrane could provide a mechanism for selective loss of a single class of receptors analogous to the removal of specific immunoglobulins from the surface of lymphocytes[17].

Increased human red cell cation passive permeability below 12 °C

G. W. Stewart, J. C. Ellory & R. A. Klein*

Physiological Laboratory, Downing Street, Cambridge CB2 3EG, UK

* Medical Research Council, Molteno Institute, University of Cambridge, Cambridge CB2 3EE, UK

The rate of most biological reactions declines as the temperature is reduced; indeed, cooling is often used to limit or terminate reactions. We report here a paradoxical temperature response of red cell K and Na permeability below 12 °C. This may be interpreted thermodynamically in terms of a membrane-ordering phenomenon, an observation supported by a variety of other physical measurements on red cell membranes reported in the literature.

Surprisingly few data are available on the effects of temperature on Na and K transport in human erythrocytes. This may be due in part to the presence of at least three components of Na and K movement in human red cells. These can be resolved as the ouabain-sensitive Na–K pump[1,2], the furosemide-sensitive Na–K co-transport system[3] and a residual process showing linear concentration dependence[1]. For normal human red cells, at 5 mM external K, K influx is roughly divided between these three processes in the proportion 60%, 35% and 5%, respectively, at 37 °C. We have measured the temperature dependence of the three components of K uptake over the temperature range 4–37 °C (Fig. 1). The two K transport systems which show saturable kinetics and which can be identified using known inhibitors (ouabain for the Na–K pump and furosemide, or other loop diuretics such as bumetanide, for the Na–K co-transport system), fell off sharply with decreasing temperature, no significant fluxes being measurable below about 4 °C (Fig. 1). In marked contrast, however, the residual K influx, which shows a linear K concentration dependence and is ouabain- and furosemide-resistant, reached a minimum at about 12 °C, below which temperature the flux began to increase again. In three experiments in which this flux was measured at 0 °C and 10 °C, the ratio K influx 0 °C : 10 °C was 2.1 ± 0.5 (s.e.m.). Ouabain- and furosemide-resistant Na efflux (Fig. 2), K efflux and Na influx (data not shown) all showed a similar paradoxical pattern of temperature dependence with a minimum at about 12 °C. In a second series of experiments, net Na accumulation was measured following long-term (22 h) incubation in media containing ouabain and bumetanide (used as an alternative to furosemide because of its greater potency). The results (Table 1) demonstrate that Na accumulation was significantly lower following incubation at 10 °C than with either 20 °C or 0 °C. This experiment, therefore, confirms the observations from tracer fluxes that there was a minimum around 10 °C for Na permeability, as also shown by Dalmark & Wieth[17].

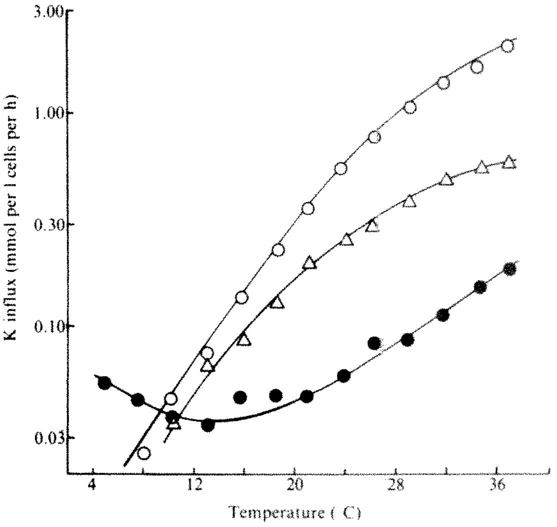

Fig. 1 The three components of K influx as a function of temperature. K influx was measured by previously described methods[15] using ^{42}K or tracer ^{86}Rb (ref. 16) in a 142 mM NaCl, 7.5 mM KCl, 15 mM MOPS (Sigma) and 5 mM glucose solution, *p*H 7.4, at 20 °C, 7.3 at 0 °C, 7.48 at 37 °C. Inhibitors (ouabain and furosemide, Hoechst) were added to final concentrations of 0.1 mM and 1 mM, respectively. Cells were preincubated at 37 °C for 15 min before cooling to allow binding. The cells were exposed to isotope for up to 3 h before rapid washing four times in ice-cold $MgCl_2$ 106 mM and Tris 10 mM. ○, Ouabain-sensitive; △, furosemide-sensitive; ●, ouabain/furosemide-insensitive.

Table 1 Changes in internal erythrocyte [Na] after storage as a function of temperature

	$[Na]_i$ µmol per gHb	Difference
Before storage	31.9 ± 0.1	
After storage		
20 °C	51.8 ± 0.3	19.9 ± 0.4
10 °C	46.7 ± 0.2	14.8 ± 0.2*
0 °C	52.0 ± 0.3	20.1 ± 0.4*

After washing 4× in (mM) NaCl 145, KCl 5, MOPS 15 and glucose 5, *p*H 7.4, at 20 °C, followed by 15-min incubation with inhibitors at 37 °C, cells were incubated for 22 h at 4% haematocrit at the temperatures shown with ouabain and bumetanide 10^{-4} M each, with continuous gentle mixing. After storage, the cells were washed 4× in 106 mM $MgCl_2$ and 10 mM Tris, packed and lysed in water. [Na] was measured by flame photometry and haemoglobin (Hb) was measured with Drabkin's reagent at 540 nm. The results are expressed per g Hb (± s.e.m., *n* = 6) to exclude any effects of temperature on cell volume.

*Significantly different at $P < 0.001$, Student's *t*-test.

Although ouabain binding shows a very low reversibility at 0 °C (ref. 4), it was important to rule out the possibility of reversal of bumetanide (or furosemide) binding at low temperatures. Cells were always pretreated with maximal concentrations of inhibitors for 15 min at 37 °C before flux measurements, and as the K concentration dependence of K influx, measured at 0, 4, 11 and 37 °C, was found always to be linear, reversal of inhibition at low temperatures, which would restore a saturable component of K influx, can be discounted. Possible participation of the anion transport protein in this effect (through, for example $NaCO_3^-$ or KCO_3^- transport)[5] is unlikely because the anion exchange flux rate is markedly inhibited by temperature between 10 and 0 °C (ref. 6). In any case 0.1 mM SITS (4-acetamido-4′-isothiocyanatostilbene-2,2′-disulphonic acid, sodium salt, BDH), a potent inhibitor of the anion transport system[7], had no effect. Membrane potential effects can be ruled out because both influx and efflux tracer cations were increased at low temperatures, and there was no significant temperature-dependent change in membrane potential (measured by the dis-C_3-(5) dye method[8]) in ouabain- and furosemide-treated cells.

In the present work, we have shown that the linear components of Na and K fluxes have minimum values at around

0028-0836/80/300403—02$01.00

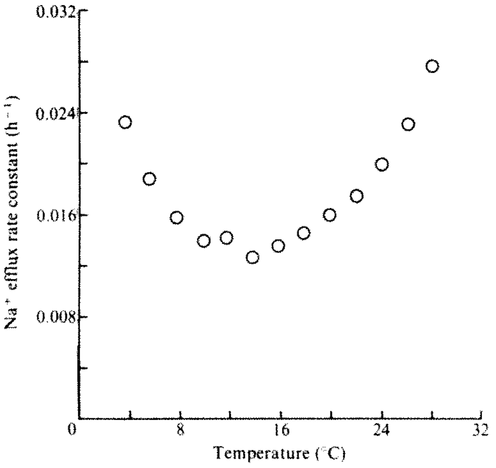

Fig. 2 Na efflux as a function of temperature. Fresh human cells were loaded with ^{24}Na as previously described[15]. Ouabain (10^{-4} M) and bumetanide (10^{-4} M) were added towards the end of the loading incubation to allow binding before rapid washing in cold 145 mM NaCl, 5 mM KCl, 15 mM MOPS and 5 mM glucose solution, containing the inhibitors.

12 °C. Wieth[9] has reported a temperature-dependent stimulation of the ouabain-insensitive Na and K fluxes in human erythrocytes by the anions SCN$^-$ and salicylate (used at 100 mM concentration) which gave rise to a flux minimum at about 18 °C. In thermodynamic terms such paradoxical behaviour could be the result of two mechanisms: the summation of two processes with enthalpies of activation of opposite sign (for example, Wieth[9] suggested that the ions SCN$^-$ and salicylate titrated fixed membrane charges exothermically at low temperatures) or the result of a single process whose entropy change is a function of temperature. According to Eyring's theory[10], the temperature dependence of diffusion (D) is given by

$$D = cTe^{-\Delta G^*/RT}$$

where c is a constant, T the absolute temperature, R the gas constant and ΔG^* the Gibbs free energy change for activation of the transition state. From the Gibbs equation $\Delta G^* = \Delta H^* - T\Delta S^*$ where ΔH^* and ΔS^* are, respectively, the enthalpy and entropy changes for activation. In the first case, ΔS^* is invariant with temperature. If ln D is differentiated with respect to $1/T$, one obtains

$$\frac{\mathrm{d}\ln D}{\mathrm{d}(1/T)} = -T - \frac{\Delta H^*}{R}$$

If $T \ll \Delta H^*/R$, this reduces to

$$\frac{\mathrm{d}\ln D}{\mathrm{d}(1/T)} = -\frac{\Delta H^*}{R}$$

the Arrhenius equation. If, in the second case, ΔS^* is a function of temperature denoted by $\Delta S^*(1/T)$, the expression becomes

$$\frac{\mathrm{d}\ln D}{\mathrm{d}(1/T)} = \frac{\mathrm{d}}{\mathrm{d}(1/T)}\left\{\frac{\Delta S^*(1/T)}{R}\right\} - \frac{\Delta H^*}{R} - T$$

The function ln D (and therefore D) can show a minimum if at some temperature

$$\frac{\mathrm{d}}{\mathrm{d}(1/T)}\Delta S^*(1/T) = \Delta H^* + RT$$

This equation expresses the thermodynamic condition necessary for a minimum to be observed in the relationship between ion flux and temperature, consistent with the present data. A temperature-dependent change in the entropy of activation for the transition complex could result from a change in membrane ordering. In this context workers using physical techniques to study membrane ordering have reported relevant observations: (1) Raman spectroscopy (Verma and Wallach[11]) showed discontinuities in lipid CH-stretching and membrane-bound β-carotene intensities in the temperature range −4 °C to 20 °C; (2) Tanaka and Ohnishi[12] demonstrated an inflection point at 18 °C in the phosphatidylcholine spin label line splitting for erythrocyte ghosts; (3) in ether-extracted erythrocyte ghosts, Cullis[13] found a change in ^{32}P nuclear magnetic resonance linewidth at about 20 °C; (4) using a fluorescence probe to assess membrane fluidity, Kapitza and Sackmann[14] observed a marked increase in this parameter between 12 and 17 °C. All these methods reflect membrane ordering and therefore entropy. However, as the temperature of the flux minimum is a function not only of $\mathrm{d}/\mathrm{d}(1/T)\Delta S^*(1/T)$ but also of ΔH^* and RT, points of inflection identified from these data cannot be simply related to the flux minimum described here.

Our flux measurements may therefore represent a functional correlate of the temperature-dependent changes in membrane ordering evidenced by other physical methods.

We thank Dr T. J. Rink for measuring membrane potential, Dr V. L. Lew for helpful discussions, and the Wellcome Trust for supporting G.W.S.

Plateau potentials in pancreatic islet cells are voltage-dependent action potentials

Daniel L. Cook, Wayne E. Crill & Daniel Porte Jr

Veterans Administration Hospital, 4435 Beacon Avenue So., Seattle, Washington 98108

Islet cells stimulated by a steady glucose concentration above a certain threshold (usually 5–7 mM) display cyclic membrane potential changes[1]. This islet electrical activity consists of action potentials (spikes) superimposed on a depolarized plateau (see Fig. 1). Higher levels of glucose prolong the plateau phase and shorten the silent phase until the plateau potentials merge to produce continuous spiking at 20–25 mM. The fraction of each cycle spent in the plateau phase correlates with glucose concentration and insulin release rate[2], suggesting that control of the onset and offset of the plateau is important in the regulation of insulin release. The abrupt transitions between silent and plateau phases suggest that the plateau is a persistent, voltage-dependent action potential as in cardiac muscle. This idea is supported by evidence[3] that $\mathbf{Ca^{2+}}$ influx is stimulated by $\mathbf{K^+}$ depolarization of islets. However, this voltage dependency can be explained by electrical evidence[4,5] that the spikes are generated by voltage-dependent $\mathbf{Ca^{2+}}$ currents. Furthermore, there is evidence against the voltage dependency of the plateau because it seemed to be unaffected by intracellular current injection and $\mathbf{K^+}$ depolarization, which clearly affected spik-

ing[5,6]. As there are alternative explanations (see below) for these last negative findings, we have re-examined this important question using a new technique of direct electrical stimulation of entire, isolated islets using a suction electrode. Contrary to the previous negative findings, our present results clearly show that the plateau potential is a voltage-dependent, persistent action potential.

Pieces of pancreas from Swiss–Webster mice fed *ad libitum* were perfused in a Krebs–Ringer bicarbonate buffer gassed with O_2/CO_2 (95:5) and maintained at 37 °C. Individual islets (100–300 μm diameter) were microdissected free of exocrine tissue and held by the hollow glass electrode (90–200 μm inside tip diameter) with gentle suction (5–10 mm H_2O). A stimulus isolation unit provided constant current stimuli through this suction electrode. Standard electrophysiological techniques with glass microelectrodes (tip resistance 300–400 MΩ) were used to record islet cell membrane potentials. Because the suction electrode current passes through the entire islet, extracellular potentials within the islet cannot be assumed equal to the bath ground potential. Therefore, potentials measured during stimulation are not a true measure of transmembrane potential. Glucose-responsive islet cells were identified by their typical pattern of electrical activity and were used only if recordings were stable for at least 10 min. These records typically had silent phase potentials between −50 and −60 mV, and at the time of recording the islets had been exposed to 11.1 or 13.7 mM glucose for at least 30 min.

Figure 1, line 1, shows the rhythmic electrical response to 11.1 mM glucose. In line 2, this regular endogenous rhythm was interrupted by an 8-μA, 2-s-long depolarizing current (from the suction electrode) which evoked an all-or-none plateau potential indistinguishable from endogenous plateaus. The ensuing electrical rhythm is identical to that observed before the stimulus but is shifted as if a pacemaker had been reset. Line 3 of Fig. 1 demonstrates that this all-or-none response has a definite electrical threshold, as a slightly weaker stimulus (6 μA) did not initiate a plateau and had no effect on the plateau rhythm.

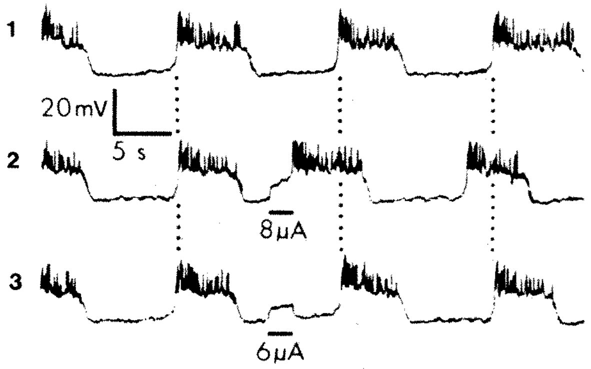

Fig. 1 Responses to depolarizing currents. Three excerpts from a membrane potential recording from a single islet cell in the presence of glucose (11.1 mM). Line 1, control activity; line 2, a premature plateau potential initiated by an 8-μA, 2-s-long depolarizing current presented 2 s into the silent phase; line 3, failure of a similar 6-μA stimulus to initiate a plateau.

Plateau termination is also voltage dependent because an endogenous plateau can be aborted by a brief (100 ms) hyperpolarizing stimulus current of −18 μA (Fig. 2, line 2). This all-or-none response has the same slow time course of repolarization and length of silent phase as seen in the endogenous activity. There is also a sharp stimulus threshold, as a slightly weaker current (−15 μA) does not interrupt the plateau (Fig. 2, line 3). Although not clearly shown in Fig. 2, artificial termination of plateaus interrupted and reset the endogenous rhythm as effectively as artificial plateau initiation (Fig. 1).

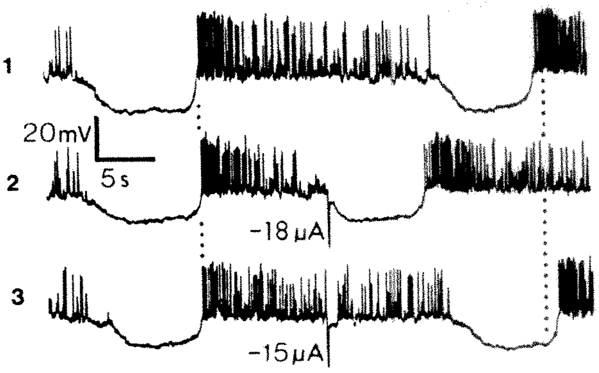

Fig. 2 Responses to hyperpolarizing currents. Membrane potential records from a second cell in the presence of glucose (13.7 mM). Line 1, control electrical activity; line 2, endogenous plateau prematurely terminated by a −18-μA, 100-ms-long hyperpolarizing current presented 10 s after the beginning of the plateau; line 3, failure of a similar −15-μA current to terminate a plateau.

For both the initiation and termination of plateaus in all cells tested, we have consistently observed a reciprocal relationship between stimulus current strength and stimulus duration (data not shown), as is characteristic of excitability phenomena in other systems. For example, in one cell, a 10-μA current required 2 s to trigger a premature plateau whereas a 20-μA current required only 1 s. Similar relationships were found for termination of plateaus, although typically, plateau initiation has required longer stimuli that plateau termination (1–2 s compared with 50–100 ms).

Previous studies[5,6] found that neither plateau length nor frequency was affected by stimulus currents passed through the recording electrode or by elevation of bath K^+ concentration. These results probably reflect the difficulty of driving a coupled[7] population of cells by stimulating a single cell, as well as accommodation to slow changes in K^+. More rapid (1–2 s) bath K^+ changes elicit premature plateaus (unpublished results) as readily as electrical stimulation through the suction electrode.

It is possible that our electrical stimuli affect plateau potentials indirectly by releasing endogenous islet neurotransmitters. However, this is unlikely because it seems to require that depolarizing stimuli selectively release acetylcholine (known to depolarize islet cells)[8] whereas hyperpolarizing stimuli selectively release catecholamines (known to hyperpolarize islet cells)[9]. A more likely explanation is that the electrical stimuli are directly activating and deactivating a voltage-dependent membrane conductance. This conductance change underlies the prolonged plateau depolarization which drives the more rapid spiking activity. Thus, the islet cell plateau potential resembles voltage-dependent, persistent action potentials seen in myocardial cells[10] and the slow potentials of molluscan pacemaker neurones[11]. The underlying ionic mechanism in islet cells is unclear but may be due to increased conductance to Na^+ or Ca^{2+} as in these other systems or to a decreased conductance to K^+, as proposed for islet cells[5].

The second key observation in the present work is that electrical stimuli interrupt and completely reset the rhythm of islet cell electrical activity. This seems to rule out electrically insensitive pacemaker mechanisms such as autonomous biochemical oscillators which merely drive membrane events. Furthermore, the pacemaker mechanism must depend on either the membrane potential directly or the fluxes of ions underlying the voltage changes. For instance, as in heart cells and molluscan neurones, one or more slow, voltage-dependent K^+ conductances may serve as the pacemaker. Alternatively, islet cells are known to possess an electrogenic Na^+–K^+ pump[12] and a Ca^{2+}-dependent, K^+ conductance[13]. Thus, intracellular accumulation of Na^+ or Ca^{2+} during the active plateau phase could, by either mechanism, activate a hyperpolarizing current which would eventually trigger plateau repolarization. Depletion of the cation pool during the silent phase would lead to slow depolarization and the next plateau.

Although the specific ionic mechanisms of the plateau conductance change and the pacemaker mechanism remain unclear, these data conclusively show the islet cell plateau potential to be a persistent, voltage-dependent action potential whose pacing must involve membrane potential or ion fluxes.

Linkage relationship between variable and constant region allotypic determinants of human immunoglobulin heavy chains

J. P. Pandey*, E. Tung*, S. Mathur*, K. K. Namboodiri†, A. C. Wang*, H. H. Fudenberg*, W. A. Blattner‡, R. C. Elston† & C. G. Hames§

*Department of Basic and Clinical Immunology and Microbiology, Medical University of South Carolina, Charleston, South Carolina 29403; †Department of Biostatistics, The University of North Carolina, Chapel Hill, North Carolina 27514; ‡National Institutes of Health, Bethesda, Maryland 20014; §Evans County Health Department, 2 North Newton Street, Claxton, Georgia 30417

Allotypic (genetic) variations in the variable (V) region of immunoglobulin chains have been extensively studied in the domestic rabbit[1-3]. The first allotypic determinant identified in the V region of human immunoglobulins, described in our laboratory, is designated Hv(1). Its detection, using protein McE and a rabbit antiserum to McE, and its mode of inheritance based on family and population studies, have been reported previously[4]. Briefly, Hv(1) is located in the V region of human immunoglobulin heavy (H) chains of G, M and A classes. It is inherited as an autosomal dominant trait, with a gene frequency in white people of 0.189 ± 0.023. The polymorphic nature of Hv(1) has also been confirmed in black people, studies on a large black kindred ($n = 80$) having confirmed its autosomal dominant mode of inheritance. The gene frequency (determined by the Elston–Stewart method using maximum likelihood[5]) in blacks is 0.278 ± 0.067. Hv(1) seems analogous to murine idiotypes of the so-called *Idx* category[6] and to rabbit V_H-region allotypes in that it is not restricted to any particular immunoglobulin class. This observation is consistent with our previous finding that the same V-region amino acid sequence is able to associate with constant (C) regions of different H-chain classes[7]. However, an important difference between Hv(1) and the idiotypic markers in mice and rabbits is that the former is presumably associated with the framework residues whereas the latter are associated primarily with the hypervariable regions. We now report results obtained from family studies which indicate absence of linkage between Hv(1) and the human C-region markers Gm (human IgG H chains) and Km (κ-type light chains). These results provide new information about the genetic control of immunoglobulin synthesis in man.

Serum samples from one large black kindred ($n = 80$) and one large white kindred ($n = 220$) and from three smaller white families ($n = 84$) were typed for Hv(1), Km(1) and nine Gm markers (1, 2, 3, 5, 6, 13, 14, 17, 21) by our standard haemagglutination inhibition method[4,8]. All sera were diluted 1:16 for detection of Gm and Km markers. The Hv(1) marker was detected by the use of serial dilutions, with inhibiting titres of 1:16 or greater considered as positive. The lod score method of Morton[9] was used to test for linkage between Hv(1) and the C-region markers, basing the likelihood on the complete pedigree structures[5,10]. This method takes advantage of available data from every sort of informative test cross, that is, from double intercrosses and single backcrosses as well as double backcrosses. It determines the relative odds that a sequence of genotypes among siblings resulted from linked loci with a certain percentage of meiotic crossing over, as compared with the possibility that the sequence occurred by chance from unlinked loci. For convenience, the ratio of these two probabilities—recombination fraction $\theta < 1/2$ (linkage) compared with $\theta = 1/2$ (no linkage)—is expressed as its logarithm. The $\log_{10}$ of this relative probability is called the log of the odds or 'lod score', and the value of θ which corresponds to the maximum value of the lod score is taken as the estimate of the recombination fraction θ. Computer program LIPED[10] was used to calculate lod scores. The lod scores for linkage between Hv(1) and Gm and Km markers were negative (Table 1). (A negative value argues against linkage, a lod score greater than 2 is suggestive of linkage, and a value greater than 3 is accepted as proof of linkage.) On the basis of the data presented here, close linkage between Hv(1) and Gm and Km is excluded.

Investigations in humans, as well as mice and rabbits, suggest that unlinked genes code for H chains, κ-type light (L) chains and λ-type L chains[11-14]. Absence of linkage between Hv(1) and Km is compatible with these observations. However, the absence of linkage between Hv(1) and Gm does not concur with findings in the rabbit and the mouse.

Most models of immunoglobulin genes predict close linkage between V- and C-region genes. V_H-region markers have been analysed in considerable detail with regard to linkage to C_H loci. Rabbit a-group allotypes, located on the V_H region, are linked to the d- and e-group allotypes located on the γ-chain of C_H (refs 15, 16), and in mice some idiotypic (V-region) markers are linked to C_H allotypes[6,17,18]. However, the results reported here are not entirely unprecedented. For example, one study of b-group allotypes and the LId idiotype in rabbits gave no evidence of linkage between V_L and C_L genes[19].

The simplest interpretation of the present finding is that Hv(1) is not a V-region allotype. However, extensive inhibition

experiments involving Fab and Fc fragments and isolated H and L chains, reported previously[4] demonstrated that the antigenic determinant for Hv(1) is located on the V region of human immunoglobulin heavy(1) chain. Another interpretation of our results is that [illegible] phenotypes are controlled by two [illegible] structural genes coding for the antigenic [illegible] genes controlling the [illegible] regulatory genes need not be [illegible] and the genes they regulate[20]. A [illegible] several species suggest that the [illegible], in which allotypes are encoded by [illegible] structural genes, may be an oversimplification. [illegible] humans, discrepancy between the genotype [illegible] expressed phenotype, and in rabbits, allotype [illegible] latent allotypes and the 'pecking order' in the [illegible] of allotypes, all suggest the existence of regulatory [illegible] which control the expression of structural genes coding immunoglobulin allotypes[21–27]. Indeed, it has been suggested that expression of other genetic polymorphisms (for example, HLA and ABO) may also be under the control of regulatory genes[28].

Alternatively, the loci for Hv(1) and Gm may be on the same chromosome, but very far apart. In murine H and L chains, the V-region structural genes are located at some distance from the C-region structural genes in the germ-line DNA[29–33]. When two loci are very far apart, their genetic behaviour in family studies is often indistinguishable from that of independently segregating loci (that is, those on different chromosomes). One approach to this problem is genetic mapping by the somatic cell hybridization technique[34]. Such studies are in progress in our laboratory.

A test for the selective origin of environmentally correlated allozyme patterns

J. M. Malpica & J. M. Vassallo

Departamento de Genética, INIA, Carretera de La Coruña Km.7,
Madrid-35, Spain

Differences in the kinetic and/or endurance properties of enzymes encoded by alternative alleles have been suggested as the basic level at which selection could act on allozyme polymorphisms[1,2]. The correlation between spatial differences in gene frequencies and an environmental variable (hereafter designated cline, in its widest sense), when not spurious, has been proposed to show the working of selection[3]. Let us suppose that a given cline has originated through an environmentally imposed selection on enzyme activity. Because differences in enzymatic activities among individuals can be split into structural-gene and 'genetic-background' components[4–6], selection should act on both components in the same direction. That is, a correlation should exist between the environmental variable and the background component and it should be of the same sign as that between the environmental variable and the frequency of the most active allele. It should be less likely for clines conforming to these expectations to be spurious. Here we have investigated the relationship between the alcohol dehydrogenase locus (*Adh*) polymorphism and temperature in Spanish populations of *Drosophila melanogaster* and have found that it meets the above criterion.

It has been shown that the specific activity is higher for the Adh^F than for the Adh^S allelic variant of the enzyme[7–9], and that loci other than *Adh* affect ADH activity[4,5], although the extent of the two effects has been questioned[10]. A temperature cline has been reported for this locus[8], but a widespread association of the Adh^S allele with an inversion in the same chromosome arm (II left; refs 11, 12 and our unpublished results) makes interpretation of the cline difficult.

We have chosen the average temperature of the coldest month of the year (t_{min}) as the environmental variable. (Average temperature of the year ($\bar{t}$) and average temperature of the hottest month (t_{max}) are correlated with it over locations; $r_{t_{min},\bar{t}} = 0.961$, d.f. $= 22$, $P < 0.001$; $r_{t_{min},t_{max}} = 0.712$; d.f. $= 22$,

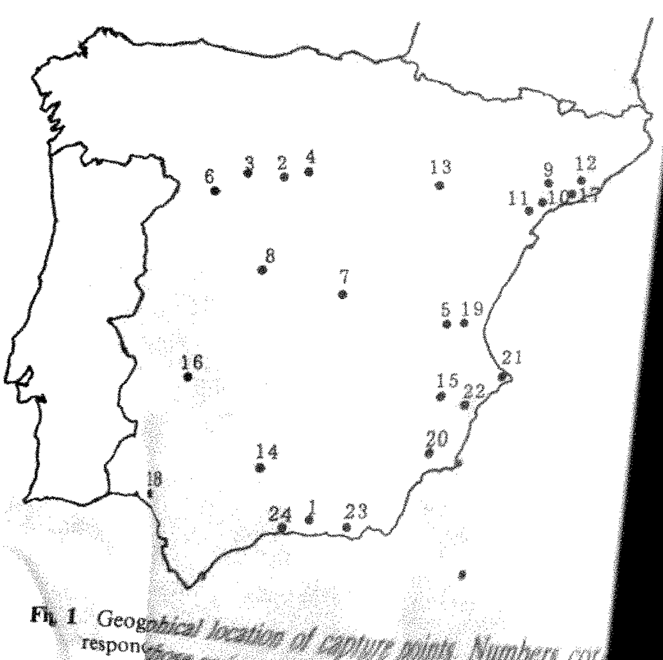

Fig. 1 Geographical location of capture points. Numbers correspond to those assigned to the samples in Table 1.

Correlation with t_{min}			−0.749‖		−0.764¶		

* Results from captured wild flies; no significant differences were observed between sexes.

† ADH activity was assayed in descendents of the captured individuals, kept in population cages for no more than 3 months. The heads were electrophoresed and the b of $Adh^{F/F}$ individuals pooled in groups of 10. Reaction mixture: 0.5 ml of 6 mM NAD, 1 M isopropanol + 0.1 ml of homogenate (10 flies per ml), all in 0.05 M Tris-HCl b pH = 9.0 Assay temperature 25°C. Results in ΔE per m per fly, at 340 nm.

‡ Chromosomes extracted from wild captured males and assayed for cross-over suppression against an *all* chromosome[15]. LAI, Left arm inversion.

§ Samples captured in the same month, but a year later than the rest.

‖ Angular transformation has been applied to the frequencies (d.f. = 26, $P < 0.001$).

¶ d.f. = 13, $P < 0.001$.

$P < 0.001$.) There is a close correlation between the angular transform of Adh^F frequency and t_{min} (Table 1). The cline is not strictly latitudinal, in contrast with that observed on the US East Coast[8] (see Fig. 1 and Table 1).

We have assumed the among-populations differences in ADH activity, measured in $Adh^{F/F}$ individuals, to be due to the genetic background. This is a valid approach as the available evidence shows that there is little structural variability segregating within *Adh* electromorphs[13]. ADH activity was measured in $Adh^{F/F}$ individuals from 15 locations ($r_{\text{ang.transf.}Adh^F\text{freq.},t_{min}} = -0.747$) and a negative correlation with t_{min} was found (Table 1). Activities were expressed on a per fly basis as no significant over-locations correlations were found between body weight (x_1) and t_{min} or between body weight and activity per fly (x_2) ($r_{x_1,t_{min}} = -0.2814$, d.f. = 10, $0.4 > P > 0.3$; $r_{x_1,x_2} = 0.1339$, d.f. = 11, $0.7 > P > 0.6$).

In general, this type of result should reduce the probability of a non-selective origin for an observed environmentally correlated allozyme pattern. In our particular case, we note that the environmental variable is an *a priori* one, in the sense that a imilar cline has been described already[8]. The other potential ource of spuriousness, non-random association, can be easonably excluded, as the non-random associated gene (or lock of them) would have to fulfill the following conditions:) to be selected, (2) to have a relevant role in determining the zymatic activity, and (3) to be associated by chance with the ectrophoretic allele that modifies the activity in the same irection. In the present case, as the above statd association between Adh^S and the inversion is not absolu (our unpublished results), we have checked the frequen of left arm inversions within Adh^F chromosomes for so the samples in the cline (Table 1). They were always small significant differences were found between samples loc he first and the second half of the temperature range ($\chi_1^2 = 0.335, 0.6 > P$ 0.5).

We regard these results as strong support for the hypothesis a selective origin of the *Adh* cline in Spanish populations *D. melanogaster*. We do not imply that temperature is the age of the probable selection in the cline; any other temperature correlated variable (such as average concentration of alcohol i the food available to the flies) or a combination of them could b the actual agent.

The present study provides a new approach for investigatin the selective origin of clines. We believe it could be applied to fair proportion of enzymatic polymorphisms as, in most case there are differences in the specific activities between allel forms[1], and, at least in some species, spatial patterns of ge frequencies are not uncommon[11,14].

L. Silió carried out the activity assays. We thank F. Garcí Olmedo, G. N. Somero and C. Wills for their help in th preparation of this manuscript.

Feline sarcoma virus polyprotein P115 binds a host phosphoprotein in transformed cells

Fred H. Reynolds Jr & Wim J. M. Van de Ven

Carcinogenesis Intramural Research Program, Frederick Cancer Research Center, Frederick, Maryland 21701

John R. Stephenson

Laboratory of Cellular and Molecular Biology, National Cancer Institute, Frederick, Maryland 21701

Several independent isolates of feline sarcoma virus (FeSV) have been described[1–3]. Such viruses are apparently derived by genetic recombination between feline leukaemia virus (FeLV) genomic RNA and host cellular genetic sequences with transforming potential[4]. Two FeSV isolates, one originally described by Gardner and the second by Snyder-Theilen, have been shown to encode polyproteins of around 115,000 molecular weight[5–8,18,19]. Both polyproteins contain FeLV structural components (p15, p12) at their amino terminus in addition to nonstructural carboxyl terminal components encoded by acquired sequences within the FeSV genome. We have previously shown that Gardner FeSV P115 contains multiple sites of phosphorylation within its nonstructural component and possesses an associated protein kinase activity[9]. In the present study we describe the expression in cells derived from a number of mammalian species, of a highly conserved cellular phosphoprotein with binding affinity for Gardner FeSV P115. This protein, designated P150, exhibits an associated protein kinase activity and is immunologically and structurally distinct from polyproteins encoded by the Gardner or Snyder-Theilen strains of FeSV.

In view of accumulating evidence implicating the non-structural components of Gardner and Snyder-Theilen FeSV encoded polyproteins in transformation (see ref. 10 for review), we analysed uninfected and FeSV transformed mammalian cells for the presence of proteins which exhibit specific binding affinity, and thus possible functional interaction with FeSV P115. Initially, ^{14}C-amino acid labelled control and Gardner FeSV transformed mink cells were analysed by immunoprecipitation and SDS-polyacrylamide gel electrophoresis (SDS-PAGE) using goat antisera directed against detergent-disrupted FeLV. In addition, a high-titred antiserum prepared by immunization of a goat with FeSV P115 partially-purified from Gardner FeSV(4070-A) pseudotype virions by gel filtration was used. As shown in Fig. 1, immunoprecipitation of FeSV P115 and its major cleavage product, P72, from Gardner FeSV transformed mink cells was obtained with either anti-FeSV P115 (lane *b*), or anti-FeLV (lane *a*), but not by normal goat serum (lane *c*). The viral specificity of these proteins is indicated by their absence from control mink cells (lanes *d-f*). Precipitation of Gardner FeSV P115 by anti-FeLV has previously been shown to be due to immunological recognition of FeLV p15 and p12 structural components[6,8,18,19]. An additional protein, of around 150,000 molecular weight (P150), was precipitated from both FeSV transformed and control mink cells by anti-FeSV P115 and from FeSV transformed but not control mink cells by anti-FeLV. These findings demonstrate recognition of P150 by our anti-Gardner FeSV P115 serum and raise the possibility that FeSV P115 may have binding affinity for P150. Such affinity could account for immunoprecipitation by anti-FeLV of P150 from FeSV transformed but not control mink cells.

To explain the above results it is necessary to account for precipitation of P150 from control mink cells by anti-FeSV P115. One possibility is that P150 might have been incorporated into FeSV pseudotype virions as a consequence of an affinity for FeSV P115. Antisera prepared by immunization with partially-purified FeSV P115 might thus recognize mink cellular P150 due to low level P150 contamination of the original immunogen. Alternatively, immunoprecipitation of P150 by anti-FeSV could reflect immunological cross-reactivity between the two proteins. A high-titred antiserum was prepared by repeated immunization of a Fisher rat with FeSV nonproductively-transformed syngeneic tumour cells. If P150 and FeSV P115 shared immunological determinants, sera prepared by this means should also recognize mink cellular P150. As shown in Fig. 1, immunoprecipitation of FeSV P115 and P72 from FeSV

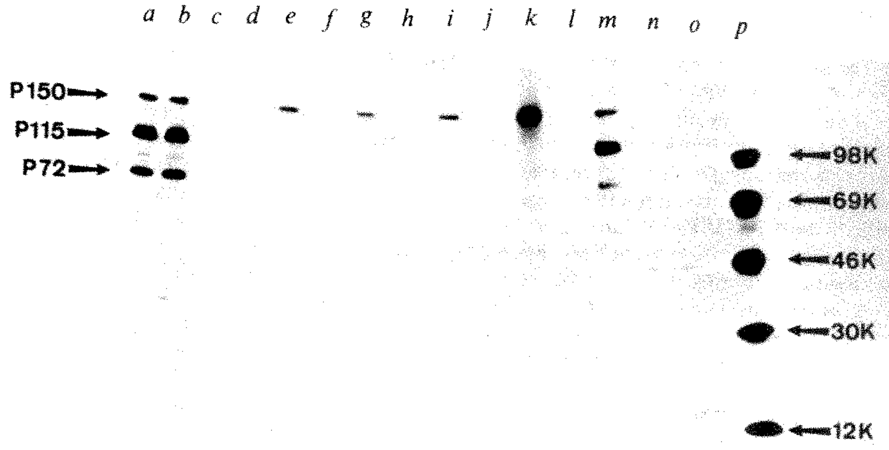

Fig. 1 Analysis by SDS-PAGE of polyproteins encoded by the Gardner strain of FeSV and 150,000 molecular weight cellular phosphoproteins. Cell lines have been previously described[6,8] and include a fetal mink cell line, CCL64 (*d–f, k, l, n*); a Gardner FeSV transformed subclone of CCL64, designated 64F3 (*a–c, m*), a kitten embryonic lung cell line, KeLu (*g, h,* 0) and a canine embryo thymus line, FCf2Th (*i, j*). Metabolic labelling of exponentially-growing cells for 2 h at 37 °C with either ^{14}C-amino acids (10 µCi per ml) (57 µCi/m Atom, Amersham) (*a–j*; *m*–0) or ^{32}P-orthophosphate (100 µCi per ml) (carrier-free), NEN) (*k, l*) was performed as reported previously[9]. Following labelling, cell monolayers were washed twice in serum-free Dulbecco's modified Eagles medium and disrupted at 4 °C in 10 mM sodium phosphate *p*H 7.2, 0.9% NaCl, 1% Triton X-100, 0.5% sodium deoxycholate and 0.1% SDS (PBSTDS) lysis buffer. Extracts (5 ml) were incubated at 4 °C for 18 h following addition of RNase A (200 µg ml^{-1}), RNase T$_2$ (0.1 µg ml^{-1}), DNase I (4.0 µg ml^{-1}), normal goat serum (25 µl), protein-A Sepharose Cl-4B (1.0 ml of 10% v/v suspension) (Pharmacia), and clarified by centrifugation at 100,000 *g* for 1 h. Specific proteins were immunoprecipitated by addition of 5 µl of specific antisera to 1 ml lysate, incubation for 18 h at 4 °C, addition of 50 µl of a 10% (v/v) protein-A Sepharose Cl-4B suspension and incubation for a further 2 h at 4 °C. Immunocomplexes were collected by centrifugation at 2,000*g* for 10 min, washed three times in PBSTDS, resuspended in 20 µl 0.65 M Tris-HCl *p*H 6.7, 1% SDS, 10% glycerol, 2.5% 2-mercaptoethanol and 0.1% bromophenol blue and heated for 2 min at 90 °C. Finally, samples were electrophoresed through a 5% acrylamide stacking gel and a 9 cm 5–20% linear polyacrylamide (30:0.8 acrylamide: bis-acrylamide) gradient separation gel in a Tris-glycine-SDS-buffer system at 20–30 mA (ref. 17). Radioactivity was visualized by autoradiography using Kodak X-0mat XR2 film. Sera used included goat anti-FeLV (*a, d*); goat anti-FeSV P115 (*b, e, g, i, k*), normal goat serum (*c, f, h, j, l*) and serum from a Fisher rat repeatedly immunized with syngeneic FeSV transformed tumour cells (*m–o*). Molecular weight standards include ^{14}C-labelled phosphorylase B (98,000), bovine serum albumin (69,000), ovalbumin (46,000), carbonic anhydrase (30,000) and cytochrome *c* 12,000 (P).

8-0836/80/300409—04$01.00

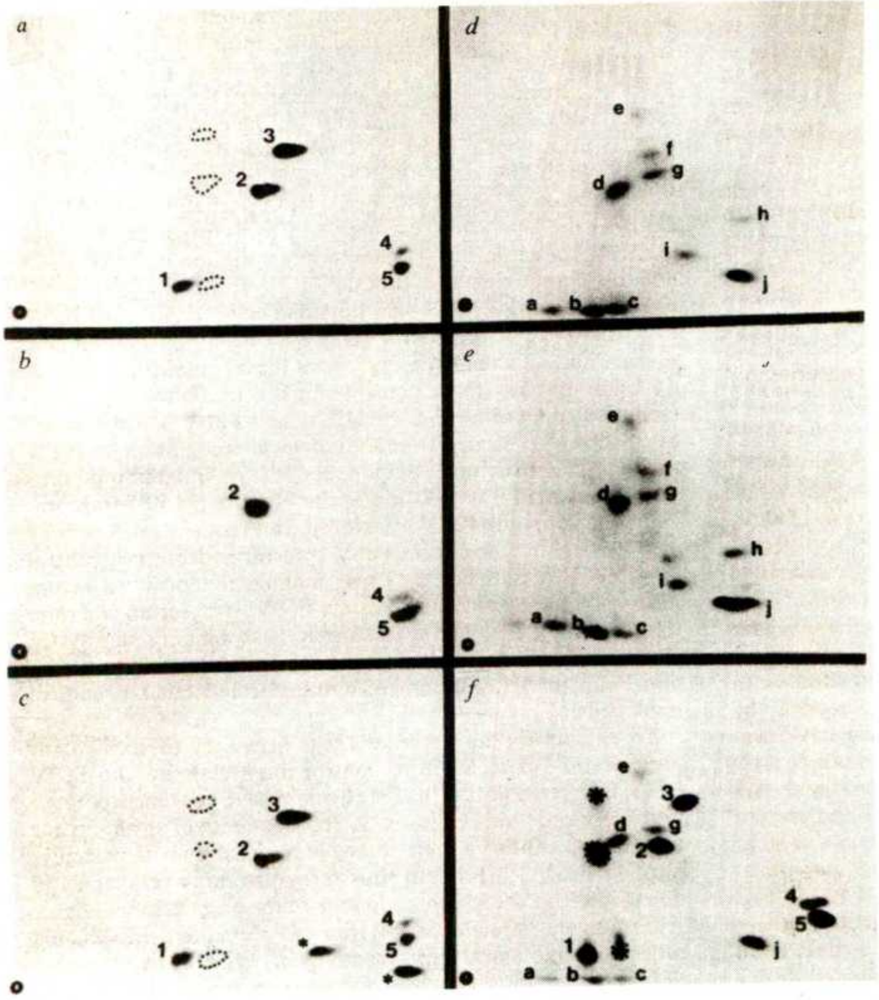

Fig. 2 Comparison by two dimensional tryptic peptide analysis of Gardner and Snyder-Theilen FeSV P115s to the 150,000 molecular weight phosphoproteins expressed in mink and cat cells. Proteins were labelled for 2 h at 37 °C with ^{35}S-methionine (200 μCi per ml) (1075 Ci mmol^{-1}, Amersham) and purified by immunoprecipitation and SDS-PAGE as described in the legend to Fig. 1. Following electrophoresis, gels were washed extensively with 10% trichloroacetic acid, and subsequently with a 10% solution of acetic acid and methanol in water and dried under vacuum. Labelled proteins were localized by autoradiography, and selected gel slices further washed in methanol (10%) and lyophilized. Proteins were digested by incubation of gel slices in tolylsulphonyl phenylalanyl chloromethyl ketone (TPCK)-trypsin (Worthington Biochemicals) (50 μg ml^{-1} in 0.05 M ammonium bicarbonate *p*H 8.0) for 6 h at 37 °C. Following filtration through a 0.45 μm Millex filter (Millipore) and removal of ammonium bicarbonate by repeated lyophilization, tryptic digests were incubated for 2 h at 0 °C in 0.1 ml of chilled performic acid (30% H_2O_2 and 90% formic acid (1:9) preincubated for 2 h at room temperature). Samples were diluted with 2 ml H_2O, lyophilized, resuspended in electrophoresis buffer comprised of acetic acid : formic acid : water (15:5:80) and spotted on 10 × 10 cm cellulose coated TLC glass plates (EM Laboratories). Electrophoresis was performed for 30 min at 500 V and chromatography was conducted in the second dimension in buffer containing butanol, pyridine, acetic acid and water (32:25:5:20). Radiolabelled tryptic peptides were visualized by autoradiography using Kodak X-Omat XT 2 film. Detection of peptides was enhanced by spraying TLC plates with a solution of 7% diphenyloxazole in diethyl ether. Proteins analysed included: Gardner FeSV P115, (*a*); Snyder-Theilen FeSV P115 (*b*); a mixture of FeLV Pr65^{gag}(*) and Gardner FeSV P115 (1–5) (*c*); CCL64 P150 (*d*); KeLU P150 (*e*); and a mixture of KeLu P150 (*a–j*) and Gardner FeSV P115 (*f*).

transformed (lane *m*), but not control mink (lane *n*) or cat (lane *o*) cells was obtained. The absence of detectable precipitation of P150 from uninfected control cells (lane *n*) argues against the possibility that P150 and FeSV P115 possess common immunological determinants.

The availability of a high-titred goat antiserum with specificity not only for FeSV P115 but also for mink cellular P150 provided a means for examining cells of additional species for immunologically cross-reactive proteins. As shown in Fig. 1, proteins similar in molecular weight to mink cellular P150 were precipitable from uninfected feline embryo and canine thymus cells by anti-FeSV P115 (lanes *g*, *i*) but not control (lanes *h*, *j*) goat serum. In other studies we have observed expression of analogous proteins in each of several established human tumour cell lines (data not shown). Thus, mink cellular P150 seems to be representative of a class of proteins of around 150,000 M_r expressed in cell lines of many different mammalian species.

To explore further the relatedness of the 150,000 molecular weight proteins in uninfected mink and cat cells both to each other and to the 115,000M_r Gardner and Snyder-Theilen FeSV encoded polyproteins, ^{35}S-methionine tryptic peptide mapping studies were performed. As shown in Fig. 2*a*, Gardner FeSV P115 contains five ^{35}S-methionine labelled peptides, none of which correspond to the two ^{35}S-methionine labelled peptides specific to the p30 component of FeLV Pr65^{gag} (Fig. 2*c*). Three of the five Gardner FeSV P115 peptides are also represented in Snyder-Theilen FeSV P115 (Fig. 2*b*) consistent with the contention that these independently-derived FeSV isolates possess common or overlapping acquired genetic sequences[4,8,19]. Additional minor peptides within the Gardner FeSV P115 peptide map, indicated by dotted circles, are probably nonspecific in that their presence is variable, and in contrast to the five major ^{35}S-methionine labelled peptides, is dependent on the species of origin of cells analysed. Analysis of mink and cat cellular P150s revealed 10 major ^{35}S-methionine labelled peptides which seemed very similar by two dimensional analysis (Fig. 2*d*, *e*). When analysed in a mixing experiment, none of the 10 ^{35}S-methionine labelled peptides specific to P150 corresponded to the five major ^{35}S-methionine labelled peptides present in Gardner FeSV P115 (Fig. 2*f*). This latter observation is consistent with the above described lack of immunological cross-reactivity between these two proteins and further argues against the possibility that P150 is encoded by cellular sequences homologous to those encoding the non-structural component of FeSV P115.

The non-structural components of Gardner and Snyder-Theilen FeSV 150,000 M_r polyproteins are known to contain multiple sites of phosphorylation[9]. It was thus of interest to establish whether the above described 150,000 M_r cellular proteins are also phosphorylated. To examine this possibility, we analysed extracts of cells metabolically labelled with ^{32}P-orthophosphate by immunoprecipitation and SDS-PAGE. As shown in Fig. 1, mink cellular P150 was efficiently labelled and was immunoprecipitated from mink cells by anti-FeSV P115 (lane *k*) but not normal goat serum (lane *l*), establishing its phosphorylated nature. Tryptic peptide analysis of ^{32}P-labelled P150s from mink and cat cells revealed each to possess 10 to 1 major well-resolved phosphopeptides. The high degree o relatedness of the tryptic peptide patterns of the two protein further indicates that these proteins are relatively conserve (data not shown).

We have previously reported[9] the presence of readily detect able levels of protein kinase activity in immunoprecipitates of

Gardner FeSV P115. The polyprotein itself has been shown to represent a major substrate for this enzymatic activity. Because of the above findings indicating the invariable presence of P150 in such immunoprecipitates, it was of interest to find whether cellular P150s exhibited similar reactivities in the absence of FeSV P115. Extracts of FeSV transformed and control mink cells were prepared, immune precipitated by anti-FeLV, anti-FeSV P115 and normal goat serum and analysed for protein kinase activity. Enzymatic reactivities and substrates involved were identified by SDS-PAGE. As shown in Fig. 3, both Gardner FeSV P115 and mink cellular P150 were efficiently labelled by this means. Incorporation of phosphate into both P150 and FeSV P115 was in the range of 10–20 fmol per min. Even in the absence of FeSV P115, efficient labelling of P150 was observed (lane *e*) establishing that *in vitro* [γ-^{32}P]ATP labelling of P150 is not dependent on an FeSV P115 associated protein kinase. Additional substrates for the P150 associated protein kinase included proteins of around 45,000–50,000 molecular weight in control and FeSV transformed mink cells and a 40,000 molecular weight protein detectable only in control mink cells. The significance of these proteins and their relationship to P150 remain to be determined.

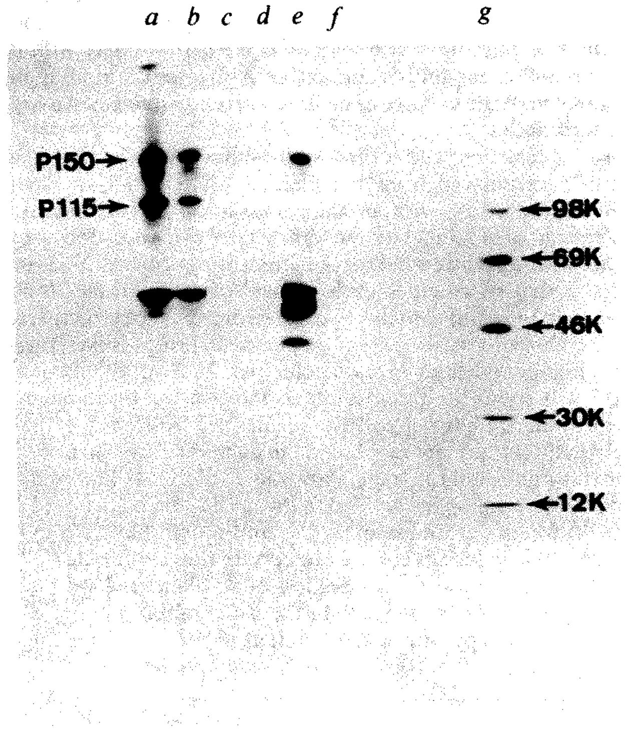

Fig. 3 Analysis of Gardner FeSV P115 and mink cellular P150 containing immunoprecipitates for protein kinase activity. FeSV transformed (*a–c*) and control (*d–f*) CCL64 mink cells were disrupted by repeated aspiration of 1.0×10^7 cells in 5 ml 10 mM Tris-HCl *p*H 7.2, 100 mM NaCl, 1 mM EDTA and 0.1% Triton X-100 through a 25-gauge needle. Disrupted cells were clarified by centrifugation at 2,000 r.p.m. for 10 min, preabsorbed by addition of 50 μl normal goat serum and 0.5 ml of a 10% (v/v) suspension of protein-A Sepharose Cl-4B (Pharmacia), incubated overnight at 4 °C and reclarified by centrifugation at 100,000*g* for 2 h. Following addition of 5 μl specific antiserum, lysates (1 ml) were incubated at 4 °C for 18 h, 50 μl of a 10% (v/v) protein-A Sepharose suspension was added and incubation continued for a further 2 h at 4 °C. Immunocomplexes were collected by centrifugation for 10 min at 2,000*g* and washed in PBSTDS. Protein kinase activity was assayed by resuspension of immunoprecipitates in 20 mM Tris-HCl, *p*H 7.2, 5 mM $MgCl_2$ buffer containing 1 μCi [γ-^{32}P]ATP (2000 Ci mMol^{-1}, NEN) and incubation for 10 min at 30 °C. Reactions were terminated by addition of 3 ml ice cold PBSTDS and nonprotein-bound [^{32}P] label removed by repeated centrifugation in excess PBSTDS. After the final wash, immunoprecipitates were analysed by SDS-PAGE as described in the legend to Fig. 1. Sera used included goat anti-FeLV (*a*, *d*); goat anti-FeSV P115 (*b*, *e*) and normal goat (*c*, *f*). Molecular weight standards are as described in the legend to Fig. 1.

Immunoprecipitation of P150 from both normal and FeSV transformed cells of various species by the anti-FeSV P115 serum used in the present study suggests that P150 is incorporated into pseudotype virions in association with FeSV P115 and represents a probable minor contaminant of the purified FeSV P115 used as the original immunogen. To test this possibility directly, immune precipitates of density-gradient purified FeSV(4070-A) and control 4070-A virions were analysed for protein kinase activity. As shown in Fig. 4, both P150 and FeSV P115 were precipitated from FeSV (4070-A) pseudotype virions by anti-FeLV but not by normal goat serum.

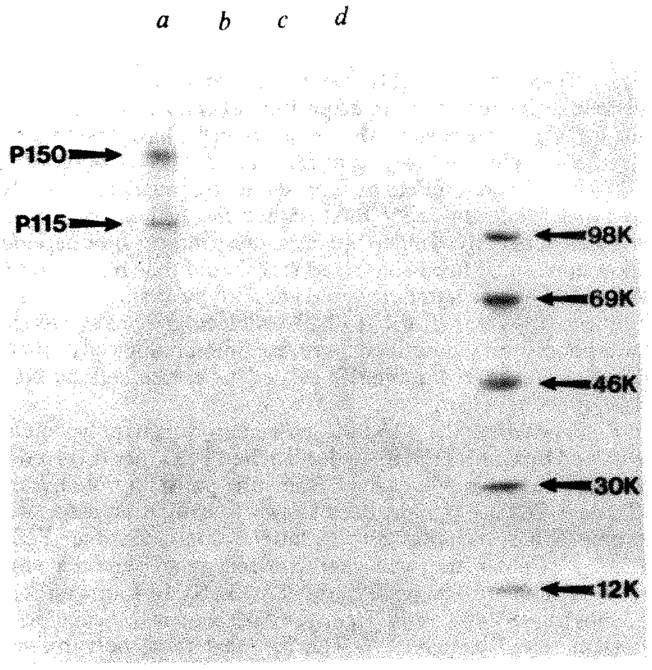

Fig. 4 Association of P150 and FeSV P115 in FeSV(4070-A) pseudotype virions. FeSV(4070-A) (*a*, *b*) and 4070-A (*c*, *d*) virions were purified by sucrose density gradient centrifugation, disrupted and analysed for protein kinase activity as described in Fig. 3. Sera used included goat anti-FeLV p12 (*a*, *c*) and normal goat (*b*, *d*). Molecular weight standards are as described in the legend to Fig. 1.

Both proteins represented efficiently labelled substrates for protein kinase activities present in these immune precipitates. Proteins of around 40,000–50,000 M_r seen in immunoprecipitates of FeSV transformed and control mink cells were not present in immunoprecipitates prepared from FeSV pseudotype virus, arguing against the possibility that their presence is necessary for the protein kinase activities associated with FeSV P115 and P150.

The present findings establish the expression in mink cells of a highly conserved 150,000 molecular weight cellular phosphoprotein with binding affinity for Gardner FeSV P115. Although the biological role of this cellular phosphoprotein is unknown, its affinity for FeSV P115 may have functional significance. P150 and FeSV P115 both represent efficient substrates for protein kinase activity present in immunoprecipitates of FeSV P115. While *in vitro* [γ-^{32}P]ATP labelling of mink cellular P150 is shown to proceed in the absence of FeSV P115, the converse is not necessarily true. Thus, the possibility that P150 possesses intrinsic protein kinase activity and is responsible for phosphorylation of FeSV P115 must be considered. Such a model would be consistent with the affinity that these proteins exhibit for each other. The possibility that both P150 and FeSV P115 possess intrinsic protein kinase activity or alternatively, that an as yet undetected cellular protein kinase is responsible for phosphorylation of one or more of these proteins cannot, however, be excluded.

It is of interest to compare the 150,000 molecular weight cellular phosphoproteins described above to a protein of similar molecular weight recently shown to be expressed in mouse thymus and to a lesser extent, spleen and bone marrow cells[11]. This latter protein, designated NCP 150, has not as yet been characterized with respect to phosphorylation and protein kinase activity. However, NCP 150 has been shown to share immunological determinants with the non-structural component of a 120,000 molecular weight polyprotein encoded by Abelson murine leukaemia virus and is apparently encoded by normal cellular sequences analogous to acquired cellular sequences represented within the AbLV genome. In contrast, on the basis of immunological and structural criteria, the 150,000 molecular weight cellular protein described in the present study is immunologically and structurally unrelated to FeSV P115. The possibility that this lack of relatedness is due to genetic drift subsequent to acquisition of cellular sequences by the FeSV genome seems to be excluded on the basis that three of five ^{35}S-methionine labelled tryptic peptides of Gardner FeSV P115 have been found to be represented by analogous peptides in Snyder-Theilen FeSV P115. Since the two sarcoma virus isolates were derived independently, these three tryptic peptides have apparently been conserved and should thus be present in feline P150 if the latter protein is encoded by analogous genetic sequences. Whether the 150,000 molecular weight cellular phosphoproteins described here are immunologically, structurally or even evolutionarily related to mouse cellular NCP 150, is not yet clear.

Evidence that the 115,000 molecular weight polyproteins encoded by Gardner and Snyder-Theilen FeSV are involved in transformation is increasing. Both are phosphoproteins and Gardner FeSV P115 has been shown to exhibit an associated protein kinase activity[9]. In this latter respect, Gardner FeSV P115 resembles the well characterized avian sarcoma virus transforming protein, pp60^{src} (refs 12, 13), SV40 T antigen[14], an adenovirus–SV40 hybrid T antigen (D2 protein)[15,16] and polyoma middle T antigen[20–22]. The fact that these polyproteins, encoded by independently-acquired cellular sequences, share tryptic peptides, argues for the existence within the normal cellular genome of a limited number of genetic sequences which, on insertion into the type C viral genome, can lead to malignant transformation. The identification of a highly conserved cellular phosphoprotein with associated protein kinase activity and binding affinity for FeSV P115 may have significance with respect to the elucidation of cellular regulation mechanisms involved in transformation of eukaryotic cells.

We thank S. E. VanLaningham-Miller and R. P. Nalewaik for technical assistance. This work was supported under NCI contract NOI-CO-75380, and by a fellowship awarded to W. J. M. Van de Ven by The Netherlands Organization for the Advancement of Pure Research (ZWO).

Note added in proof: Gardner FeSV P115-associated protein kinase specifically phosphorylates tyrosine acceptor sites represented both within P115 itself and in cellular P150.

Fraying of A-filaments into three subfilaments

Maria C. Maw & Arthur J. Rowe

Department of Biochemistry, School of Biological Sciences,
University of Leicester, Leicester LE1 7RH, UK

Since Huxley[1] established their bipolar structure, direct ele microscopy of A-filaments isolated from vertebrate sk muscle has yielded little further interpretable information the mode of packing of the myosin molecules within filament. Using A-filaments prepared from rat psoas muscle have now found it possible to induce clear fraying of these filaments into subfilaments, by exposure of the preparation to very low ionic strength before contrasting with uranyl acetate. The number of such filaments observed is generally (and never in excess of) three. Considerations of symmetry suggest that the formation of these frayed filaments is compatible only with a 'three-stranded' model for the native A-filament, a finding in agreement with the balance of evidence recently published using other techniques[2–5].

X-ray diffraction and other studies have shown that the cross-bridges emerge from the filament shaft in an approximately helical array, with an axial translation of 14.3 nm and axial repeat of 43 nm, but the diffraction evidence does not indicate with certainty whether the cross-bridge helix is 2-, 3- or 4-start[6,7]: that is, whether each 'crown' of cross-bridges (one 'crown' per 14.3 nm) contains two, three or four such structures. If the number of myosin molecules per cross-bridge is one, then *n* (the number of myosin molecules per 14.3 nm of filament length) will equal the number of 'strands' in the three helical models. If there are two myosin molecules per cross-bridge then it is virtually certain that $n = 4$, and the filament is two-stranded. Estimates published for *n* are shown in Table 1. As Squire has pointed out[2], opinion has tended to favour $n = 3$, and two recent studies[3,4] which determine mass per unit length have strongly supported this value, in contrast to certain other estimates[5].

While studying the reconstruction of A-filaments[8] we have used rat psoas muscle rather than the usual rabbit muscle, and electron microscopy of relaxed filament preparations revealed that a significant proportion of the A-filaments were 'frayed' at

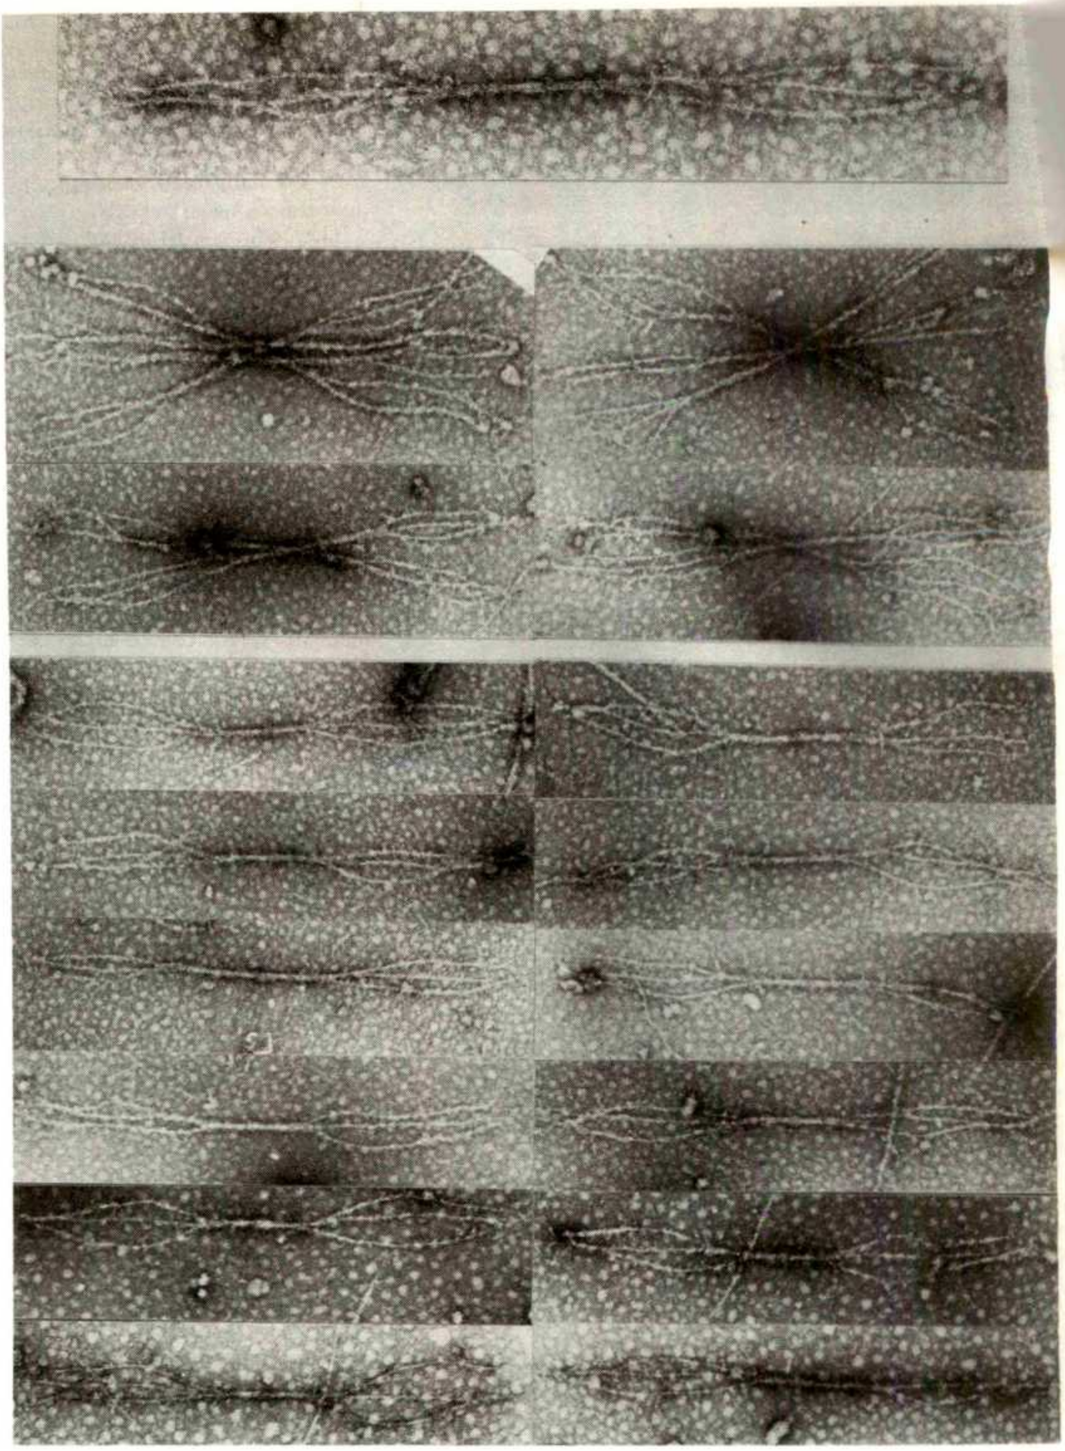

Fig. 1 Electron micrographs of A-filaments and small a-segments (second and third rows) in relaxed filament preparations prepared from rat psoas muscle by the method of Emes and Rowe[4]. The preparations were rinsed on the support grids first with 0.12 M KCl and then with several drops of distilled water before contrasting with unbuffered 2% uranyl acetate. 'Frayed' filaments of the type shown here are routinely seen when this procedure is followed, both in areas where the filaments are negatively contrasted (as shown) and were positive contrasting has occurred. top, ×114,500; Others, ×45,000.

the ends into subfilaments (Fig. 1). We have occasionally observed this effect with rabbit A-filaments prepared in identical conditions. Filaments that 'fray' are indistinguishable in length or width (of the 'non-frayed' region) from intact filaments (Fig. 2); as the proportion that fray varies from preparation to preparation, and even from area to area within the same specimen grid, it is unlikely to constitute a genuine subpopulation of filaments. The variation presumably arises from exact drying-down conditions which are not yet fully controlled.

More than 800 frayed filaments were photographed, measured and examined. In every case only two or three subfilaments were present. Where two subfilaments were counted one was usually significantly thicker than the other (Fig. 1); the thicker one is presumed to comprise two unfrayed subfilaments. We never observed an A-filament that frayed into more than three subfilaments. Fraying, which commences at the distal region, can proceed to any point along the filament axis (Fig. 2) up to a central region ~0.3 μm wide. Within experimental error this corresponds to the innermost stripe of the A-segment which stains with impure anti-C-protein (that is, stripe 9, following the terminology of Craig and Offer[9]). Although the subfilaments are not smooth and show evidence of projections which may be cross-bridges, a clear repeating structure has not as yet been demonstrated.

Subfilaments formed only when the preparation on the microscope grid was washed with several drops of distilled water before contrasting with uranyl acetate. In control experiments, preparations made by this technique showed from 32 to 79% of frayed filaments in randomly selected areas; however a further wash with 0.12 M KCl before contrasting produces almost complete reversal of the effect. No significant proportion of frayed filaments is found if washing with ammonium formate solution (pH 7, $I = 0.12$) is substituted for the distilled water wash. The simplest explanation for this phenomenon is that at

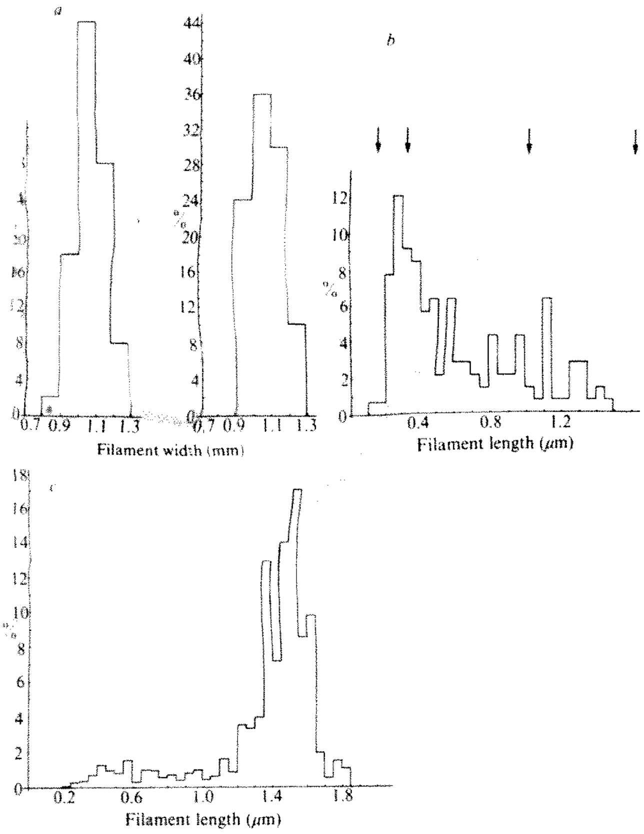

Fig. 2 Statistical analysis of the dimensions of frayed A-filaments showing: *a*, the measured width (×68,700) of the unfrayed central region, avoiding the presumed M-line region, as compared with the similarly measured width of normal, unfrayed filaments (R) from adjacent fields: *b*, the distribution of the length (from one side of the filament to the other) of the unfrayed central region of the frayed filaments, with vertical arrows showing (from L to R) the distances corresponding respectively to the M-line, stripe 9, stripe 1 (terminology of Craig and Offer[9]) and the filament tip: *c*, the length distribution (weight-averaged) of the frayed filaments, this being completely comparable to that obtained with normal, unfrayed filaments[4]. Approximately 800 filaments measured.

low ionic strength the expansion of the electrical double layer around the myosin molecules leads to greatly increased repulsive forces[10]. An increase in net negative charge on the filaments might be expected to have a similar effect, and with synthetic filaments made from rat myosin, Pinset-Härström and Truffy[11] show that high concentration of ATP induces a rather poorly defined tendency to fray. The whole phenomenon may be related to one of the first observations made on myosin, by Szent-Györgyi[12], who showed that prolonged dialysis of myosin solutions at low ionic strength (that is, synthetic filament preparations) against distilled water yielded clear but viscous solutions.

We therefore conclude that the A-filaments from rat psoas muscle contain three asymmetric units which appear as subfilaments after fraying. Our micrographs give no clear evidence to suggest that these subfilaments are packed in the intact A-filament into other than a simple linear array: certainly any large degree of coiling of the subfilaments seems implausible in the light of their ability to fray apart and then re-associate whilst loosely adsorbed on to a carbon film. Our evidence does not, of course, yield a direct estimate for *n*, but it is entirely compatible with 3-start helical models supported by recent measurements of mass per unit length of A-filaments[3,4].

This finding provides an important constraint on the type of molecular model which can be postulated for the A-filament. An obvious conclusion is that if the tails of the myosin molecules are organized into three subfilaments along the shaft, then all the myosin molecules cannot be equivalent at the level of near-neighbour contacts in the main cross-bridge region, and may not even be helically packed. This is not, however, a necessary conclusion. If the subfilaments arise as a result of fraying, initiated (as it seems) from the tip region, then detailed model-building (A.J.R., in preparation) shows that a model which will fray into three subfilaments can be devised, which conserves the conventionally made assumptions regarding equivalence and helical packing.

The finding of 3-fold physical symmetry in the A-filament is consistent with data such as the near-triangular appearance of the shaft in cross-sections[13]; however, no currently published model immediately suggests the fraying into three subfilaments now observed. The model of Pepe[14,15] packs the myosin tails into linear array, but it is two-stranded with respect to the cross-bridge lattice and hence unlikely to fray into three subfilaments. Moreover, recent evidence[16] casts doubt on the existence of the myosin dimer as a kinetic unit, almost certainly an essential feature of a two-stranded, two myosin/cross-bridge model. Squire's model[7,17], like that of Wray[18] for crustacean thick filaments, could only fray into subfilaments with pronounced coiling. The finding of Davey and Graafhuis[19] of three highly coiled subfilaments after tryptic digestion has been shown (A.J.R. and M.C.M., in preparation) to be an artefact of trypsin incubation. We conclude that a thorough re-examination of possible models for A-filament structure is now necessary, in which long-held but never fully proved assumptions as to the equivalence and helical packing of the molecular packing units may be called into question.

The yeast transposon Ty*1* generates duplications of target DNA on insertion

Jürg Gafner & Peter Philippsen

Microbiology Department, Biozentrum, University of Basel,
Klingelbergstrasse 70, CH-4056 Basel, Switzerland

Genetic elements which can transpose into different chromosomal sites causing modulation of gene expression have been found in maize[1] and several other organisms[2]. Most intensively characterized are those in enterobacteria: the insertion sequences, short DNA segments with probably no coding information, the transposable drug-resistance genes and the phage Mu (refs 2–4). The molecular details of transpositions in bacteria are under investigation; important results are the duplication of short target sequences at the integration site[5–15] and the identification of a transposase protein[16,17]. The yeast transposable element Ty*1* is present in about 35 copies per genome; it is 5,600 nucleotide pairs long with terminal direct

0028-0836/80/300414—05$01.00

repeats of 300 nucleotide pairs and is able to integrate into new chromosomal sites[18]. The resemblance of this yeast element to mobile elements in *Drosophila melanogaster*[19,20] is striking. The best characterized element, called copia, is present in about 30 copies in the *Drosophila* genome[19,21] and can integrate into many sites[22], in some cases as part of a large transposable segment[23]. Another remarkable structural resemblance exists with the proviral DNA of retrovirus, which can insert into different chromosomal sites, as found in avian sarcoma virus transformed rat cells[24]. We focus here on the DNA sequence at the termini of element Ty*1* (ref. 18). Our sequence data show that transposition in yeast and bacteria have several features in common, such as integration into different sites without any apparent sequence specificity and duplication of five nucleotide pairs of target DNA at the integration site. In addition, we find that the terminal repeats in two Ty*1* elements consist of identical 338 nucleotide pairs.

The upper part of Fig. 1 shows the basic structure of Ty*1* as deduced from heteroduplex experiments with cloned yeast DNA[18]; the 300 nucleotide pair repeats, called δ, flank a 5,000-nucleotide transcribed sequence which we call ε. Short sequences with homologies to the δ sequences at the Ty*1* termini were also found frequently alone in the chromosomal DNA[18]. These so-called solo δ sequences show up to 15% sequence divergence as determined by DNA sequence analyses in our early experiments (J. G., unpublished). Determination of whether the δ sequences at the Ty*1* termini also show some divergence or whether they are identical should clarify the problem of whether the synthesis of both termini is guided by one template or not. The integrated DNA of retroviruses, for example, probably has identical termini of several hundred nucleotides, as concluded from the known sequence arrangement of the template, the retrovirus RNA[33]. On the other hand, the direct or inverted terminal repeats of bacterial transposons need not be identical according to plausible transposition mechanisms[25,26]. In other words, the two termini need not originate from the same template in the transposition event.

Two separate Ty*1* elements were investigated: Ty*1*-B10, located to the left of the Sup4 locus on chromosome X in strain B596, and Ty*1*-D15 of unknown but different location in strain D585-11C (ref. 18). Cloned restriction fragments containing the Ty*1* termini were sequenced according to the Maxam and Gilbert protocol[27] and the strategy for this analysis is outlined in Fig. 1. The reading of the sequence gels reveals identical δ sequences of 338 nucleotide pairs at the four termini. Figure 2 shows part of the autoradiograms for the left terminus of Ty*1*-D15 and Fig. 3 gives the actual sequences with the identical parts written only once.

A single δ sequence does not show any immediately obvious coding or structural information. It contains 15 start codons and several octanucleotides similar to the sequence 5'-TATAAATA, which are common to eukaryotic promoter regions[28]; but the δ sequence also contains 53 stop codons i reading frames and the longest possible translation prod coded by a δ sequence would consist of 42 amino ac However, there is an open reading frame running out of th sequence starting at nucleotides 41–39 in the lower strand (3). A search for structural features revealed some short inver repeats up to 13 nucleotides long (Fig. 3), but these were located at the ends. Terminal short inverted repeats have be found in bacterial transposable elements and are probably functional importance[9,10].

Work on several other Ty*1* elements is in progress. We ha seen some divergence from the δ sequence in Fig. 3, but t alterations appear in both ends. It is possible that, despi variations among different Ty*1* elements, both termini a always identical.

Transposition events in bacteria create duplications of sho sequences of target DNA at the integration sites which are the flanking the transposed DNA. DNA sequence analysis show clearly that the number of the duplicated nucleotides, but no the sequence itself, is specific for a given transposable element: nucleotides for IS2, Tn*3* and Mu[11–14], 9 nucleotides for IS*1*, Tn*9*, Tn*10* and Tn*903* (refs 5–10) and 11 or 12 nucleotides for IS4 (ref. 15). Analysis of the sequences surrounding the yeast transposable element shows direct repeats of 5 nucleotides flanking the Ty*1*: 5'-GAAAC in the case of Ty*1*-B10 and 5'-ATTTT for Ty*1*-D15 (Fig. 4). For the first case it was demonstrated that these repeats originate from a duplication. As mentioned above, the Ty*1*-B10 is located to the left of the Sup4 locus on chromosome X. Cloned DNA from this locus of strain S288C, which lacks the Ty*1* at this position[18], was analysed. The sequences surrounding the Ty*1*-B10 were found with the 5'-GAAAC present only once (Fig. 4).

It is unlikely that the pentanucleotide which becomes duplicated is a recognition sequence for Ty*1* integration, because this pentanucleotide is different for Ty*1*-B10 and Ty*1*-D15. (A third case shows a 5'-GAGAA adjacent to Ty*1*; P.P., unpublished.) Looking for possible recognition characteristics or preferable sites of Ty*1* insertions, we only note that the 30 nucleotides on either side of each Ty*1* examined consist of 70% or more A + T pairs (Fig. 4). A preference for A + T-rich regions is also found for the bacterial IS*1* transposition[29].

Both Ty*1* elements analysed here also have direct 5-nucleotide repeats (5'-TACCA) at the junctions between the δ and ε segment (Fig. 4). These internal repeats might have functional significance although such internal duplications at comparable locations have not been observed in bacterial transposons.

The solo δ sequences mentioned above probably mark former sites of Ty*1* elements which were deleted by homologous recombination between the termini, leaving one δ sequence behind. Such deletion processes are known in bacteria for λ phages carrying the chloramphenicol transposon Tn*9*, which has direct repeated IS*1* termini; the deletion generates λ phage with

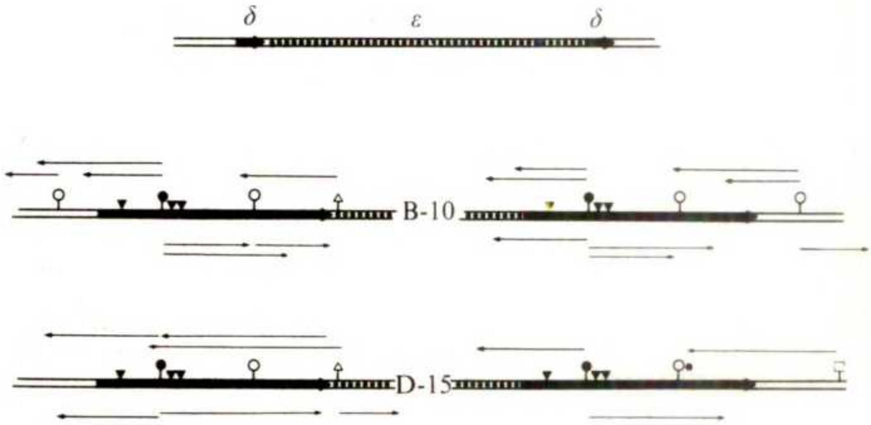

Fig. 1 Structure of Ty*1* and strategy of DNA sequence analysis. The general structure of an integrated Ty*1* is shown in the upper part (chromosomal DNA, double line; δ sequences, thick black arrows; ε sequence, dotted line). The δ sequences of Ty*1*-B10 and Ty*1*-D15 and of some adjoining DNA were sequenced according to Maxam and Gilbert[27]. The arrows mark the length and direction of sequences determined in restriction fragments which were labelled at their 3' ends and also sometimes at their 5' ends. *Xho*I (●), *Taq*I (○), *Hin*fI (▼), *Bgl*II (△) and *Hpa*II (□) restriction sites are indicated. Because of the sequence identity of the four δ sequences we did not determine in all four cases the sequence of both DNA strands.

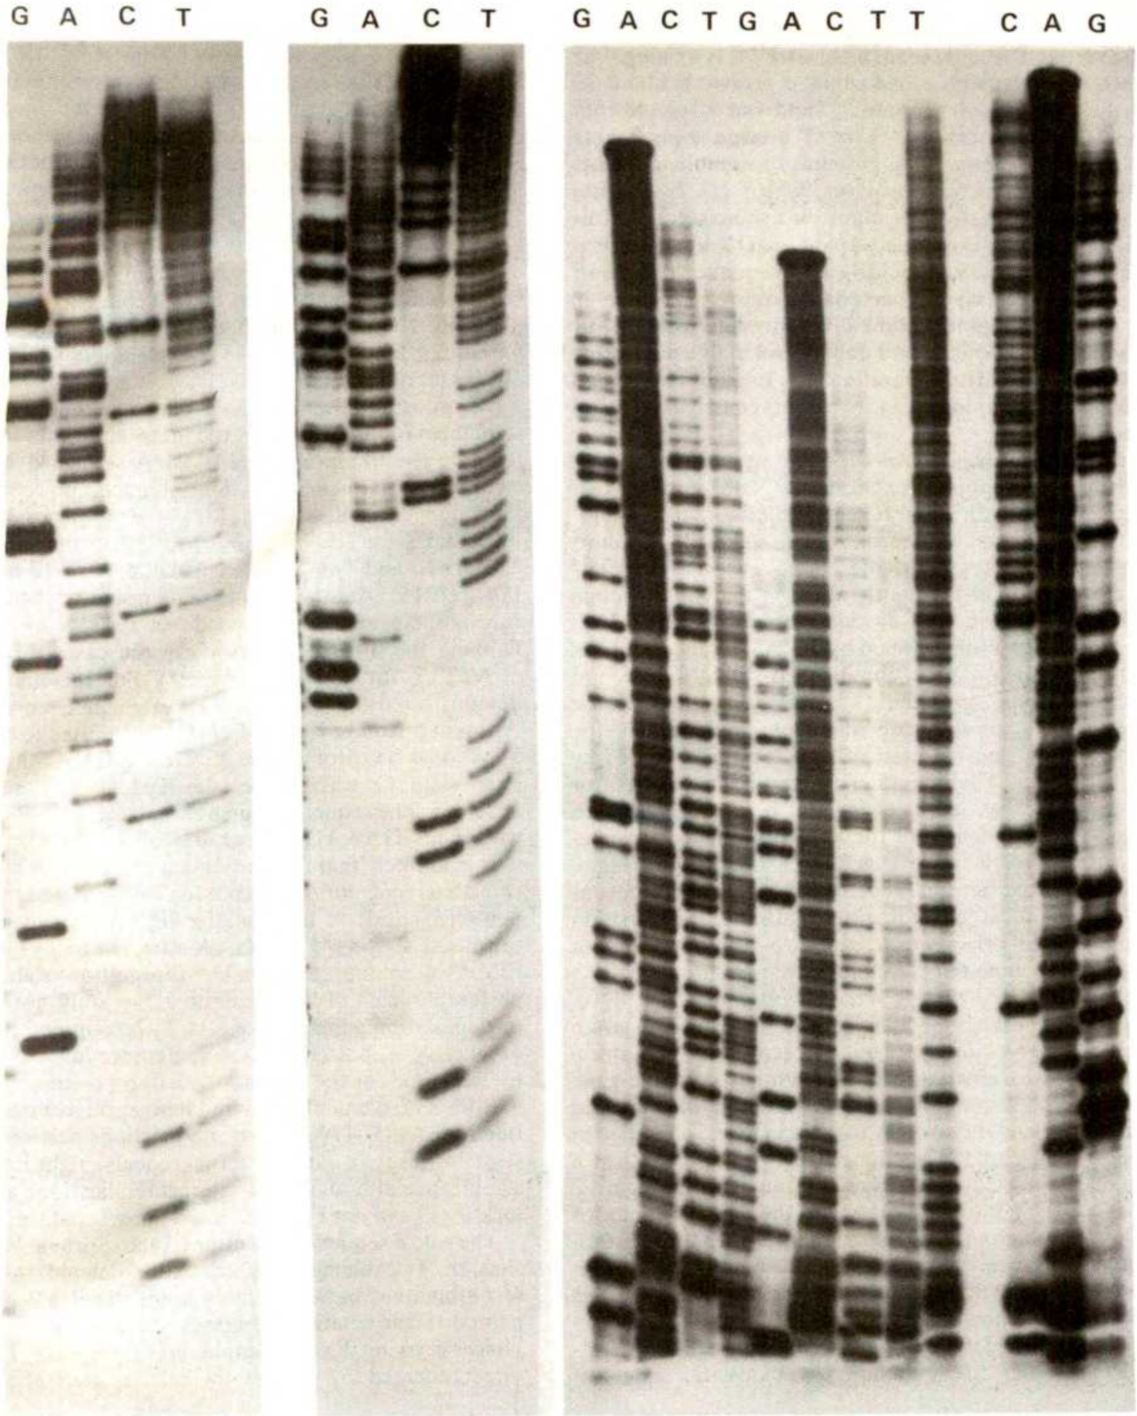

g. 2 Autoradiograms of sequence gels (left part of Ty*1*-D15, Fig. 1). Left, two 18% gels showing the sequence from the *Xho*I site towards the chromosomal DNA d towards the centre of the δ sequence, respectively. Right, 8% gel showing the sequence from the end of the δ sequence towards the *Xho*I site. Electrophoresis of the DNA in the left, middle and right tracks in the 8% gel continued for 8, 12 and 4 h, respectively.

ngle IS*1* sequence[30]. The observed sequence divergence
ng solo δ sequences (base differences and small deletions)
probably reflects either random mutations after the Ty*1*
tion, the terminal heterogeneity among different Ty*1*, or
ı. Clearly, the solo δ sequences are potential targets for a
Ty*1* integration if homologous recombination is involved.
omparable process in bacteria is the homologous recom-
ition between two IS*1* sequences from different replicons
ch creates transposable sequences flanked by two direct
eated IS*1*[31]. An interesting result concerning the question of
nilar mechanism for Ty*1* insertion comes from the analysis
he target sequence for Ty*1*-B10.

As presented above, the sequences to left and right of Ty*1*-B10 are identical to the continuous sequence of the same chromosomal site in strain S288C, which lacks the Ty*1*-B10, except for the duplicated pentanucleotide. By reading the S288C sequence (upper line, Fig. 4) in the inverse orientation, one recognizes the central part of a δ sequence (nucleotides 237–119 of Fig. 3 with point mutations and a deletion of nucleotides 175–179). By sequencing several hundred additional nucleotides on both sides of the S288C sequence and the Ty*1*-B10, we confirmed the Ty*1*-B10 transposition into the middle of a solo δ sequence but one inverted relative to the δ sequence termini of Ty*1*-B10. This rules out the necessity of a

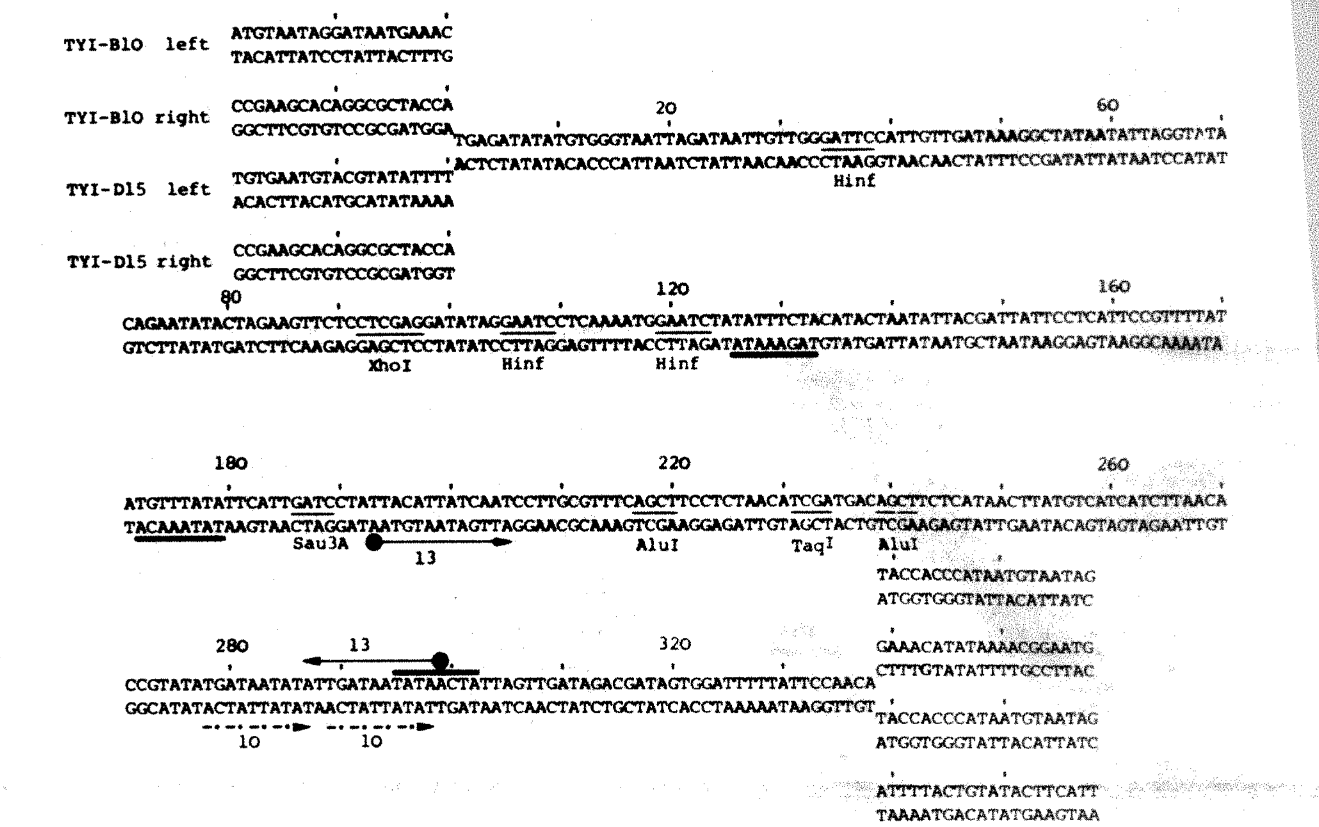

Fig. 3 Nucleotide sequences at the left and right termini of Ty*1*-B10 and Ty*1*-D15. The δ sequence of the four termini is written only once. The left termini start with a stretch of 20 nucleotides of the adjoining chromosomal DNA and continue at the end of the δ sequence with 20 nucleotides of ε DNA. The right termini start with 20 nucleotides of ε DNA and continue at the δ sequence end with 20 nucleotides of the adjoining chromosomal DNA. The three octanucleotides in the δ sequence which are very similar to the 'Hogness box' (5'-TATAAATA), common to eukaryotic promoter regions[28], are marked with a thick bar. Five other similar octanucleotides start at nucleotides 67 and 199 in the upper strand and at nucleotides 70, 143 and 171 in the lower strand. The longest open reading frame in the δ sequence consists of 42 codons (nucleotides 171–296 in the upper strand). One tandem repeat of 10 nucleotides and one inverted repeat of 13 nucleotides are indicated. The terminal sequence 5'-CCAACA appears inverted close to the beginning of the δ sequence (nucleotides 33–28). The adenosine phosphate at position 188 was difficult to read because of a very weak A signal at this position. The sequence of the opposite strand clearly showed a T at position 188. This was confirmed by cleavage with *Sau*3A restriction endonuclease. A poly-adenylation sequence is present at nucleotides 332–327.

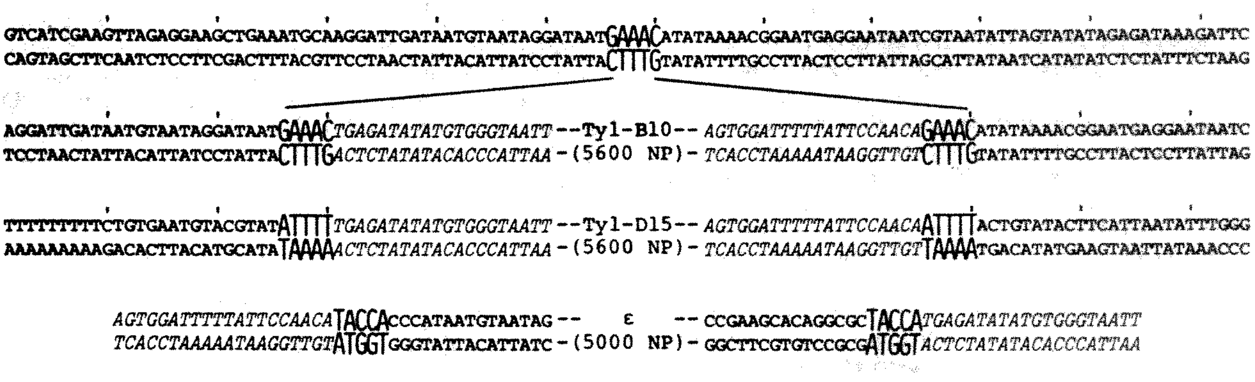

Fig. 4 Five nucleotide pairs duplication at δ sequence junctions. The first and second DNA sequences represent the same region left of the Sup4 locus in strain S288C (no Ty*1* inserted) and B596 (Ty*1*-B10 inserted), respectively. The relationship between the S288C and the B596 strain is unknown. The S288C sequence was obtained from both strands of a 130 nucleotide *Taq*I sequence. The third sequence shows the junction between the δ termini of Ty*1*-D15 and chromosomal DNA. The fourth sequence describes the internal Ty*1* junctions between δ and ε DNA.

sequence homology between the Ty*1* termini and the target DNA for Ty*1* transposition. This is consistent with most of the sequence data from the insertion sites of bacterial transposons, although sequence homology might be involved in Tn*3* transposition in the site selection but not the insertion process[32].

It is unclear whether the 5-nucleotide deletion in the S288C sequence as compared with the inverted δ sequence of Fig. 3 is of any importance for the transposition. This deletion creates the 5'-GAAAC, the actual site of integration for Ty*1*-B10 (Fig. 4). The sequence without the deletion reads 5'-*GAA*TA-TAA*AC* (nucleotides 182–173 of Fig. 3). Possibly, this sequence alteration made the A+T-rich region in the solo δ sequence more receptive for a Ty*1* transposition.

Our sequence data allow a comparison between an eukaryotic transposable element and the bacterial transposons on a molecular level. Shared features are the terminal repetition within the element, the duplication of target sequences at the sites of insertion and the lack of homologous recombination in the transposition process. We also noted some dissimilarities; the δ sequences at the Ty*1* termini lack inverted repeats at their ends the 5-nucleotide internal duplication at the δ–ε juncture Ty*1* is not found at comparable positions in bacterial sposons. When compared with higher eukaryotes, Ty*1* shows certain similarities with the proviral DNA of roviruses, such as the direct repetition of probably identical quences of several hundred nucleotides at the two ends the insertion into different chromosomal sites. As learn more about eukaryotic transposable elements we y find universal features for DNA transposition processes nature, although the various elements will surely have dividual characteristics.

Transcriptional control of two gene subclusters in the tRNA operon of bacteriophage T4

Alexander Goldfarb[*] & Violet Daniel

Biochemistry Department, Weizmann Institute of Science, Rehovot, Israel

In bacteriophage T4 DNA, transcription units recognized *in vitro* by host RNA polymerase consist of promotor-proximal 'immediate early' (IE) genes and promotor-distal 'delayed early' (DE) genes separated from each other by ρ-dependent transcription terminators[1]. *In vivo*, the transition from IE to DE transcription requires phage-specific protein synthesis and can be prevented by chloramphenicol (CAM)[2]. Most of the information about IE/DE transition has been obtained by hybridization analyses of mixtures of RNA species synthesized simultaneously on several T4 transcription units (for review see ref. 3). A useful model for the study of T4 gene expression at the level of primary transcripts and individual gene products is provided by the T4 tRNA operon, a cluster of genes coding for eight T4-specific transfer RNAs and two stable RNAs (species 1 and 2) of unknown function (Fig. 1). The 10 genes of the tRNA operon are arranged in two subclusters (I and II) with a promotor located about 1 kilobase pair upstream[4,5]. The primary transcripts and the final gene products of this region have been identified and isolated[6,7]. Moreover, this genetic region was recently cloned and a part of it sequenced[5,8]. We describe here the expression of T4 tRNA genes *in vivo* and *in vitro* in terms of the IE/DE concept and demonstrate that the two subclusters of the tRNA operon are subject to different modes of control.

The transcription of individual tRNA genes *in vitro* can be monitored by digesting the total synthesized RNA with nucleases present in the 100,000*g* supernatant (S-100) of *Escherichia coli* and analysing the stable products by gel electrophoresis[7,9]. Figure 2 shows the S-100 digestion products of RNA synthesized in the presence and in the absence of ρ-factor. As templates for transcription in this experiment we used wild-type T4 DNA (lanes 1, 2) or DNA with deletions in the tRNA operon (lanes 3–6), the map locations of which are shown in Fig. 1. The digestion products migrating in the 4S region of lanes 1 and 2 (Fig. 2*a*) were analysed by a second-dimension electrophoresis (Fig. 2*b*). One can see that factor ρ prevents the transcription of genes coding for tRNA^{Arg} and RNA species 1 and 2 from the wild-type DNA. However, in the presence of ρ, these genes are expressed from DNA containing deletion Δ119, and species 1 RNA is synthesized in the case of deletion Δ27. The addition of ρ does not block the expression of genes of subcluster I. These results can only be explained by assuming the existence of a ρ-dependent transcription terminator in DNA between subclusters I and II of the tRNA operon. The absence of ρ-effect in the case of deletions Δ119 and Δ27 seems to be due to the removal of this site from DNA by the deletions.

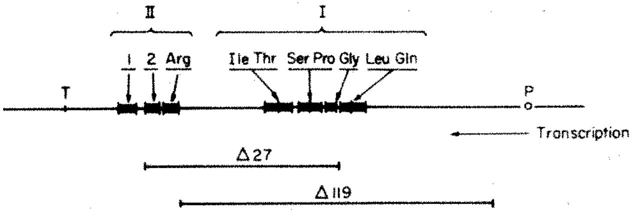

Fig. 1 T4 tRNA operon (modified from refs 4, 5, 7, 13). I and II, the two subclusters of stable RNA genes. The distance between promotor (P) and terminator (T) is about 3,000 base pairs. Lower bars represent deletions used in the present work.

The effect of ρ on the transcription of tRNA genes was further analysed at the level of primary transcripts. Elsewhere[7] we have studied the *in vitro* transcription of this region at high ionic strength when ρ-factor is not active and demonstrated that the major transcript of the wild-type tRNA operon is a 3.0-kilobase long RNA molecule (RNA species A_{wt}) which contains all 10

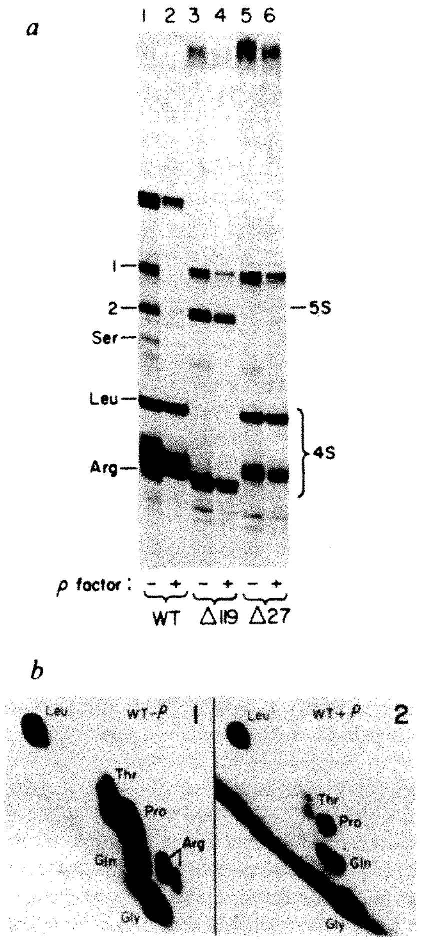

Fig. 2 Autoradiograms showing stable RNAs synthesized *in vitro* in the presence and absence of ρ-factor. DNA (10 μg) from wild-type (WT) T4 or psu_b^- deletion mutants Δ119 and Δ27 were transcribed by 4 μg RNA polymerase in 100-μl reaction mixtures containing 40 mM Tris-HCl *p*H 7.9, 10 mM $MgCl_2$, 7 mM 2-mercaptoethanol, 50 mM KCl, 0.25 mM each of ATP, GTP and UTP and 0.08 mM [α-^{32}P]CTP (1 Ci mmol^{-1}, Amersham); 4 μg of ρ-factor were added where indicated. After 15 min incubation at 37 °C, 5 μg ml^{-1} rifampicin was added and incubation continued for 10 min followed by addition of 10 μg DNase 1 (RNase-free, Worthington). After 10 min incubation the samples were deproteinized with phenol, RNA precipitated with ethanol, dried, dissolved and digested with 5 mg ml^{-1} 100,000*g* supernatant fraction of *E. coli* (S-100) for 2 h at 37 °C. The digestion products, after phenol deproteinization and ethanol precipitation, were separated by electrophoresis in acrylamide gels containing 6.6 M urea. The isolation of RNA polymerase and DNA, preparation of S-100, conditions of S-100 digestion and gel electrophoresis and identification of digestion products were as described elsewhere[7]. Factor ρ was purified according to ref. 14. *a*, Separation of S-100 digestion products in 10% acrylamide gel. *b*, Two-dimensional separation of 4S wild-type products. The 4S regions of lanes 1 and 2 of gel *a* were cut out and applied to 20% acrylamide gel slabs for the second-dimension electrophoresis.

genes of the operon and is terminated about 0.3 kilobases downstream from subcluster II. It was also shown that deletions Δ27 and Δ119 result in the synthesis of new deletion-specific transcripts A_{27} and A_{119} which are initiated and terminated at the same sites as the wild-type transcript A_{wt} (ref. 7). We now find (Fig. 3) that at low salt concentrations, transcripts A_{wt}, A_{27} and A_{119} are still synthesized on their respective DNA templates. The addition of ρ-factor results in the disappearance of the wild-type transcript A_{wt} whereas the two deletion-specific transcripts are still synthesized. This confirms the above conclusion about ρ-dependent termination of transcription between the two subclusters of tRNA operon.

On the basis of these observations one can expect that genes of subcluster II would not be transcribed *in vivo* in t absence of phage-specific protein synthesis. Accordingly, analysed the formation of phage-specific stable RNA in ce infected in the presence of CAM (Fig. 4). In this experiment v compared RNAs induced by wild-type phage (lanes 2, 4) a deletion mutant psu_b^- Δ119 (lanes 3, 5) in the presence (lanes 5) and absence (lanes 2, 3) of CAM. Note that in the presence CAM host transcription is not completely shut off by bacteri phage and the continued synthesis of bacterial tRNA gives high background. Nevertheless, the products of subcluster I tRNA^{Arg} and species 1 and 2, can be detected. It is clear tha CAM strongly inhibits the formation of these three products in the cells infected with wild-type phage. In the case of deletio Δ119, however, the formation of RNA species 1 and tRNA^{Arg} i CAM resistant. The CAM sensitivity of RNA species 2 can be attributed to its degradation in the absence of the product o bacteriophage gene *mb*: the product of this early gene has been shown to be required for the appearance of tRNA^{Pro}, tRNA^{Ser},

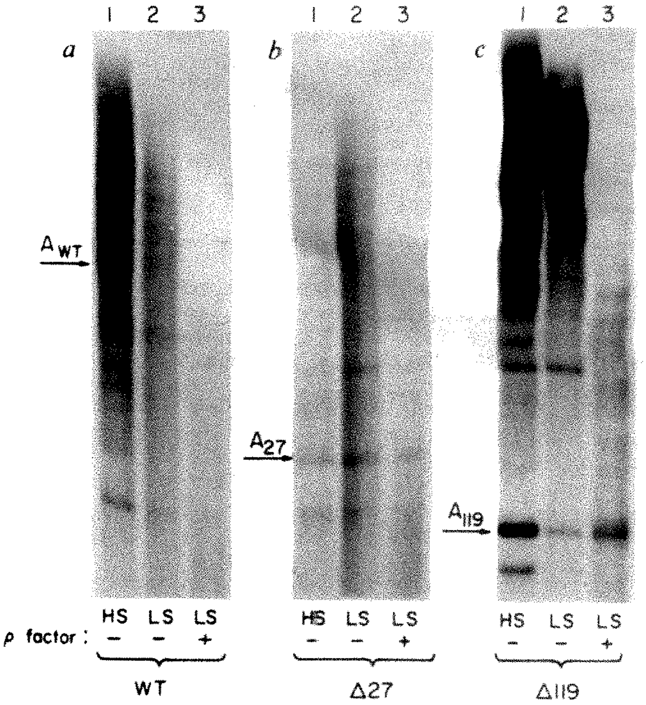

Fig. 3 Autoradiogram showing primary transcripts of T4 DNA made in the presence and absence of ρ-factor. DNA of wild-type T4 (WT) and deletion mutants psu_b^- Δ27 and Δ119 was transcribed at low (LS, 50 mM KCl) and high (HS, 250 mM KCl) salt concentrations. Otherwise, the conditions of transcription were as in Fig. 2. After the first phenol deproteinization, RNA transcripts were precipitated with ethanol, dissolved and separated in composite acrylamide–Agarose SDS gels as described elsewhere[7]. The lengths of RNA species A_{wt}, A_{27} and A_{119} are about 3,000, 1,500 and 750 nucleotides, respectively, *a*, *b*, 2.2% acrylamide–0.5% Agarose gels. *c*, 2.5% acrylamide–0.5% Agarose gel.

tRNA^{Ile} and RNA species 2 in the infected cell[10,11]. Although, in the absence of *mb* function these RNAs are transcribed and probably processed, they cannot be detected *in vivo*, apparently due to their fast degradation. As for tRNA^{Arg} and RNA species 1, we conclude that phage-specific protein synthesis is required for their transcription from the wild-type template but not from DNA with deletion Δ119. This, as well as the above *in vitro* experiments, demonstrate that the genes of subcluster II are expressed as DE functions in the wild-type phage and as IE functions in psu_b^-Δ119 (and Δ27) mutant.

he CAM inhibition of subcluster II transcription can hardly explained by the polar effect of nonspecific inhibition of slation[3] because tRNA genes are not likely to be translated ll. Rather, one can assume that a phage-specific protein se target sequence is situated between the two subclusters of A genes is responsible for the transcription of subcluster II.

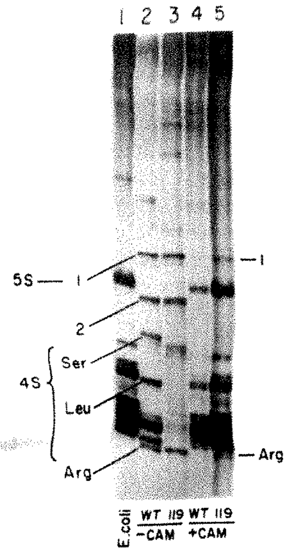

Fig. 4 Autoradiogram showing T4-specific stable RNAs induced in *E. coli* in the presence and absence of CAM. The cells of *E. coli* were infected with wild-type T4 (WT) or deletion mutant psu$_b^-$ Δ119 at MOI = 10 and labelled with ^{32}P as described elsewhere[7]. Where indicated, 100 μg ml^{-1} CAM was added to the culture 1 min before phage infection. RNA was extracted and separated in 10% acrylamide urea gel. Lane 1 shows stable *E. coli* RNAs.

The existence of a phage-specific product responsible for IE/DE transition has been postulated in T4 (ref. 3). Its action may be similar to the anti-termination effect of *N* gene product of bacteriophage λ (ref. 12). The study of such proteins has hitherto been hampered by the absence of suitable assay systems. Our results provide a convenient *in vitro* system for the search and analysis of the factors responsible for IE/DE transition.

We thank Drs K. Fukada and J. Abelson for psu$_b^-$ Δ mutants and for communicating their results before publication, and Mr Y. Tichauer for isolating ρ-factor. This research was supported in part by a grant from the US-Israel Binational Science Foundation (BSF), Jerusalem, Israel.

Evolution of DNA sequences has been retarded in Malagasy primates

Tom I. Bonner*, Robert Heinemann† & George J. Todaro*

†Program on Genetics, George Washington University, Washington, DC 20052

It is generally accepted[1] that there are six major groups of living primates: (1) lemurs (including all the primates of Madagascar), (2) lorises (including galago and potto), (3) tarsiers, (4) New World monkeys, (5) Old World monkeys and (6) apes (including man). Tree shrews, once considered to be primates, are now generally recognized[2] as not significantly more closely related to the six groups than other mammals. The first surviving primate lines to diverge from the common primate ancestor are believed to have given rise to one or more of the first three groups. However, the fossil record is insufficient to determine their relative branching order[3]. Furthermore, neither morphological considerations[2,4–7] nor studies of protein evolution[8,9] produce unanimity as to whether tarsiers are more closely related to the prosimians (the lemurs plus lorises) or the simians (the monkeys and apes). In an attempt to resolve these discrepancies, we have measured the DNA sequence *difference* between several primates. We report here that the evolution of DNA of primates from Madagascar is significantly less than that of all other groups of living primates. This is not expected in the simplest form of the theory of neutral selection and may be important for our understanding of evolution at the molecular level.

To measure genetic differences between the various primates as directly as possible, we followed Kohne *et al.*[10] in using the sequences which are present in a frequency of one copy per haploid genome, commonly referred to as single copy DNA. As the single copy fraction amounts to approximately half the DNA in the genome, the evolutionary fluctuations which can occur within a single gene are thoroughly averaged out. To determine the branching order in the early evolutionary history of the primates, we divide the living primates into four groups: lemurs, lorises, tarsiers and simians—New World plus Old World monkeys and apes. Our experiment consists of preparing ^{125}I-labelled single copy DNA from a representative species of each of the four groups, hybridizing each labelled DNA to the unlabelled total DNA of two to four members of each group in conditions such that each labelled DNA molecule hybridizes to an unlabelled molecule, and measuring the sequence divergence between the two species of DNA by measuring the melting temperature of the hybrid molecules. From experiments with various model systems, we can expect a 1 °C decrease in melting temperature for each ~1% nucleotide difference[11]. Thus, what we measure is the accumulation of single base mutations in the two lineages since their divergence. We expect that these accumulated mutations account for the bulk of the evolutionary difference between the species. We will not, however, measure any additions to, deletions from or rearrangements of the DNA. Thus, we may not detect some of the changes in gene regulation which would be expected to be relatively rare but evolutionarily quite significant[12,13].

Our results are shown in the form of melting curves (Fig. 1). From these it is clear that with labelled DNA from the simian, loris or tarsier groups, the most closely related DNAs are always from the lemur group. The only explanations for this are that either the data are defective or the lemurs have diverged substantially more slowly than the other groups. As the melting curves for all the DNAs within a single group are nearly identical when hybridized with ^{125}I-DNA from another group, the only

0028-0836/80/300420—04$01.00

possible defect would be one which simultaneously affects all the DNAs of a single group. This would require either the degradation of all the DNAs within one group or the presence of an impurity in some of the groups of DNAs that affects the stability of hybrids with some but not all of the other groups. The fact that all the homologous melting curves are nearly identical demonstrates that the DNAs of all four groups are comparable. When, as a further test, separate extractions (obtained from B. Hoyer) of DNAs from *Lemur catta* and tarsier were compared with those used for Fig. 1, identical results were obtained. Thus, we believe that the data can only be accounted for by the hypothesis that the lemur DNA has evolved more slowly than the other primate DNAs.

To construct a phylogenetic tree consistent with the data we must consider Fig. 1 quantitatively. If we define the hybridizable fraction of a given labelled DNA as the fraction which hybridizes to the homologous DNA, the data of Fig. 1 show that only 50–70% of the hybridizable DNA actually hybridizes to DNAs from other groups. The most reasonable explanation of this reduced hybridization is that a portion of the hybridizable sequences have diverged so much between the two groups that they are not able to form stable hybrids at the hybridization temperature. We can take these sequences into account if we use the melting temperature of the potentially hybridizable sequences rather than those which actually hybridize[10]. We therefore characterize each melting curve with the temperature (T_{50}H) at which 50% of the hybridizable sequences are bound to hydroxyapatite. These values are presented in Table 1. We then convert the measured T_{50}H values to the actual number of nucleotide substitutions which have occurred since the divergence of the two species. There is some uncertainty in this conversion as results from different model systems vary over 1.5–0.7 °C in melting temperature reduction per per cent nucleotide difference. We will assume the intermediate value of 1.0 °C in our calculations. However, choice of any conversion factor within the above range does not significantly affect the relative amounts of change along the different branches. An additional correction must be made because the degree of sequence divergence in our measurements is sufficiently great for the probability of multiple changes at the same site to be appreciable. Assuming only that a given base can mutate to any other base with equal probability, statistical corrections[14] can be made (see Table 2) and, as we are comparing about 10^9 nucleotides, the corrected values should reflect the actual number of base substitutions quite accurately. Once this correction is

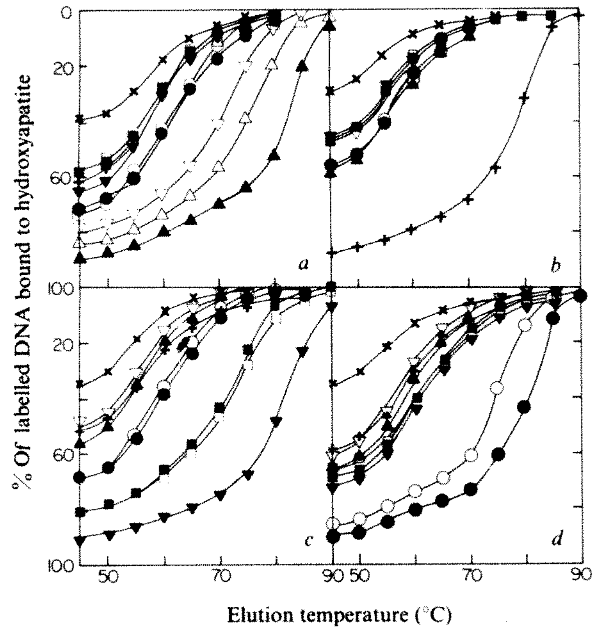

Fig. 1 Melting curves of hybrid DNA molecules formed between ^{125}I-labelled single copy DNAs and unlabelled cellular DNAs. DNAs were iodinated to a specific activity of 3×10^7 c.p.m. per μg by a modification of the procedure of Chan *et al.*[20], hybridized to a C_0t of 200 and fractionated on hydroxyapatite at 45 °C in 0.14 M phosphate buffer (PB, sodium phosphate, *p*H 6.8). The single copy fraction, that is, the fraction which did not bind, was then fractionated by electrophoresis on an alkaline 2% agarose gel and the portion between 200 and 1,200 nucleotides was used for the hybridizations. 100 μg of cellular DNA was hybridized with about 2,000 c.p.m. of labelled DNA in 1.0 M PB at 60 °C to a C_0t of 22,000, the hybrid was bound to hydroxyapatite in 0.14 M PB plus 0.02% SLS at 45 °C and eluted in 5 °C steps as described elsewhere[21]. The cellular DNAs are: ▲, human; △, baboon; ▽, spider monkey; +, tarsier; ▼, galago; □, slow loris; ■, slender loris; ○, *L. catta*; ●, *L. mongoz*; ×, pig or mouse. The labelled DNAs are: *a*, human; *b*, tarsier; *c*, galago; *d*, *L. mongoz*.

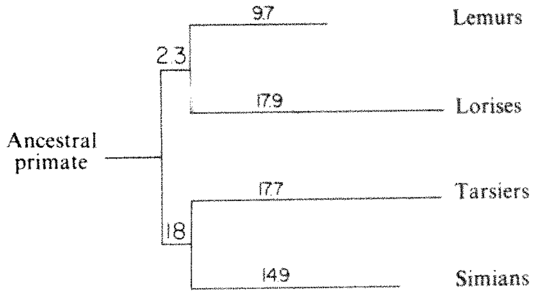

Fig. 2 Phylogenetic tree for the primates derived from the single copy DNA sequence divergences. The number of actual nucleotide substitutions since the divergence of the lineages as obtained from Table 2 were used to construct the tree as follows. The sum of the lemur and loris branches is given by the average of their reciprocal hybridizations. The difference between the lemur and loris branch lengths is obtained from the experiments in which labelled tarsier or simian DNA is hybridized to both lemur and loris DNAs (the differences within columns of Table 2). These values would be expected to be more accurate than the differences obtained by hybridizing labelled lemur and labelled loris DNAs to either simian or tarsier DNAs (the differences within rows of Table 2). Combining these values, we can solve for the length of the two branches. Similarly, we can solve for the length of the tarsier and simian branches. Using these four branch lengths we can then determine the length of the branch interconnecting the lemur–loris branch point and the tarsier–simian branch point necessary to fit the eight measurements which include this branch. Finally, these branch lengths are combined with the estimated distances measured with tree shrew DNA to determine the branch point with the common primate ancestor. The numbers on the branches represent the percentage of nucleotide substitutions along that branch.

Table 1 Sequence divergence as measured by reduction of hybrid melting temperature

Unlabelled DNA	Labelled single copy DNA			
	Human	Tarsier	Galago	*L. mongoz*
Human	0	24.6	29.3	23.4
Baboon	6.9	—	27.8	25.1
Spider monkey	11.2	26.4	30.7	24.5
Tarsier	26.2	0	30.2	26.9
Galago	26.7	30.1	0	22.1
Slow loris	27.6	—	11.5	23.0
Slender loris	28.6	28.6	11.3	23.1
L. catta	22.6	24.6	22.4	6.0
L. mongoz	21.2	24.6	22.0	0

The T_{50}H for each melting curve in Fig. 1 and for other melting curves which are not shown was determined as described in the text. The reduction in T_{50}H compared with the homologous DNA was averaged and this average is tabulated. The homologous T_{50}H values are 78.8–81.3, 78.1, 78.8–80.7 and 79.5–81.1 °C for human, tarsier, galago and lemur DNAs, respectively. The values for comparable pairs of DNAs are very close to those reported by Kohne, Chiscon and Hoyer[10]. The reciprocal values (for example, the divergence between human and tarsier as measured with either labelled tarsier or labelled human DNAs) are in general but not precise agreement. This difference probably results from the various labelled single copy DNAs not being precisely equivalent in sequence composition.

ble 2 Difference matrix in terms of per cent actual nucleotide substitutions

Unlabelled DNAs averaged within groups	Labelled single copy DNA Simian	Tarsier	Loris	Lemur
mian	0	32.0	38.2	30.1
arsier	33.0	0	39.7	34.3
oris	35.2	38.2	0	28.1
emur	26.6	30.6	27.1	0

The values of ΔT_{50}H from Table 1 were averaged over the various unlabelled DNAs within a taxonomic group and were converted to per cent actual nucleotide substitutions. The conversion assumes that 1 °C in ΔT_{50}H equals 1% sequence difference and that any given base can mutate to any other base with equal probability. The use of Holmquist's[14] equation (20) then corrects for multiple changes at a particular site in one lineage and for changes at the same site in both lineages.

made, it is clear that the total number of base substitutions along individual lineages should be additive. We can then use the six pairwise differences between the four primate groups to determine distances along each branch of the tree.

The only tree consistent with the data but without substantially negative branch lengths places the loris and lemur groups at one branch point separated by about 4% base substitution from the branch point between tarsiers and simians. It is not, however, possible to determine the location of the branch point for the divergence from the common primate ancestor without data which include a more distant DNA. We have therefore used single copy tree shrew (*Tupaia glis*) DNA which is so distant that we cannot directly measure ΔT_{50}H. We can, however, measure ΔT_{25}H values of 24.8, 26.8 and 28.0 °C for lemur, simian and loris groups, respectively. As Fig. 1 indicates that $\Delta T_{50}\mathrm{H} = 1.18 \times \Delta T_{25}\mathrm{H}$, we can extrapolate to obtain approximate ΔT_{50}H values of 29.3, 31.6 and 33.0 °C. When combined with the branch lengths derived in Fig. 2, these values indicate that the common ancestor branch point is located between the lemur-loris branch point and the simian–tarsier branch point. This position is consistent with both protein phylogenetic trees[8,9]. The full branching diagram can then be drawn as shown in Fig. 2. With the exception of the length of the lemur and simian branches, the tree is qualitatively quite similar to that of Dene *et al.*[8]. In particular, the first branching is that of the lemur–loris ancestor from the tarsier–simian ancestor, followed shortly after by further splitting in both these branches to give rise to the four separate groups. The slight shortening of the simian branch relative to the loris and tarsier branches may reflect the fact that simian generation times are two to four times greater than those of prosimians. Whether the extent of molecular evolution depends strictly on time or on the number of generations remains unclear[10,15]. The present data seem to support the latter hypothesis. However, the observation that lorises and tarsiers are approximately equidistant from the common primate ancestor whereas lemurs are nearly twice as close must have a different explanation because all three groups have comparable generation times. We believe that this result constitutes the first case in which a phylogenetic tree constructed using single copy DNA has branches of substantially unequal lengths.

As the *Lemur mongoz* and *L. catta* DNAs represent only one genus within the broader lemur group, the question arises as to how widespread the reduced divergence is within the lemur group as a whole. We have therefore tested the DNA from three additional genera of Malagasy primates, *Microcebus*, *Cheirogaleus* and *Propithecus*. Except for *Daubentonia*, the protein phylogenies[3,9] place *Microcebus* and *Cheirogaleus* as the most distant Malagasy relatives of the genus *Lemur* and place *Propithecus* approximately half as distant from *Lemur*. Hybridization with various labelled single copy DNAs indicates that the *Propithecus* branch length is the same as for the genus *Lemur* and that the *Microcebus* and *Cheirogaleus* branches are only slightly longer (that is, 12.5% actual substitution). Thus, reduced divergence rates occur throughout the lemur group. Similar evidence can be derived from the protein data of Sarich and Cronin[9]. Of 10 genera of Malagasy primates tested, 7 have branch lengths which are 61–83% of the loris group branch length. Considering all the evidence it is clear that essentially all the primates from Madagascar have had a reduced evolutionary rate since their divergence from the lorises.

Our results demonstrate that lemurs are genetically the most primitive of the modern primates in the sense that their DNAs most closely resemble that of the common primate ancestor. Although lemurs are considered quite primitive morphologically[1], this is unexpected on a molecular basis. Kimura[16] has argued that the genetic load imposed by the observed rate of DNA divergence is so great that only a few per cent of the DNA could be subject to natural selection and that most mutations must therefore be of neutral selective value. In this case the rate of fixation of base substitutions should be proportional to the mutation rate[16] and all the branch lengths would be expected to be equal, whereas in fact the average rate of DNA divergence for lemurs during the 50–70 Myr since their divergence from the lorises is approximately half that of the other prosimians. The reason for this discrepancy may be either that the bulk of the DNA is subject to selection or that the mutation rate is reduced for lemurs. The fact that this effect occurs for all Malagasy primates and not for their closest relatives, the lorises, implies that it is either an environmental effect or the result of a major genetic change which occurred after the divergence of the lemurs from the lorises and before the divergence of the various lemurs from each other.

There are three possible solutions. First, the basic premise of the theory of neutral selection could be wrong and most of the DNA could be subject to selection at the nucleotide level. If this is true, it follows that the Malagasy environment has required less adaptation than the environments experienced by other primates. Alternatively, the Malagasy primates could have a reduced mutation rate due to a change in the genes which affect the spontaneous mutation rate. This could happen in a somewhat trivial but strictly neutralist fashion as the result of a founder effect. If the lemurs are descended from a small number of ancestors which populated Madagascar[17–19], these individuals could have fortuitously represented a rare low mutation rate variant which was then perpetuated on Madagascar. In the absence of a founder effect, a reduced mutation rate in lemurs could also result from selection for an optimum spontaneous mutation rate without direct selection on the genome as a whole. As in the case of selection on the whole genome, this hypothesis would require that there has been a reduced selective pressure for change on Madagascar.

The selection and founder effect hypotheses could be evaluated by looking for the same effect in other orders of mammals present on Madagascar, such as carnivores or rodents. Assuming that such experiments do not establish the founder effect hypothesis, an understanding of the basis for the reduced evolutionary rate of the primates of Madagascar could resolve the question of whether darwinian selection or selective neutrality is the major force in molecular evolution.

We thank Dr Morris Goodman for suggesting these measurements, for his continuing help and for some of the prosimian tissues, especially the tarsier tissue which was made available to him by the Chicago Zoological Society. We also thank Dr Bill Hoyer for helpful discussions and for tarsier and *L. catta* DNAs, and the Duke University Center for the Study of Primate Biology and History for *Propithecus*, *Cheirogaleus* and *Microcebus* tissues. This work is in partial fulfilment of the requirements for the Ph.D degree to be submitted to the George Washington University by R.H.

The *lac* repressor, a tetrameric protein of identical subunits [molecular weight (MW) 4×38,500], interacts specifically with the *lac* operator, preventing the expression of the structural genes of the *lac* operon[1,2]. The presence of an inducer (such as isopropyl-β-D-thiogalactoside; IPTG) which binds to the repressor, prevents operator binding by lowering the association constant by a factor of 10^3 (ref. 3). Genetic and biochemical analysis have shown that the major part—if not all—of the binding site for the *lac* operator is located in the 60 N-terminal residues of the protein[1,4,5]. In certain conditions, limited trypsinolysis of the protein yields four N-terminal 'headpieces' each containing 51 or 59 residues, and a tetrameric core with full inducer binding activity[4,5]. It was shown recently that this headpiece is able to bind nucleic acids, and interacts with the *lac* operator[6], giving the same pattern of sensitivity with respect to the methylation of the bases as does the intact repressor[7]. We are studying the interaction of *lac* repressor with DNA by neutron scattering using contrast variation and discuss here measurements on the protein, its tryptic core and their complexes with IPTG. Our results demonstrate that the headpieces are located far (67 ± 10 Å) from the centre of mass of a somewhat elongated core, and that the inducer does not significantly change the radius of gyration of the protein.

Guinier plots[8] of *lac* repressor and its tryptic core are shown in Fig. 1. Two parameters were obtained from the Guinier plots—a radius of gyration of excess scattering length density, R_G, and the scattered intensity extrapolated to zero angle $(I/C)_0$, which is related to the MW and concentration C of the particle[9]. In this case, the MWs of the particles are well known[10] and the concentrations were measured by absorption spectrophotometry. These values provided a criterion for each measurement of $(I/C)_0$, as aggregation or interparticle effects would lead to misleading observations of both $(I/C)_0$ and R_G. Aggregation was not negligible above concentrations of about 5 mg ml^{-1} and appeared more readily in D_2O solvents, an observation which has also been made in other systems (B. Jacrot and G. Zaccaï, personal communication). Values of R_G and $(I/C)_0$ measured in different conditions are shown in Table 1. The difference between R_G in H_2O and D_2O is expected because of the hydrophilic amino acid residues lying predominantly on the protein surface[9]. There seems to be no change in R_G on binding of IPTG.

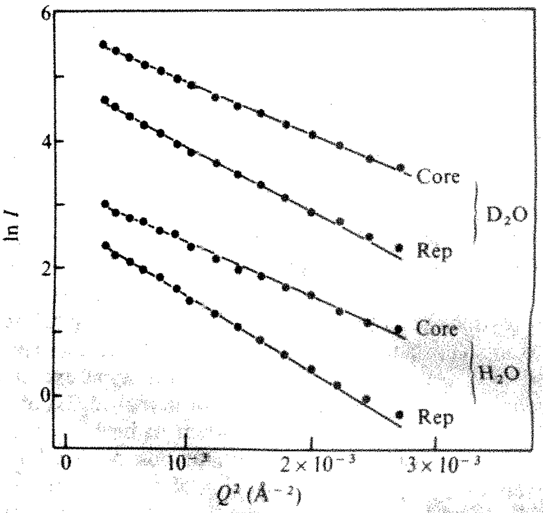

Fig. 1 Guinier plots of the scattering data for the *lac* repressor and its tryptic core. The logarithm of the scattered intensity is plotted against Q^2; $Q = (4\pi \sin \theta)/\lambda$, where θ is the half of the scattering angle and λ is the wavelength of the incident neutrons (10 Å in these measurements). Data were obtained with the protein concentrations 2.0 mg ml^{-1} (rep) and 2.5 mg ml^{-1} (core) in D_2O, and 5.0 mg ml^{-1} (rep) and 6.6 mg ml^{-1} (core) in H_2O. Buffers are described in Table 1 legend. The *lac* repressor was isolated by the method of Müller-Hill *et al.*[24]. The tryptic core was prepared according to Files and Weber[5]. For clarity, the curves are shifted arbitrarily along the ordinate axis.

The radius of gyration of a compact protein such as lysozyme or haemoglobin, for example, is proportional, to a good approximation, to the cube root of its molecular weight[11]. By extrapolating, we find the radii of gyration of compact multi-subunit proteins of MWs 128,000 and 154,000 to be about 30 Å and 32 Å, respectively. A higher value is observed for the tryptic core, and the experimental R_G of *lac* repressor is considerably larger. A larger R_G could indicate a less compact distribution of

Table 1 Neutron scattering data for *lac* repressor and its tryptic core

	Repressor	Core
MW	154,000	128,000
Volume (Å^3)	196,700	163,800
R_G HKPD (Å)	42.5 ± 1.5	35.0 ± 1.5
R_G DKPD (Å)	39.0 ± 0.2	34.2 ± 0.2
R_G DKPD + IPTG (Å)	39.2 ± 0.3	34.2 ± 0.2
$(I/C)_0$ obs. HKPD	0.0750 ± 0.0050	0.0620 ± 0.0010
$(I/C)_0$ calc.	0.0733	0.0608
D_{max} (Å)	115 ± 15	100 ± 15

MW and volumes are calculated from the sequence of the protein[10] using data given in ref. 9. R_G and $(I/C)_0$ are, respectively, the radius of gyration and the scattered intensity at 0 angle per mg per ml of protein normalized by the incoherent scattering of H_2O. The values are obtained from Guinier plots. $(I/C)_0$ calculated (calc.) is obtained from the formula

$$(I/C)_0 = 4\pi 10^{-3} \times (T/1 - T) \times t \times N_A \times [\sum b/\mathrm{MW} - \rho_S \times \bar{V} \times 10^{-24}/N_A]^2 \times \mathrm{MW}$$

where T is the neutron transmission of the sample in H_2O buffer, t the path length in cm, N_A the Avogadro's number, $\sum b$ the sum, in cm, of the scattering length of the amino acid residues (given in ref. 9), $\bar{V}$ the partial specific volume, ρ_S the neutron scattering density of water in cm Å^3 and MW the molecular weight[12]. HKPD buffer is 0.2 M potassium phosphate and 10^{-4} M dithiothreitol, *p*H 7.25, in H_2O; DKPD buffer is 0.2 M potassium phosphate, 0.5 M potassium chloride, 10^{-4} M dithiothreitol, *p*D = 7.25 in D_2O. The concentration of inducer IPTG (10^{-3} M) is large enough to complex all repressor or core molecules ($K_a \approx 10^6$ M^{-1}). D_{max} is the maximum dimension of the particle, calculated from Fourier transform of the scattering curves.

0028–0836/80/300423—03$01.00

cattering mass within a similar shape, or a more elongated hape.

By examining the scattering curves at large angles, a 'scatterng equivalent' to the shape of a particle can be deduced. It is a imple shape (an ellipsoid or a cylinder of given axial ratios, for xample) whose calculated scattering curve best approximates he observed curve. Scattering curves of *lac* repressor and its ryptic core are shown in Fig. 2. Up to $R_G \times Q \simeq 3$, the observed points fit very well to the curve calculated for a 2:1:1 prolate ellipsoid. The shape of compact proteins usually lies between that of a sphere and a 2:1:1 prolate ellipsoid. It is likely, therefore, that the large observed radius of gyration arises from a less compact packing of the subunits. The headpieces must be located so as not to change significantly the apparent shape of the particle. Although the data are poor in that region of Q, the shoulders in the scattering curves seem to be higher in D_2O buffers than in H_2O buffers. A similar observation has been discussed with respect to the packing of subunits in bacterial F_1-ATPase[12]. These shoulders must arise from a pronounced inhomogeneity in the scattering density distribution in the particle, probably associated with the packing of the subunits. The shoulders cannot be fitted by the scattering curves of homogeneous ellipsoids. Their heights as well as the angle at which they occur are approximately correct for hollow ellipsoids. Because the shoulder is higher in D_2O, we can say that the inhomogeneity is more pronounced in that solvent, as would be the case if there were solvent regions lined with hydrophilic amino acid residues 'within' the general ellipsoidal shape of the particle.

The maximum dimensions of the particles were deduced from the scattering curves in D_2O (the data from D_2O are better than those from H_2O solvents because of increased signal-to-background ratio) using the characteristic function given in ref. 8:

$$\gamma_0(r) = C' \times \int_0^\infty Q^2 I(Q) \frac{\sin Qr}{Qr} \, dQ$$

They are 115 ± 15 Å for *lac* repressor and 100 ± 15 Å for its tryptic core.

Assuming no major rearrangement on trypsin digestion, as supported by several experiments[13-15], the large R_G of *lac* repressor shows that the headpieces extend outwards from the core particle. The distance d between the centre of mass of each headpiece and the centre of mass of the protein can be calculated using the relationship (parallel axes theorem)

$$MR_G^2 = M'R_G'^2 + 4\,mr_G^2 + 4\,md^2$$

where M, M' and m are the masses of the repressor, the tryptic core and the headpiece, respectively, and R_G, R'_G and r_G are their respective radii of gyration. The calculation can be made for two extreme hypotheses concerning the conformation of the headpiece: either a spherical compact headpiece whose MW (6,400) leads to a radius of gyration of 10 Å, or an elongated ellipsoid with a long axis of 35 Å so as to cover half the operator, for example[16], leading to $r_G = 16$ Å. From these values, the calculated distances between the centre of mass of the protein and that of the headpieces are 67.5 ± 10 Å and 66.5 ± 10 Å, respectively. This calculation seems to be very insensitive to the assumed value of the radius of gyration of the headpiece. Combining these results with data on the structure of the headpieces[17] and its mobility[18,19], a model emerges with the headpieces as partly compact bodies at the end of flexible sequences attaching them to the core.

Two models have been proposed for the structure of *lac* repressor, based on packing considerations in microcrystals[20] and electron micrographs[21]. Our results do not allow us to confirm or reject either of these models. The size given by the authors is too uncertain to calculate valid radii of gyration and scattering curves (for example, the radii of gyration calculated from the extreme values given by Ohshima *et al.* are 38.4 and 45.5 Å)[21]. The situation of the headpieces at about 68 Å from the centre of mass implies an outward localization of these parts of the protein. Because at least two subunits are necessary to bind the operator[22,23] and because chemical cross-links between two headpieces have been observed[23], the headpieces must be arranged in pairs. In the elongated model proposed by Steitz *et al.*[20] the headpieces should be located in pairs near the extremities of the molecule. In this case, it is probable that the operator interacts with one pair of adjacent headpieces located at the same extremity of the repressor. In the model proposed by Ohshima *et al.*[21] more possibilities of localization exist; however, in any case, the headpieces must be located on the outside of the proposed volume. In this latter case the headpieces probably do not appear clearly in the electron micrographs after negative staining. Repressor could bind to the operator with the two adjacent interacting headpieces fitting perfectly the sequence of bases and the conformational state of the DNA. When the inducer is present the relative positions of the headpieces might vary in such a way that the positions of the interacting residues no longer fit the operator sequence exactly, to result in a decrease of three orders of magnitude in the association constant with DNA. This movement of the headpieces on IPTG binding might be small as it must not change the radius of gyration significantly. On the other hand, it could be quite large provided the distance between the headpieces and the centre of mass of the particle did not change; such a displacement would not change the radius of gyration at all. Experiments are in progress to test this model.

We thank C. Hélène and B. Jacrot for encouragement and useful discussions, and W. Gilbert for communication of unpublished results. Part of this work was supported by the Délégation Générale à la Recherche Scientifique et Technique (contract 79-7-0150 to J.C.M., ACC Mécanisme de Reconnaissance Moléculaire).

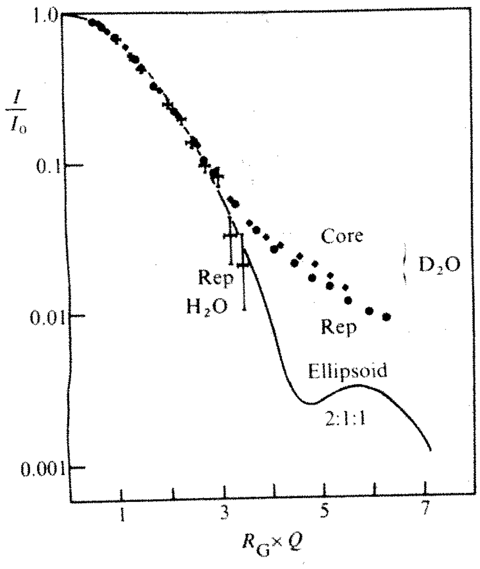

Fig. 2 Scattered intensity for large values of Q. Data are plotted against $R_G \times Q$, to compare directly the shape of normalized curves. Circles, diamonds and crosses are experimental values obtained for the indicated samples. The continuous line is the calculated curve for a prolate ellipsoid 2:1:1, according to ref. 8. Buffers are described in Table 1 legend. Protein concentrations are 5 mg ml^{-1} (rep) and 3.5 mg ml^{-1} (core) (neutron wavelengths 5 Å).

The caries resistance of human teeth is determined by the spatial arrangement of hydroxyapatite microcrystals in the enamel

‡ Dental Clinic, Medical School, University E. Kardelj, Hrvatski trg 6, 61000 Ljubljana, Yugoslavia

Teeth from different people differ in their susceptibility to caries. The beginning and the development of tooth decay depend on the presence of bacterial plaque[1] and on the structure of the tooth enamel[2]. But it has not been established whether the organic or the inorganic component of the enamel (which is comprised principally of hydroxyapatite microcrystals organized in a firm matrix), is responsible for most of the resistance of teeth to caries. We report here that the electron spin resonance (ESR) lines of the CO_3^{3-} defect of samples of enamel prepared from caries-resistant teeth differ significantly from the corresponding spectra of the caries-sensitive samples. We have traced these differences to the hydroxyapatite microcrystalline alignment in the tooth enamel, and found that this alignment is specific to indivduals and is therefore probably nutritionally or genetically determined.

We used samples of enamel 2 × 2 × 1 mm, cut from the human maxillary incisors of adults of different sex and age. The outer, square face was taken from the buccal tooth surface (insert in Fig. 1*a*). To facilitate comparison, several deciduous teeth were also measured and analysed. We had two groups of adult teeth: those removed (because of periodontal disease) from people with above average resistance to caries (25 samples) and those considered to be caries-sensitive because they were grossly decayed (26 samples). In the latter case, care was taken to prepare ESR samples from areas which were completely unaffected by caries.

All samples were γ-ray irradiated at room temperature to a final dose of 0.5 Mrad to introduce defects into the enamel. The CO_3^{3-} centre was predominant; this arises from electron capture by the CO_3^{2-} radical[3], but a weak signal of O^- was also observed. The lines were assigned by comparison of the irradiated enamel ESR spectra with those of synthetic hydroxyapatite. Irradiated samples were placed in sealed quartz–glass tubes for measurement on a Varian E-9 ESR spectrometer. Spectra were recorded with the magnetic field perpendicular to the square face of the sample and thus also perpendicular to the long axis of the tooth. Representative spectra were also recorded from enamel samples powdered in a mortar. The spectrometer was operated in the X-band range and only the central part of the spectra[4], corresponding to the CO_3^{3-} centre, was analysed.

The carbonate in the enamel may be contained within the hydroxyapatite lattice or present as a separate phase with counterions[5,6]. ESR studies of natural carbon-containing apatites have, however, shown that the CO_3^{3-} ESR lines originate from the carbonate radicals CO_3^{2-} which replace PO_4^{3-} in the apatite lattice and are therefore firmly bound to it[3]. For tooth samples, we compared the angular dependence of the ESR lines of the CO_3^{3-} and O^- defects (the orientation of the latter with respect to the crystal axes being well established from other studies of synthetic hydroxyapatites[5–7] and thereby obtained further evidence that the ESR-observable CO_3^{3-} indeed reflect the *order* within the hydroxyapatite matrix[4].

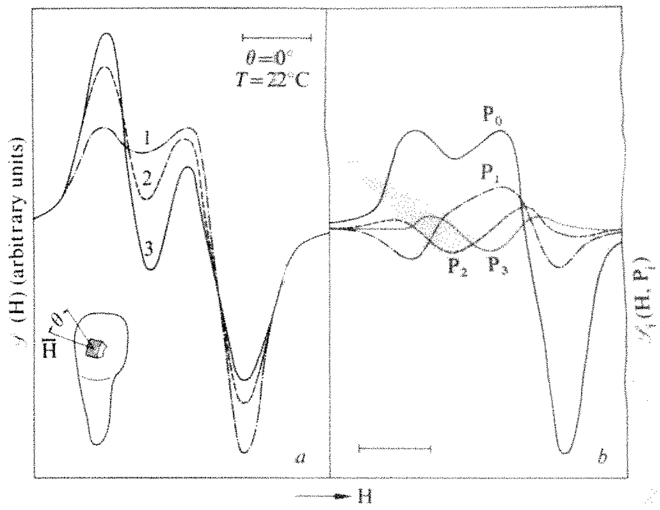

Fig. 1 Measured and simulated CO_3^{3-} centre ESR lines of γ-ray irradiated adult human incisor enamel. *a*, The experimental spectra of representative powdered (1), caries-sensitive (2) and caries-resistant (3) teeth; *b*, the first four calculated ESR spectra $\mathscr{S}_i(H)$, $i = 1,2,3,4$, which correspond to the angular distribution function of the CO_3^{3-} centre preferential axes given by the lowest four Legendre polynomials. Insert shows the site on the tooth buccal surface from where the samples were cut and their orientation in the magnetic field. Scale bars represent 10 G. $\vartheta = 0°$; temperature = 22 °C.

The ESR spectra of oriented, cut samples differ from spectra of powdered samples (Fig. 1*a*). As the ESR lines, which arise from the paramagnetic centres, mirror internal order within the sample, it is possible to deduce the orientational distribution function of these centres in the tissue studied. This function is correlated with the probability that the molecular axes of the observed centres are aligned preferentially in a certain direction with respect to the external magnetic field, corresponding to the state of the internal order of the system.

To understand and simulate the ESR spectrum, the energy states of the observed spin, which can be calculated from the values of the anisotropic hyperfine coupling tensor, as well as the lineshape parameters, must be known. In the procedure that we have developed[8] the ESR spectra of powdered enamel have first been simulated. A linear combination of the gaussian and lorentzian convolution functions[9] has been used. The optimal parameters have been determined in the standard way by minimizing the squared differences between the measured and the calculated spectra. Then, the ESR spectra of the corresponding partially ordered specimen have been simulated: the ESR line-determining parameters used were those obtained from the simulation of the powdered enamel spectra, and the Legendre polynomials[10] $P_i(\vartheta)$, $i = 1, 2, \ldots, 12$ have been

0028–0836/80/300425—02$01.00

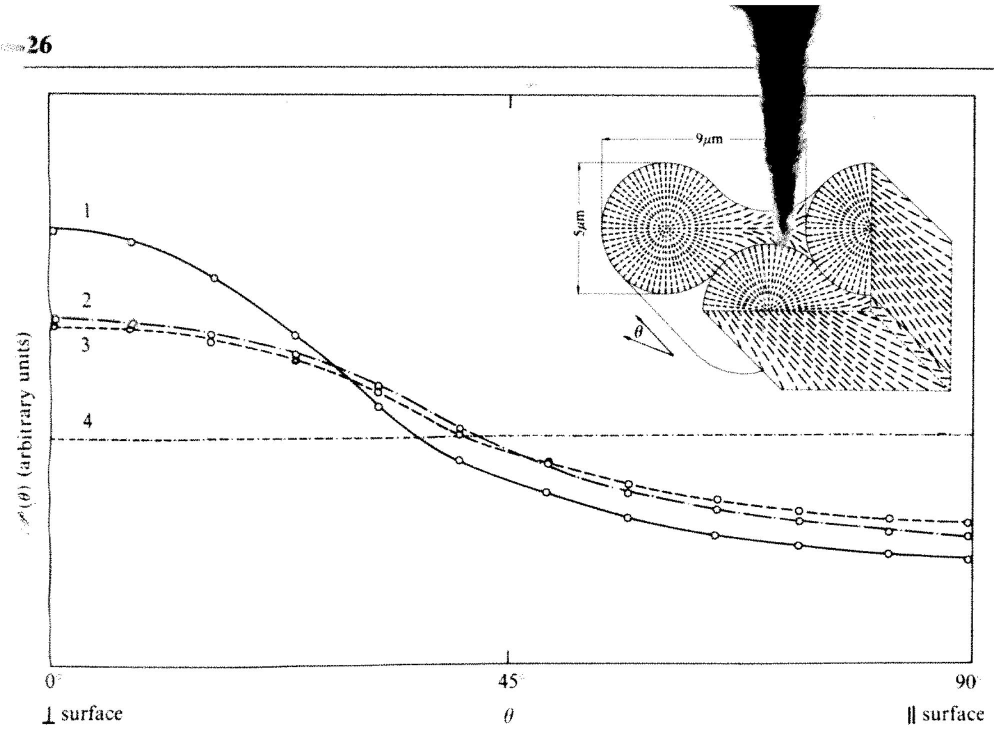

Fig. 2 The angular distribution function of the hydroxyapatite microcrystals within human incisor enamel. Their alignment is defined with respect to the normal to the tooth surface. The points have been obtained by summing the values of Legendre polynomials at respective angles and weighted by the factors α_i, defined in equation (1), and determined from the simulation of the tooth enamel ESR spectra. The curves correspond to the caries-resistent (1), caries-sensitive (2), milk (3) and powdered (4) human teeth. The insert presents schematically the arrangement of the hydroxyapatite microcrystals in lockhole-shaped tooth enamel prisms which are the basic units of the enamel[13].

assumed to represent the angular distribution function of the CO_3^{3-} centres — and therefore of the hydroxyapatite microcrystals — in the sample. The angle ϑ was defined with respect to the external magnetic field, that is, normal to the enamel surface (insert in Fig. 1*a*). We have calculated a set of the spectra $\mathcal{S}_i(\mathrm{H}) = \mathcal{S}_i\,(\mathrm{H}, \mathrm{P}_i(\vartheta))$, $i = 1, 2, .., 12$, (Fig. 1*b*), which have been normalized properly[11] as a basis for the expansion of the experimental spectrum of the tooth enamel $\vartheta(\mathrm{H})$ into the series

$$\mathcal{S}(\mathrm{H}) = \sum_{i=1}^{12} \alpha_i \mathcal{S}_i(\mathrm{H}) \qquad (1)$$

The factors α_i in the above sum therefore define the relative contributions of the hypothetical samples of known microcrystalline alignment, given by $\mathrm{P}_i(\vartheta)$, in the experimental ESR spectrum. This macroscopic sample spectrum is actually a result of the overlap of the particular ESR lines corresponding to the single hydroxyapatite microcrystals. The factors α_i therefore also reveal the relative amounts of the Legendre polynomials $\mathrm{P}_i(\vartheta)$ used for obtaining $\mathcal{S}_i(\mathrm{H})$ in the actual distribution function of these hydroxyapatite microcrystals in the bulk sample $\mathcal{P}(\vartheta)$

$$\mathcal{P}(\vartheta) = \sum_{i=1}^{12} \alpha_i \mathrm{P}_i(\vartheta) \qquad (2)$$

We conclude that the differences in the CO_3^{3-} centre ESR lines of the teeth studied (Fig. 1*a*), which correlate significantly to their resistance to tooth decay[4], are a consequence of a higher degree of alignment of the hydroxyapatite microcrystals in the enamel of the caries-resistant teeth as compared to caries-sensitive teeth.

The electron microscope studies of etched enamel have shown that the hydroxyapatite in the human enamel is ordered in well defined patterns[12,13]. Around the areas of well aligned microcrystals there are zones of lesser microcrystalline order. As yet, such studies have only yielded localized information about the tooth surface whereas our approach permits conclusions to be drawn about the order averaged over the whole sample, and can thus be compared with the neutron diffraction studies of apatite orientation in bones[14]. In this study we have found that the hydroxyapatite order, as revealed by the angular distribution function of microcrystals, extends throughout the outer layer of the enamel (Fig. 2). In this layer, which acts as the main tooth-protecting barrier, the enamel seems to be organized in such a way that the long axes of microcrystals are on average perpendicular to the tooth surface, an arrangement which confers optimal resistance to the detrimental influences of the oral environment (insert in Fig. 2). The more randomly oriented microcrystals (which contribute to the flat portion of the distribution function, $\vartheta = 45°–90°$) would imply little resistance of the corresponding regions to caries. However, these areas constitute the inner enamel parts and are therefore less significant for the overall sensitivity of the tooth to caries: the ESR spectra of the consecutive layers of tooth enamel show a decrease in alignment of microcrystals with distance from the tooth surface[4]. It may also be significant that milk teeth have a poorly organized hydroxyapatite matrix and in this respect resemble caries-sensitive teeth. The limited lifetime of milk teeth suggests that they need not be very resistant to caries (Fig. 2). In caries-resistant teeth, however, a larger proportion of the microcrystals is well oriented. In the angular distribution function this better alignment of hydroxyapatite in the outer enamel region is partially screened by the large background of more randomly oriented inner parts of bulky samples.

The alignment of the microcrystals in the hydroxyapatite matrix of human tooth enamel of different incisors of the same subject are alike[4]. We therefore conclude that the degree of hydroxyapatite microcrystal alignment is an individual property which may, for each individual, determine resistance to tooth decay. However, it remains to be seen whether nutritional or genetic factors, or both, are responsible.

BOOK REVIEWS

Trials of Jewry

Vera Rich

It Seems I Am a Jew. By Grigori Freiman. Pp.98. (Southern Illinois University Press: Carbondale, Illinois/Feffer and Simons: London, 1980.) $9.95, £5.45.

OVER the past ten years, the problems facing Soviet Jews in general and Soviet Jewish scientists in particular have frequently been raised in both the general and the scientific press. To a large extent, however, this has been a matter of Jews wishing to emigrate to Israel: Jews, it may be argued, who have chosen to opt out of the Soviet system. What is less often realized is that in one branch of Soviet life there appears to be active discrimination against Jews, however little they themselves feel aware of their Jewish identity — namely in mathematics.

It Seems I Am a Jew, originally a *samizdat* (privately circulated) essay and now published in English translation, is basically a record of one man's experiences in trying to make for himself a career in mathematics while handicapped by the implications of the word 'Jew' in his internal passport, under Point 5, 'Nationality'. For, from the point of view of the Soviet administration, Jewishness relates not to religion, not to self-identification with an ancestral cultural tradition, but simply to ethnic descent. Thus in the case of some anti-Jewish prejudice or campaign, as with the notorious 'Doctors' plot' in the last days of Stalin, any person of Jewish descent, no matter how *déraciné*, is liable to fall victim.

Such prejudices or campaigns are, of course, totally contrary to the Soviet constitution. The Soviet press constantly reiterates that there is no 'anti-Semitism' in the Soviet Union and that Soviet policy is opposed only to 'Zionism'. Nevertheless, as Freiman's essay indicates, there is growing evidence that discrimination against Jews, particularly in the academic professions, and especially in mathematics, does exist. Promotions over one's head, unreasonable delays in the acceptance of a doctoral thesis, refusal (or at least non-provision) of a passport for foreign travel — these are phenomena all too common in the life of the Soviet Jewish intellectual. (Ironically, such incidents have sometimes driven a hitherto uncommitted Jew right into the arms of the emigration lobby. Aleksandr Ioffe, whose mathematical work recently formed the basis of a two-day seminar in London, had shown no signs of wanting to emigrate to Israel — until he was refused a passport to take a temporary post as 'visiting lecturer' in Paris.)

To such a situation, which could so easily become fraught and over-emotional, Freiman brings a rare, if black, humour. The 'documentary poem' of his attempts in the early 1950s to enrol as an external graduate student of mathematics, while working at the Kazan Institute of Aviation, is a masterly analysis of 'Catch-22' bureaucracy. Yet since that time, he says, the situation has significantly deteriorated, with admission of Jews to the more prestigious mathematical departments and institutes being phased out almost completely since 1970. The universities of Moscow, Leningrad and Novosibirsk, the main stepping-stones to a career in creative mathematics, have, says Freiman, virtually ceased to admit Jews. He describes a special selection process by which Jews and cerain other 'undesirables', such as Armenians, are concentrated for the entrance examination into special groups, which are then set far more difficult problems than the racially more acceptable candidates. Examples of these 'Jewish problems' are given in the text; further examples, from the examination of 1978 for the Moscow University Faculty of Mechanics and Mathematics, are cited in an appendix. Although there has been previous mention of such 'Jewis problems' in print, this is the first time tha a sufficient number have been cited t make it possible to assess them.

Grigori Freiman

Since this review was written, Professor Freiman has been dismissed from his post at *Kalinin State University*.

Judging from these, for 'speci selection' the examiners seem to favou number theory and classical geometry subjects in which intuition plays particularly significant role. One or two o the questions, incidentally, notably th solution in integers of the equation $x^y = y^x$ can be solved intuitively and virtuall instantaneously — in the context o pseudo-mathematical party-games. *If* however, a rigorous mathematical proo must be produced — orally, within 15 minutes, under the pressure of examination conditions, by a nervous 19 year old — the situation takes on a rather differen aspect. The standard Soviet explanation o such questions, as Freiman points out, is that the examiners cannot admit everyone but are on the look out for excellence. In that case, he asks, why do Jewish students who have come out in the top bracket of the All-Union Mathematical 'Olympiads' do so badly in the entrance examinations? (And why, one may add, are such supplementary tests of excellence not administered to all of the candidates?)

Yet the entrance examination is only the first of the problems to be faced in the academic careers of Soviet Jews. Not only are they refused admission to the best universities, but at every step their advancement is blocked. The thesis is turned down, not because *the aspirant* is called Goldberg *or Finkelstein*, but because it was not *quite* up to standard. The promotion bypassed Lazar Izaakovich *in* favour of Ivan Petrovich *not on grounds of* nationality, but simply because *the* ethnically Russian candidate happens to be the better, more qualified and more capable applicant. Such 'explanations' are notoriously difficult to refute — all the more so since, according to Freiman, the examiners, expert committees and appointments' boards all have to play a double game; knowing that they must reject a Jewish candidate, they *have to* produce an academic *alibi*. "The mathematics is mechanical . . ."; "He is a brilliant mathematician but superficial"; "He has about a hundred works to his name. He must be chasing after recognition". Such gems, taken, says Freiman, from the official stenographic reports of the various assessing bodies, show only too clearly the *cynical nature of their verdicts.*

Freiman's essay is *essentially* a personal statement, founded on his own *experience* and on data which he has been able to garner from acquaintances. He does not attempt to explain or find psychological or political motivation behind the drive to render Soviet mathematics *judenfrei*. He is content simply to state the facts as he sees them, and to cite, in an impassioned *J'accuse* addressed to the President of the Soviet Academy of Sciences, the names of half-a-dozen leading Soviet mathematicians, the Expert Committee for Mathematics and Mechanics of the Higher Attestation Committee (the body responsible for higher degrees) and the Steklov Institute of Mathematics of the Soviet Academy of Sciences. These few put prestigious persons and bodies, he says, have made Soviet mathematics "a cesspool of scientific unprincipledness".

Granted the conditions described in Freiman's essay, and the resolute official denials that anything in the nature of anti-Semitism can exist in the Soviet Union, it would seem virtually impossible for any impartial third party to assess the validity of Freiman's claims. A certain weight should undoubtedly be given to the fact that at the time of writing the essay Freiman himself was neither a refusnik nor an *émigré*. (Since then, he has filed an application to emigrate to Israel.) Weight, too, should be given to the style of the essay, remarkably free from the introspective self-pity that mars so many *samizdat* biographies of repression. One piece of evidence mentioned by Freiman is, however, open to checking by the Western reader — the virtual disappearance over the past few years of Jewish surnames from the contributors to the *Matematicheskii Sbornik* and other leading Soviet mathematical journals. Thanks to the various cover-to-cover translation bureaux, most of these journals are available, in their entirety, in English translations. Those readers who find Freiman's revelations difficult to accept can count for themselves. ☐

Publicity for exotic atoms

C.J. Batty

Exotic Atoms '79: Fundamental Interactions and Structure of Matter. Edited by Kenneth Crowe, Jean Duclos, Giovanni Fiorentini and Gabriele Torelli. Pp.403. (Plenum: New York and London, 1980.) $45, £28.35.

AN EXOTIC atom is an atom in which one of the electrons has been replaced by a negatively charged heavy particle such as a muon (μ), π or K-meson, antiproton ($\bar{p}$) or by a Σ-hyperon. It can be formed by stopping a beam of the appropriate particles in a suitable nuclear target. Once the heavy particle has been slowed down to an energy of order 1 keV it can be captured into a Bohr orbit about the nucleus of high principal quantum number *n*. It will then cascade down through its own sequence of atomic levels, first by Auger transitions with the emission of an electron and later by the emission of X-rays. Following each of these transitions it comes closer to the nucleus until at some stage nuclear capture takes place.

Studies of exotic atoms cover a whole range of disciplines from physical chemistry through atomic and solid-state physics to nuclear and elementary particle physics. This diversity of interests and applications is reflected in the 22 articles, of varying length, which appear in *Exotic Atoms '79*.

The exact mechanism by which the heavy particle is captured to form the exotic atom is not fully understood but the present volume contains an interesting review of this topic by Schneuwly under the heading of "Mesic Chemistry". Four other shorter articles deal with more specific aspects of capture by hydrogen and the properties of muonic-hydrogen atoms. A particularly fascinating review by J. Rafelski from CERN deals with the properties of mesomolecules of hydrogen in which the electron in the hydrogen molecule H_2^+ has been replaced by a muon. In the case of the heavier hydrogen isotopes spontaneous fusion can occur, a process first observed for the system μ^-pd at Berkeley in 1956, and there is now considerable interest in the properties of dd and dt mesomolecules.

Rather special examples of exotic atoms are muonium, the system μ^+e^-, and positronium, the system e^-e^+. The properties of muonium and positronium are reviewed by V. Hughes of Yale University, who has worked for many years in this field, and here one is particularly impressed by the elegance of the experiments and the precision of the results. Extensions of the exotic atom picture to consider bound states of quarks to form hadrons are discussed in three theoretical articles. Other topics reviewed include muon capture rates and parity non-conservation in atoms and molecules.

The whole field of muon spin rotation (μSR), so named because of its close analogy with nuclear magnetic resonance (NMR) and electron spin resonance (ESR), has expanded dramatically over the last few years and is now a valuable tool in the study of condensed matter as well as being a topic of study in its own right. It is therefore not surprising that almost half of the book is devoted to this subject. Topics covered include muon diffusion and trapping in solids, aspects of positive muons as impurities in metals, studies of μSR in semiconductors and in ferromagnetic metals, and some features of muonium chemistry.

The book is certainly a valuable contribution to publicizing the existence of a fascinating area of cross-disciplinary research, and will provide an excellent introduction to those meeting the subject for the first time and a valuable reference work for the more expert. ☐

Neurophysiological methods in entomology

Melody Siegler

Insect Neurophysiological Techniques. By T.A. Miller. Pp.308. (Springer: Heidelberg and New York, 1979.) DM54, $29.70.

IN *Insect Neurophysiological Techniques*, T.A. Miller has compiled details of techniques taken from the published works of many authors, and from his own visits to and correspondence with several laboratories. The text is divided into four parts. I, "Materials", describes electrophysiological apparatus and accessories; II, "Actographs", reports the methods used over the past 25 years to measure insect activity; III, "Free-Moving and Tethered Preparations", describes the procedures selected researchers have used to record from nerve and muscle in cockroaches, locusts, crickets and flies; IV, "Organ and Tissue Preparations", emphasizes heart, gut and salivary gland preparations, methods of recording from cockroach ventral nerve cord, and nerve–muscle preparations of locust and cockroach leg. There is a reference section, containing selected literature prior to 1977, an appendix listing suppliers and an index. The book is the first in a series to be concerned with problems of experimental entomology.

Ideally, a book that emphasizes methodology should be accurate, clear, concise and well-organized, and be designed to make its contents readily accessible to the reader. *Insect Neurophysiological Techniques* falls far short of these ideals. The text is wordy, and almost awash with minutiae. Often it strays from the topic at hand, and large sections are misplaced or mistitled. There is a wealth of detail, but it is often repetitive or with no clear objective. I wish the author had exerted more of an organizing hand, carefully and firmly integrating the information from his diverse sources. Throughout, the level of presentation is uneven. For some topics, the writing is addressed to those readers with little or no laboratory experience; for others there is little introduction and much jargon. Too often minor points are given misleading emphasis, whilst crucial details are incorrect or omitted altogether. The dedicated and cautious reader will doubtless be able to extract some useful information but, in general, the book is not a particularly helpful introduction to the considerable advantages of insects for basic or applied research. □

Insight into microbial development

Ian Dawes

Developmental Biology of Prokaryotes. Edited by J.H. Parish. Pp.297. (Blackwell Scientific: Oxford, 1980.) £19, $48.50.

THERE are few texts available that cover the many aspects of microbial development and those that are have been around for rather too many years to be of much use to students or teachers. There is, therefore, a need for a suitable text at a fairly advanced level and this book is an attempt to fill the gap.

It tries to do this by way of a brief introduction by the editor to prokaryotic diversity and unity, and to gene expression and its regulation. This is followed by ten chapters covering nine groups of organisms, each chapter written by an expert in his particular area. These include the cell cycle in *Escherichia coli*; bacterial sporulation (with two chapters in deference to the volume of research that has been carried out in this area); sphere-rod transitions in *Arthrobacter*; streptomycete differentiation; *Bdellovibrio* growth; prosthecate bacteria; cyanobacterial differentiation (filamentous and pleurocapsalean); and myxobacteria. A brief concluding chapter rounds off the book.

Foremost among the difficulties in trying to provide a text by this type of approach is the tendency to produce a collection of individual review articles, each a catalogue of the hopes, successes and failures of research in one particular area, at the expense of formulating a fundamental analysis of the subject. Is this not integrating differentiation? This book is no exception in that the two chapters that could provide an overview of the subject are too condensed to be of much value; much of the introduction is best dispensed with and the reader should consult, where necessary, the appropriate biochemistry bible of choice. The majority of material has, however, been chosen judiciously with a balanced coverage of the main bacterial development systems, although in future editions several chapters on bacteriophage development could be added to illustrate relevant control and assembly systems that have been worked out in considerable detail.

Several of the chapters are excellent. That on the cell cycle is stimulating, both for its breadth of coverage and for the critical discussion of possible models to account for the mechanisms controlling DNA replication and cell division. The two chapters on bacterial spores and sporulation also provide interesting reading despite the plethora of reviews already available on the subject. Inevitably, that concerned with the molecular biology of sporulation is beginning to date, as gene cloning techniques are rapidly exploited. Nonetheless, the chapter provides a useful summary of the main work that has been done on the control of spore formation. The authors of the remaining chapters have faced the difficulty (recognized by Parish) that "there is a lot of work to do on other groups of 'differentiating prokaryotes' to bring the state of knowledge up to the level of *B. subtilis*". In most cases, they have succeeded in avoiding the temptation to compare progress with that in *B. subtilis* by stressing the aspects of development that are unique to their system. There are occasional lapses, none more revealing than the several discussions of the lack of evidence for RNA polymerase changes during differentiation in *Caulobacter* and *Streptomyces*. One or two chapters lack freshness since the authors have little to add to recent reviews on the same subjects. Also noticeable in places is the inverse correlation between the number of pictures and the number of facts available for presentation. Also, at times, and to the greatest extent in the chapter on *Arthrobacter*, there is a tendency to catalogue biochemical studies, without regard to their relevance or completeness; this makes for less interesting reading.

These are, however, minor criticisms of a book that is valuable for the insight it gives into microbial development processes. Whilst not a text in the sense that it tries to unify the field of prokaryotic development, it provides excellent coverage of the main bacterial systems and should prove very useful to those who study, or teach, microbial development. □

A holistic approach to vision

Talbot H. Waterman

The Ecology of Vision. By J.N. Lythgc Pp.244. (Clarendon/Oxford Universi Press: Oxford, 1979.) £22, $49.

IN THE ecology of vision John Lythgoe h chosen a fascinating topic for a boo Obviously radiant energy mainly from t Sun has had far reaching effects on t nature of the Earth and its fitness for li More directly, sunlight supplies practica all of the energy needed by organisms survive, grow and evolve. In the compl mentary field of biological informatic and control natural light also functio everywhere in daily and seasonal pr gramming as well as in the spatial orie tation of both plants and animals.

Limiting one's attention to the phot biology of animals with well-develope functional eyes as implied by 'vision' st leaves an enormously challenging area be dealt with. Lying as it does at the inte section of comparative visual physiolog and ecology it has long been the major are of my own research and teaching. Indeed would have liked to write a book about th subject myself. Hence this appraisal c Lythgoe's work, while it may betray a trac of sour grapes, cannot fairly be attribute to disinterest.

However, coping well with the taxin demands of so broad and varied a subject a formidable goal. Starting with sola irradiation, the path leads insistentl through meteorological as well as sub marine optics to the biophysics and bio chemistry of visual pigments, the func tional organization of eyes, thence t visually mediated perception, orientation navigation, migration and behaviour.

Obviously most of these componen topics have often been reviewed in thei own right, sometimes with a high degree o competence. Even in the holistic sens there are several symposium volumes tha have essayed to survey the substantial are where natural radiation, ecology and sen sory physiology come together.

Thus the author of a book on this subjec not only has a big topic to deal with but h also has to encompass the previous contributions of numerous other scientists. Hence the questions: "What should be said that hasn't already been well said?" "What is the real point d'appui of the present approach?" and finally, "To whom is the work addressed?", are not trivial ones easily answered.

An unusually versatile author working resolutely with consummate skill might solve most of these problems if overall strong matching support was provided by his publisher. Yet weakness or failure in fulfilling one or more of the book's numerous desiderata will at b 'nice try' rather th pinion the present volume, while certainly timulating, is not unflawed and has roved to be rather disappointing.

On the positive side *The Ecology of ision* has, in addition to its subject, other rong points in its favour. Thus, the verall organization is fine. In outline there e two introductory chapters (80 pp.) on e photic environment and vision spectively. A middle section (89 pp.), in our chapters, details the visual con- equences of (1) low ambient light inten- ities (night, deep water, caves), (2) high urbidity of the medium (which often estricts aerial vision and always puts a evere limit on underwater visibility), (3) e interaction of directional illumination nd *preferred* lines of sight, and (4) spectral ias of non-white illumination (e.g. sky ght, mesopelagic irradiance and reflected ght from vegetation). The final chapter 35 pp.) surveys the organism–nvironment interaction as it relates to amouflage, conspicuousness and ecognition.

Thus the text overall is brief, and therefore appropriate to a broad readership which might not persist through a multi-authored encyclopaedic treatise. Yet Lythgoe has managed to include so varied a coverage that even the specialist is bound to find some fascinating correlations previously unappreciated. These fresh insights, however, may seem to lie around the periphery rather than near the centre of a given reader's area of expertise. For instance two topics of primary interest to me, compound eyes and polarization sensitivity, seemed among the less effective aspects of the book.

A further and notable positive feature of *The Ecology of Vision* is its wealth of illustrative material. This eye-catching potpourri of line drawings and colour as well as black-and-white half-tones is attractive both to the general reader and to the specialist, ranging from portrait sketches of many of the different animals cited in the text to excellent illustrations chosen from relevant research publications including Lythgoe's own. While the idea of illustrating many of the organisms referred to in this comparative study is welcome, its impact is blunted if adequate biological and aesthetic standards are not maintained. Rather rudimentary drawings of a six-legged spider, a crayfish with eight legs and a bifurcate rostrum, as well as a gecko apparently fitted with dentures, are extreme examples in point.

The bibliography, of 340 items, is reasonably up to date; however one disturbing aspect of the references is an almost total failure of the author to guide the reader to the most important sources of further original information. Thus few primary publications of innovative research workers are presented in any sort of historical or evaluative perspective. Lythgoe is surely not alone in this tendency to become lax or even irresponsible in identifying the seminal contributions to a field of science. Further, a number of experimental biologists whose contributions would loom large in some readers' view of the ecology of vision are not even mentioned: Karl von Frisch, Erich von Holst, H.K. Hartline and Werner Reichardt, for example.

This brings up another feature of the book which is particularly evident in the bibliography, namely its marked skewness towards the vertebrates. Sixty percent of the citations refer to this group and of these 57% in turn are references to fishes. This bias reflects the author's own research interest which has mainly been concerned with underwater visibility and fish vision.

Even with regard to fishes, major seemingly relevant topics are ignored. For instance the dorsal light reflex, sun compass behaviour, diurnal vertical migration, light-cued rhythms and photoperiodic influences, as well as the whole field of chromatophores and their control, are all omitted. Obviously the coverage of insects, spiders, crustaceans and cephalopods, all of which have highly developed vision, is even less representative of the great amount of research which has been done on their visual ecology.

One pervasive feature of the text suggests that the author may have surrendered his manuscript to the publisher before its due term. This is a certain lack of polish and style in the writing. In some sections repetitive and awkwardly coordinated passages are common, while the style at its least elegant may be epitomized by the disappointing introduction to Chapter 1 and the rather limp coda at the very end.

How can such a good idea for a book have materialized as unevenly as this? John Lythgoe provided an important and interesting topic generally well organized, well illustrated and well documented. But in spite of this the book fails to live up to its promise. The flaws are too many for it to be regarded as a prospective classic, though it is certainly a 'nice try'. □

Talbot H. Waterman is Professor of Biology at Yale University, New Haven, Connecticut.

Brain structures and behaviour

Richard Lynn

rain and Personality. By Graham E. owell. Pp. 113. (Saxon House: arnborough, UK, 1979.) £10.50.

N THIS *volume* Dr Powell reviews the urrent state of theory and knowledge of he relation between brain structures and ersonality. The methodology in this field onsists primarily of making lesions in ifferent parts of the brain and observing ubsequent changes in the personality of he subject. The first substantial advance vas the documentation in the nineteenth entury of the case of Phineas Gage, a onstruction worker whose frontal lobes ere severely damaged in an accident and vho subsequently became more happy-go-ucky and less socially responsible. In later ears this type of effect has frequently been eported following frontal lobe injury.

Dr Powell argues that to make progress in the field it is necessary to have a model of the major personality traits or dimensions. We assume that different brain structures serve particular personality traits. The brain can then be mapped by observing the effects of lesions in different parts of the brain on various personality traits. Dr Powell begins with Professor Eysenck's traits of neuroticism and extraversion and his theory that these are mediated by the amic and brain stem reticular This formulation has in difficulties. An made by J. Stress: 1971) who has proposed that introverts are more sensitive to punishment and that this sensitivity is mediated by the orbital frontal cortex, the medial septal area and the hippocampus. Here again, however, the new theory has met difficulties. In particular, it is still not clear whether damage to this system really does make people less introverted.

The author turns next to the more empirical studies. These consist of attempts to relate lesions of various brain structures to personality change, without any model of brain function. The chief results here are the reduction of aggressiveness following damage to the amygdala, the reduction of anxiety following damage to the cingulate gyrus and the reduction of sexual drive following damage to the hypothalamus. These findings have been used in the USA to reduce criminal aggressive and sexual behaviour. This is a useful source of knowledge of the brain mechanisms underlying these behaviours, although not one of which the author approves.

Looking at work on these problems in the century or so that has elapsed since the Phineas Gage case, one is left with a certain feeling of disappointment about the slowness of the progress that has been made. Perhaps the use of questionnaires such as Cattell's (*Personality and Learning Theory:* 1979), which measure narrower personality traits, would yield more decisive results. In the meantime, Dr Powell's book will be a useful starting point for those attempting to come to grips with the still largely unsolved problems in this field. □

Richard Lynn is Professor of Psychology at the University of Ulster, UK.

Public monopoly and private enterprise

The British government, no longer (one forgets) new, appears to have had a rush of blood to the head in the past few weeks in its reorganization of the public monopolies. With the British parliament well on the way to agreeing that the government should sell to the public a still undefined proportion of the shares in British Airways, it was flooded with a stream of proposals for the reorganization of other public monopolies. The British Post Office is to lose its monopoly on the carriage of letters. Three years from now, the telecommunications arm of the Post Office will no longer be the sole supplier of terminal equipment. To many people's surprise, the Central Electricity Generating Board is to lose its monopoly on the manufacture and sale of electricity, while British Rail is to divest itself of some of the largely peripheral activities which it has accumulated over the decades — the operation of docks and ferry services but also of hotels and golf courses. With such a flood of announcements, many British taxpayers must have been fearing that their government was about to break up the monopoly of the Inland Revenue by reverting to the ancient practice of putting-out to open tender the right to collect taxes.

In reality, of course, the explanation of this fever of activity is more mundane. It has taken the British government a year or so to put flesh on the bones of its declared intention of exposing the public monopolies to more effective competition. With the summer parliamentary recess about to begin, ministers are trying to clear their desks and also to stake a claim on parliamentary time for legislation in the next session, beginning in November. The hope that it would be possible to deal with the public monopolies more quickly, and in such a way as to reduce the government's need to borrow from the money markets in the current financial year, much cherished a year ago, has now faded — with some exceptions, assets cannot be sold in a hurry except at a loss. The danger now is not so much that the British government will give potential purchasers of public assets too good a bargain at the taxpayers' expense but that by dealing piecemeal with the problem of public monopoly will arrive at a patchwork of decisions which are self-contradictory, even mutually nugatory.

But why not do away with the public monopolies altogether? This is what some intemperate souls are inclined to ask. A little reflection will show that such a radical solution, however attractive it may seem, is entirely impractical. Public monopolies of one kind or another will persist for as long as modern states persist. The clinching example is that of sewage disposal in built-up areas such as cities. Nobody in his senses would suggest that the provision of such a service should be left to private enterprise (as it used to be in the eighteenth century and is still in some rural areas). The essence of the case for local monopolies in sewage disposal is that the cost of providing the service is to a very large extent a capital cost, that the cost of two competing systems would be approximately twice the cost of one and that, if both were to remain viable, the users of the service would be required collectively to pay twice as much as would otherwise be necessary. (Ironically, in Britain, local monopolies for sewage disposal were uncontentious until recently, when the service was administered by elected local authorities; their transfer to the newly constituted water authorities has raised all kinds of doubts about the basis on which the service should be charged for.)

The difficulties in which the independent railway systems of the United Kingdom found themselves at the height of the nineteenth century railway boom is still a memorable illustration of how competition may not always be beneficial. It is, however, important that the case for a public monopoly is not always strictly economic. Most national post offices have been given a monopoly to deliver mail on the grounds that same-cost delivery of a piece of mail to any address serves a valuable purpose in holding the community together.

At least in modern times, monopoly rights imply monopoly obligations. Because a monopoly can in principle make its customers pay through the nose for whatever service it provides, steps must be taken to prevent abuse. Even where public monopolies are financed by private, not public, capital, control of some kind is necessary, whence the great bureaucracies such as the Federal Communications Commission with which Washington is littered. Where monopolies are financed with public money, as in Britain, the agency of control is usually a nationalized industry and, paradoxically, consumers often have much less explicit evidence that their interests are well cared for. Governments are all too ready to issue directives which further short-term political interests against the long-term interests of consumers. (The way in which successive British governments have forced British Airways to buy British equipment against its wishes are only the most easily remembered scandal of this kind.) The objective of the recent wave of change in Britain is allegedly to make the public monopolies more efficient. The difficulty, by no means confined to Britain, is how to measure efficiency.

The crop of decisions that assailed the British parliament last week is from this point of view a mixed bag. The British government's decision that a proportion of the shares in British Airways should be sold to private investors is partly a money-making operation, although the government has also promised that it will "get the Treasury off the airline's back". For the rest, it is relying on the fond belief that once private investors are represented on the board of the airline, everybody will be more vigilant in looking for a healthy economic return on capital, so that the operation of the airline as a whole will be by definition optimally efficient. That expectation is, of course, naive. The best that can be hoped for is that the airline will be as efficient as it can be with one hand tied behind its back. For in the international jungle of air transport, the monopoly rights that matter are not those of being allowed to run an airline but of being allowed to land so many times a week at this or that airport, and these rights are controlled by governments, either bilaterally or through the International Air Transport Association (IATA). If nothing is done to make this system less restrictive than at present, there is no prospect that the reorganized airline will be better able to make efficient use of the technology of air transport than the airline that now exists.

The continued neglect of technology by the other public monopolies is indeed the most serious cause of discontent with the new arrangements now in prospect. In the delivery of mails, for example, private operators are to be allowed to compete with the British Post Office only in those circumstances in which it is feasible for them to charge at least £1 for each letter handled. Unless Sir Keith Joseph, the minister responsible, has cynically calculated that the Post Office will soon be charging much the same for its ordinary mail, this change will not markedly increase the pressure on the rump of the service to use automatic sorting devices more efficiently, to wonder about electronic mail or to devise other ways of making sure that people receive their mail. Similarly, although it is high time that the iniquitous monopoly of the telecommunications part of the British Post Office on the supply of terminal equipment was ended, that will not by itself

0028-0836/80/310431-02$01.00

ensure that the rump of the monopoly will not repeat the appalling errors of the past three decades — blowing hot and cold about electronic switching equipment and so on. Sir Keith Joseph, the minister responsible, has gone no further than the decision of the United States Supreme Court in 1968 (the "Carterfone decision") that the American public (but privately financed) monopoly should accept other people's equipment at the ends of its telephone lines. What is to happen, in Britain, when quite new kinds of organisations ask permission to set up special-purpose communications networks (say, for data transmission) which the public monopoly does not wish for the time being to provide? Again, on past form at least, people will have to do without the benefits of a technology that they wish to use.

The decision that the monopoly of the Central Electricity Board on the generation of electricity should be modified is, from this standpoint, the oddest of those now announced. In the old days, the publicly owned electricity utility used to prevent people generating electricity from windmills sited in their back yards, but has recently been more accommodating. The British Government has not yet explained just what advantages its new dispensation will provide. Presumably, however, it will be possible for large manufacturing plants to be equipped with their own electrical generating plants and even to sell some of the electricity surplus to their needs to consumers nearby. (Some, no doubt, will also think of building nuclear power stations.) On the face of things, however, it is hard to conceive of circumstances in which the independent generation of electricity in bulk offers advantages over the service the national grid can provide.

The scale on which electricity users opt out of the public monopoly will therefore be a crude measure of the monopoly's failure. But again, the right to opt out will not by itself ensure that the service as a whole is technically efficient.

These issues are important because the public monopolies are often closely involved with novel or advanced technology. Not only in Britain, they are also conspicuously less innovative than they might be. The modest relaxations of the monopoly rights now announced in Britain are welcome, but their consequences will be marginal. Yet some at least of the public monopolies are here to stay. The long-term interests of their customers require more radical ways than those now devised of ensuring that they are technically adventurous, neither dogs in the manger nor stick-in-the-muds.

Subject in search of discipline?

How should the education of scientists be broadened? And how should intending scientists be helped to understand the wider implications of their professions? These are questions with which teachers have been much concerned in recent years. Increasing numbers of them have taken to devising curricula that include elements labelled "social relations of science" and the like. In recent years, science courses in higher education have been the chief beneficiaries (if that is the word) of this enrichment, but now there are signs that the habit is also catching on in the schools. It is therefore worthwhile that the Nuffield Foundation should have commissioned Sir Alec Cairncross (a wily economist once the British Treasury's chief adviser) to take a cool look at schemes for broadening the curriculum in this way which have been introduced in recent years in British higher education. His report, now published (and to be had from the Nuffield Foundation, Nuffield Lodge, Regent's Park, London NW1), should give pause to all those who think that their students will be better scientists if they can be persuaded to attend courses on the ethics of radioactive waste disposal, the social responsibility of scientists and the moral implications of genetic manipulation.

It is now more than twenty years since British universities began flirting with this means of broadening the science curriculum. One of the first courses to be established (at the University of Manchester) remains both the most ambitious and the most interesting. It constitutes a serious attempt to provide an undergraduate course with roughly equal amounts of science (physics, chemistry, physiology, etc.) and other subjects (history of science, economic history and so on). The original hope was that it would yield graduates with a capacity to work either as scientists or more generally. There are some thirty graduates a year, but the course appears not to be at the centre of school-leavers' attention, while the people who emerge from it, cultivated though they are, rarely choose to practise as scientists. They contribute, rather to the pitifully small pool of people who work in business, industry or administration who also know what science is about. At other British universities, the experience of the past few years has been more disappointing. Some of the more ambitious attempts to set up genuinely amalgamating courses have had to be abandoned. Where science courses are supplemented with a small amount of more general chat about the social relations of science, the students appear enthusiastic but the value of their marginal activities cannot be evaluated.

It is easy enough to make fun of these extra components in the science curriculum. Sometimes they are superficial. Sometimes they are downright wrong-headed. University science teachers in British universities are, however, far too quick to make these and other scornful points. Cairncross says laconically in his report that "it is a great misfortune of English education that it leads to so early and final a decision between those who study science and those who do not. This is a huge understatement. Outside the United Kingdom, it may not be fully appreciated that students entering science courses are almost always people who have been for the preceding two years rehearsing at school the studies they will follow later, and that many of them have been preparing for this curious exercise for a further three years. (Cairncross's use of the word "English" is deliberate, for the Scottish universities are more liberal in what they require of new entrants.) The result is that the majority of those who enter science degree courses have long since ceased to bother with language (their own as well as other people's), with history and economics. Is it any wonder that complaints abound that new British graduates are tongue-tied or illiterate or just plainly ignorant of the social setting in which they will have to work? And in such circumstances, can it be right to demean the attempts that university teachers make, however inadequate they may be, to compensate for the deficiencies of the educational system of which they are only a part?

The only long-term remedy must be a reorganization of the educational system as a whole, but especially at the transition between secondary schools and universities. More immediately, there is a need for ways of enriching science courses in higher education that will be more substantial and more valuable than those now in vogue. Much of what is now provided for students under this heading centres around the much talked of Promethean dilemma. Nuclear fission means nuclear reactors but also nuclear proliferation. Molecular genetics means cheaper ways of making interferon (perhaps) but also (possibly) ways of undermining the natural course of evolution. The list of topics that make grist for this mill is endless. As ingredients of serious teaching, however, they are topics replete with pedagogical problems. The information available is incomplete. Books do not exist. The capacity of students maimed by their school education to grapple with the formless issues raised by such questions is quite inadequate. Their teachers are all too often bent on grinding other axes — political, ideological or religious. The Cairncross report has drawn attention to the need for some enrichment of science courses but has also spelled out the limitations of what is at present being taught. Has not the time now come for more serious attempts to make good the deficiencies of the British educational system? Science students might usefully be helped to keep up with a foreign language, to learn more serious economics or to discover in reorganized teaching laboratories that science is not cut and dried, as the textbooks have it, but as full of intellectual conundrums as any study of the humanities.

Proliferation a test of nerve in Congress

Washington

United States non-proliferation policy is facing its toughest domestic test for almost a decade, as Congress decides whether or not to veto President Carter's decision to allow the further export of nuclear fuel to the Tarapur nuclear power plant in India. The Nuclear Regulatory Commission (NRC) has already ruled that the export of 38 tons of enriched uranium requested by India would violate the Nuclear Non-Proliferation Act of 1978 (NNPA). The act forbids the export of fuel or technology to countries which have not adopted international safeguards on all their nuclear facilities.

President Carter has since overruled the NRC on the grounds that denying India the fuel would seriously prejudice political and economic relationships with India.

The dispute has brought to a head not only strategic differences between Congress and the State Department but also tensions between the United States and India rampant ever since India exploded a nuclear device in 1974.

Mrs Gandhi's return to power last year, and her subsequent firm refusal to eschew the possibility of India developing its own nuclear weapons, put an end to hopes that agreement could be reached. Now the Administration is trying to persuade Congress that political tensions in South Asia, and the consequent advantage of remaining on good terms with India, should override more narrowly focused policies.

The Administration and its critics find themselves on opposite sides of a narrow dividing line. The NRC, for example, taking a strict interpretation of the NNPA, refused to grant an export licence partly on the grounds that the shipment of the fuel would take place more than two years after the NNPA had been signed, the grace period for compliance. But the Administration points out that the request had been received in 1977; that the delays were the result of US indecision for which India should not be penalized; and that subsequent licence requests will be treated differently.

Then there is the question of whether, if the export licence is granted, it will be used as a precedent by other countries — for example Argentina, Brazil, South Africa and Iraq — to claim exemption from the act. Administration critics are standing firm on this point. The Administration however disagrees.

Another question is whether denying the fuel to India would violate the 1963 agreement, under which the United States guaranteed to provide fuel supplies to Tarapur for 30 years and, if so, whether India would then feel free to ignore other restrictions in the agreement.

"If the US breaks the agreement, then India can do what it wants, including using plutonium from the fuel rods to make nuclear weapons", Dr Betty Lall of the US State Department said at a meeting organized by the Arms Control Association in Washington last week. Others, however, argue that India has long been aware that the obligation of the United States to supply fuel is contingent on India's compliance with US licensing requirements, however these may change.

Strict non-proliferationists favour the big stick. "Congress should draw a clear line and say 'no' to further nuclear commerce with India until the Indian government accepts international safeguards on all its nuclear activities", said a statement issued last week by several public interest groups, including the Natural Resources Defense Council and the Union of Concerned Scientists. The Administration still prefers to use softer methods, arguing that in the long run non-proliferation objectives have a better chance of success through dialogue rather than confrontation.

In Congress, which can overturn the President's decision if both houses agree by a simple majority before 12 September, the issue is in the balance. In the House of Representatives, feelings against the export licence are running high; a majority of members of the Foreign Affairs Committee, for example, have signed a statement calling the decision to grant the licence "a dangerous mistake".

In the Senate, there is also some strong opposition, headed by Senator John Glenn, chairman of the Government Affairs Committee's Energy and Nuclear Proliferation Subcommittee.

In an election year, however, political dynamics could prove crucial. A certain amount of the opposition seems to have been stimulated by a desire to embarrass the Administration. The House committee's statement opposing the licences, for example, was supported by two-thirds of the committee's Democrats, but three-quarters of its Republicans.

The Administration is at present trying to convince a sufficient number of Senate Democrats of the value of treating the licence as a special case, with a promise of further negotiation towards a definite outcome one way or the other. Given that both houses have to concur in any disapproval, the Senate's refusal to do so would be sufficient to allow the export to proceed.

David Dickson

Plagiarism strikes again

The spate of publications with which Dr E.A. Alsabti has scattered the scientific literature in the past few years now seems destined to be followed by a similar spate of retractions. The accompanying letter (see page 437) from Dr Akiro Shishido, Managing Editor of the *Japanese Journal of Medical Science and Biology (JJMSB)*, says that a notice will appear in the August issue of the journal explaining that the editorial board now considers that Alsabti's contribution to that journal describes research originally carried out by Dr Daniel Wierda and Dr T L Pazdernick, first published in the *European Journal of Cancer*.

It is not yet known how many of the 23 papers listed in *Index Medicus* under Dr Alsabti's name are likely also to fall under a cloud. It is, however, known that Alsabti's paper "Lymphocyte transformation in patients with breast cancer", published in the *Japanese Journal of Experimental Medicine* (49, 101; 1979) is virtually identical with "The effects of surgery on lymphocyte transformation in patients with breast cancer", published by Dr Sylvia M. Watkins in *Clinical and Experimental Immunology* (14, 69; 1973).

As in other papers published under his name, Dr Alsabti acknowledges his gratitude to His Royal Highness Crown Prince Hassan for "financial support and encouragement". To Dr Watkins's original list of references is added in the pirated version the reference "Alsabti, E.A., Lymphocyte transformation in bladder carcinoma, *J. Clin. Hematol. Oncol.* (1978), in press".

Meanwhile, an apparently unrelated case of plagiarism involving another Jordanian scientist, has come to light. Dr K.O. Kutschke, of the Canadian National Research Council, who is Editor of the *Canadian Journal of Chemistry*, says that in February 1978 his journal received for publication a manuscript called "Influence of electric charges on the corrosion of metals" a paper previously published by a group of Swedish authors — J.A. Hedvall, Nils-Gosta Vannerberg and P.O. Blomqvist — in *Acta chemica scandinavica* (22, 363; 1968).

In that case, Dr Kutschke explained this week, the plagiarized manuscript was not accepted for publication because the list of references included one to the Swedish group whose work had otherwise been pirated. Only curiosity, Dr Kutschke explained, prompted him to look up the original publication, whereupon he recognized the identity of the two papers.

On that occasion, it appears, the Jordanian author (whose name is being withheld) gave an address at a university in the eastern United States, but had given the University of Amman as the location of his research. On complaint from Dr Kutschke, the visiting appointment of the scientist was terminated.

US budgets

End in sight?

Washington

"The best we can hope for is to try to salvage a disaster and just make it a very bad year," This is how one Washington lobbyist last week summed up the prospects for next year's research budget as Congress continued, at the President's request, to chip away at the budget.

Since the beginning of the year, the prospects for science have changed substantially. When President Carter delivered his original request to Congress in January, he proposed a 13 per cent growth for basic research, about 3 per cent above the anticipated rate of inflation.

In March, after what the President's Science Advisor Dr Frank Press has described as the "traumatic experience" of a review designed to cut public expenditure and balance the overall budget, the increase was reduced to 8 per cent, barely enough to keep pace with inflation. Now even this figure is looking optimistic.

As far as congressional authorization committees (which approve programmes for funding) are concerned, there have been relatively few problems in meeting the President's requests for cuts and in some cases even greater cuts have been made.

Both houses of Congress have agreed on an authorization bill for the National Aeronautics and Space Administration (NASA) which, at a total of $5,600 million, is $70 million above the revised request for the agency. The two houses agreed in particular to restore funding for some of the long-range support programmes that had been cut earlier.

Similarly the National Science Foundation has so far done relatively well. The House of Representatives and the Senate have passed very different authorization bills, with the latter incorporating provisions for a major "women in science" programme, and this could involve some redistribution of funds within the agency. But the total in each case is at or above the Administration's $1,074 million request.

But in the appropriations committees — which decide how the federal budget is to be allocated — it is a different story. Most appropriations bills have still to be acted on; but in their determination to pare the federal budget wherever possible, several appropriations committees have taken basic research as one of their targets.

The worst affected so far has been the Department of Energy, which supports a large proportion of the physics programme. The department's request for energy research activities, trimmed slightly by authorization committees, was recommended for a 12 per cent cut.

This proposal stimulated intense lobbying by universities and research laboratories, as well as the Office of Science and Technology Policy, and when the budget was debated on the floor of the House, an amendment proposed by Mr Don Fuqua, chairman of the House Science and Technology Committee, to restore most of this cut was agreed by a wide margin.

Furthermore the intense effort involved in protecting the energy research budget is being taken as an indicator of the strength with which scientists will increasingly have to fight to retain their share of the budget pie in other areas as well.

As far as other agencies are concerned, no action has yet been taken by Congress on the National Institutes of Health budget, which for the most part does not require separate authorization. Congress is unlikely to cut back on the Administration's request for a 5.2 per cent increase to $3,350 million; but neither is it likely to award the generous increase of previous years.

Some concern is being expressed about the Administration's decision to cut back heavily on the number of training grants. These may be traded in committee against the proposal to maintain at 5,000 the number of new and competing investigator-initiated research grants.

The House has authorized a total of $627 million for basic research in the Department of Defense, and the Senate has authorized a comparable figure. This is lower than the $644 million in the Administration's revised budget request, but still represents a real growth of 8 per cent over 1980 funding, far higher than for any other research agency. Also, for the third year in a row, the House appropriations committee has proposed cutting $30 million allocated to a competitive grants programme to the Department of Agriculture, in favour of support for programmed research support through designated land-grant colleges. As in previous years, this is likely to be partially restored in the Senate.

Despite protests that reducing the Environmental Protection Agency's research activities will restrict its effectiveness, the House has authorized a budget 3 per cent lower than the Administration had requested for research, from $413 million to $396 million.

David Dickson

International laboratory

Danes turn soft

Danish biologists are preparing to make a strong recommendation to their Minister of Education next month that Denmark should continue to belong to the European Molecular Biology Laboratory in Heidelberg. Their previous report on the question of continued membership of EMBL was lukewarm, and persuaded a government advisory committee to decide that Denmark should rescind the EMBL treaty from mid-1981 (*Nature*, 26 June).

That report, now in circulation, recommended that EMBL should increase the number of permanent scientific posts (there is at present only one) and have fewer short-term contracts (now about 50); there should be more detailed research plans than hitherto; and EMBL should submit its plans for the next five-year period (1985–90) to Denmark in time for a "well-founded" decision on membership.

Before then, says the report, the research councils should "consider whether it is desirable in principle that Denmark should participate in building up European laboratories in fields where the proportions of the problems and investment prevent attempts to establish national solutions or international collaboration in utilizing national laboratories" — thus implying that in fact EMBL was un-necessary.

EMBL's recruitment policy appears to be based in part on the assumption that the best molecular biologists are young, but the report concludes that these younger scientists require "a well-established environment with firm scientific traditions and with older experienced scientists" before they can achieve important results. Hence, the working party concluded, it is not possible to build up a good laboratory if nearly all the scientific staff are young postdoctoral fellows on short-term contracts.

Moreover "it must be expected that small working groups of scientists whose contracts are reviewed every three years will chiefly choose problems ensuring results within a short period, but on the other hand not offering great possibilities of all-important results".

The report also questioned the research management of EMBL, saying that "it does not appear very satisfactory that the individual working groups are not asked to submit fairly specific plans for their work and that the decision-making bodies, including among others the EMBL council, are given such a vague basis for making decisions". The research groups are also too small, the report considered, being no larger than those at national laboratories.

On the positive side, the report made special mention of the groups on data processing and the utilization of computers; this part of EMBL's activities was "very promising".

Nevertheless, it is felt strongly at EMBL that it is too soon to make a proper assessment of the laboratory's achievement. The laboratory was established in its present permanent headquarters in Heidelberg in 1978, and many of the staff were recruited then. The constitution of EMBL, modelled on that of the European sub-nuclear physics organization CERN, says that no person may apply for tenure until he or she has worked at EMBL for three years. Few have reached that position. The laboratory's director, Sir John Kendrew, says that there should be a marked increase in the number of tenured posts in a few years.

0028-0836/80/310434-02$01.00

EMBL acts as a service centre, with P3 and P4 laboratories, outstations using synchrotron light at Hamburg and neutrons at Grenoble, and instrumentation and computer groups at Heidelberg. So it is necessary, EMBL thinking goes, for the staff scientists concerned to pursue the most up to date lines of research, to keep them in touch with the immediate needs of the scientific community. Thus flexibility is a prime goal, and short-term contracts and small groups provide it.

The Danish meeting on EMBL towards the end of next month will consist not only of biologists. There will be representatives of the research councils for natural science, agriculture and medicine, just as there were on the original working party that produced the original report, so it is difficult to predict the outcome. However, whereas that report recommended that the government should foot the £120,000 EMBL bill, the new report may suggest that a single research council takes the subscription into its own budget. An obstacle may be that at present no Danish biologist works at EMBL, although a computer scientist and some ancillary staff do so.

Robert Walgate

Scientific instruments

Nature spin-off

The colour filters supplied with the 3 April issue of *Nature* have turned out to have an unexpected use. In some laboratories, it seems that the filters are superior to others on the market in the contrast they provide.

Dr R. Zeki of University College London, whose article on colour vision prompted the distribution of the set of three colour filters (*Nature* **284**, 412–421; 1980), said last week that he had received a number of comments on the value of the filters, which he had passed on to Polaroid, the manufacturers.

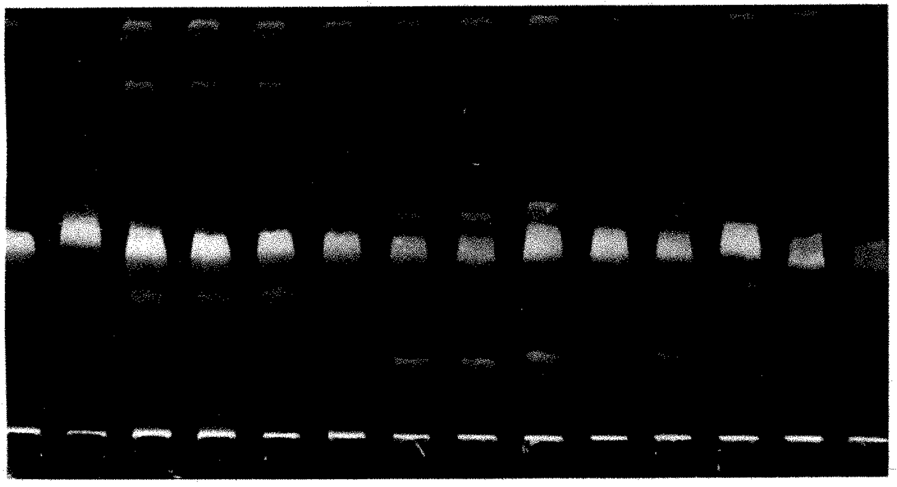
One of those who have found the red filter of particular value is Mr David Owen, a graduate student in the laboratory of Dr C. Harwood, of the University of Newcastle upon Tyne. One series of experiments is to identify extrachromosomal genetic elements in bacteria. The procedure is to separate DNA molecules by gel electrophoresis and to make molecules of different classes apparent by treating the gel with a fluorescent dye that binds to DNA.

Mr Owen explained last week that he had had some trouble finding a suitable filter for photographing the pattern of visible light stimulated by ultraviolet radiation, so he had tried "Dr Zeki's red filter".

"To our surprise", he said, "the resulting photographs were far superior . . . in that the DNA bands were clearly visible against a black background". The accompanying illustration is an example of such a photograph, in which the bright central band represents chromosomal DNA and the sidebands DNA from plasmids.

No agreed explanation of this result is available, although it seems likely that the narrowness of the transmission band of the red filter may account for the sharp contrast.

The Polarioid Corporation has apparently developed these filters largely for research purposes. A spokesman for the company said last week that filters with narrow transmission bands should be available from more conventional sources, but that the company might reconsider its decision that its filters would not be put on the market if the demand for them turned out to be sufficient.



High-energy physics

Trouble ahead

Washington

As if bleak budget prospects were not enough, high-energy physicists in the United States are facing another delicate question — what to do about continued difficulties in the development of superconducting magnets for the 400 × 400 GeV accelerator (ISABELLE) now under construction at the Brookhaven National Laboratory on Long Island.

The official line is that a substantial effort must be maintained to resolve the difficulties, even if this means cutting further into the laboratory's operating funds for experiments and bringing in help from across the physics community.

But attention is now also being paid to what have been called "graceful failure modes". At best this could mean lowering the maximum energy of each of the two intersecting beams of protons from 400 to, say, 300 GeV; at worst, it could mean cutting losses and scrapping the whole project.

Given the continued risk of failure in the ambitious superconducting magnet programmes at Brookhaven and at Fermilab some physicists are suggesting that there is a need to broaden the base of the whole nuclear physics programme — in particular, by diverting resources to electron–positron machines directly competitive with Europe's proposed LEP in Geneva.

ISABELLE is scheduled for completion in 1986, when it will be able to explore the physics of proton–proton interactions at energies an order of magnitude higher than those which can be reached on comparable existing machines.

It had always been anticipated that developing superconducting magnets to deliver the required high fields would be difficult. But given the success of early prototype magnets, nobody realized how great the difficulties were likely to be.

ISABELLE will use 1.7-m quadrupole and 5-m dipole magnets, the former operating with a gradient of 6 kG cm^{-1}, the latter at a field strength of 50 kG. So far the quadrupoles have operated with no difficulty. But major problems have arisen with the dipoles, which have not reached either the planned maximum fields or field quality — and of which more than 700 will eventually be required.

Brookhaven has mounted an intense research and development programme to pinpoint the difficulty. The number of people working on the magnets has been increased almost four-fold over the past two years. And outside help has also been sought from the Massachusetts Institute of Technology's magnet laboratory and the Lawrence Berkeley Laboratory.

The problem is one of engineering rather than theory — that of keeping the magnets in a superconducting mode while building up the required field. Although Brookhaven scientists are optimistic that an answer will eventually be found, they admit that they are still uncertain about precisely what is going wrong.

ISABELLE's difficulties were a major focus of attention when a sub-panel of the Department of Energy's High-Energy Physics Advisory Panel met in Woods Hole, Massachusetts, last month to report on the current status and prospects of US high- energy physics.

Considerable discussion took place about whether, in the light of the "serious and unexpected setbacks" to ISABELLE's construction programmes, the specifications for its performance should be revised downwards. If each beam only

0028-0836/80/310435-02$01.00

operated in the 60 to 300 GeV range, it was argued, this would still be sufficient to produce a large amount of important physics, even without the possibility of investigating collision energies between 600 and 800 GeV.

In the end, the panel refrained from making any such formal proposal. But it did state that current information from Brookhaven was insufficient to assess whether the pilot production of the dipoles was likely to begin in mid-1981 as planned. "If it is not, the ISABELLE project will encounter significant delays", the sub-panel reported.

Brookhaven scientists have been heartened by the report's recommendation that the successful completion of ISABELLE — including any necessary R and D funding — should remain a top priority of the Department of Energy, as well as becoming "the responsibility of the entire national community".

At the same time, however, others are warning of the dangers of failure in what has become recognized, both at Brookhaven and to a lesser extent at Fermilab, as a high-risk/high-benefit programme still facing large engineering uncertainties.

"The US high-energy programme is now highly dependent on the successful solution of such engineering problems and I would recommend greater diversification to reduce that dependence", Dr Wolfgang Panofsky, director of the Stanford Linear Accelerator Centre (SLAC), told a meeting held in Washington last week to celebrate 50 years of particle accelerator construction.

SLAC is promoting its own proposal, developed by Dr Burton Richter, to construct a machine which would collide bunches of electrons and positrons, passed in tandem down the linear accelerator and then in separate directions around a ring at the end.

Dr Richter is pushing for early funding of the so-called Stanford Linear Collier (SLC), attempting to finesse experiments on CERN's LEP and claim discovery of the intermediate vector boson. The Woods Hole sub-panel examined the proposal closely, describing it as a "fascinating and challenging new departure in accelerator technology". However, the sub-panel refused to endorse SLC for immediate funding. In particular, questions were raised about whether SLC's predicted luminosity would be sufficient to make it truly competitive with LEP, which will also have a larger energy range.

David Dickson

Dead Sea

Coming to life

Theodore Herzl's dream of a canal from the Mediterranean to the Dead Sea is at last a cost-effective proposal, the Israeli government was informed last week. Use of the 400 m drop between the two seas to generate hydroelectricity could now match the cheapest generation from fossil fuel stations, according to a government-appointed working party chaired by Professor Yuval Neeman of Tel Aviv University.

Assuming an initial investment of $800 million, the canal with a cascade of hydroelectric installations would, said Dr Neeman, pay for itself in 30 years, simply from the 100–150 MW of hydroelectricity produced. In addition, the canal could provide the sites for nuclear power stations which cannot be accommodated along the crowded Mediterranean coast. (That between Ashquelon and Ashdod has been found to be earthquake-prone.) A thermal power station using the water from the canal but fired by local oil shale deposits could also be built at Ein Bokek.

Ecologically, the main benefit of the canal would be to replenish the waters of the Dead Sea. The only natural feeder of the Dead Sea is the lower Jordan, which draws its water from the Sea of Galilee and from its east bank tributary, the Yarmuk. The Sea of Galilee is however the source of water for virtually the whole country, while the Jordanians have almost completed a major irrigation project involving the diversion of the Yarmuk into the East Ghor Canal. When this is complete, the lower Jordan will shrink even further to a mere 200 million m^3 annually, mostly return flow from irrigation.

Evaporation loss from the Dead Sea is 1,200 m^3 a year, so that the sea has shrunk considerably — the S'dom potash works have become stranded and a special channel has been built to pump brine to the evaporation pans. By November 1978, in a Knesset debate on the proposed canal, both government and opposition were agreed that any further shrinkage could bring irreversible ecological damage.

Then came the drought of 1979. By September, the Dead Sea had split in two at the narrowest point (some 3 km across) and, according to Shlomo Drori of the Dead Sea Development Company, there was a dry plain some 12 km long between the northern part of the Sea and the sourthern fragment, then split into a number of pools. Meanwhile, plans were going ahead to use the Dead Sea for generating electricity on the "solar pond" principle, based on the temperature difference developed in brines exposed to sunlight where the density gradient is too great to allow convection mixing. The first solar pond power station was opened at Ein Bokek in December 1979.

The ecological advantages of the proposed canal are admitted by all concerned. Until now, they have been the paramount concern, with hydroelectricity considered rather as a valuable spin-off. As late as the Knesset debate of 1978 on the canal, Energy Minister Yitzak Moda'i stressed that electricity could still be generated more cheaply from fossil fuels. Professor Neeman's estimates, for the first time, reverse this situation. However, with the Israeli economy in a state of crisis — inflation is now running at 130 per cent per annum — it is by no means clear whether the government could raise the necessary $800 million.

Vera Rich

Biogenetic hormones

Insulin trial

Eli Lilley, the US pharmaceutical company, has taken another step along the road to producing human insulin on a commercial scale. Last week, it announced a $40 million programme to build two plants at its factories at Speke in the United Kingdom and Indianapolis in the United States for the commercial production of human insulin from genetically engineered bacteria. Ultimately, human insulin produced in this way should be much cheaper than the insulin currently extracted from pig and beef pancreas.

Full-scale production, however, is still a few years off. First, any problems cropping up with manufacture on a large scale will have to be resolved and extensive clinical trials have to be done. The first trials with insulin from the company's US laboratories began on healthy people earlier this month at Guy's Hospital in London. Initially at least, the trials are being conducted in the United Kingdom to avoid delay in getting permission from the Food and Drug Administration for trials in the United States.

The tests at Guy's Hospital mark the first time that any recombinant DNA hormone has been injected into humans. Preliminary tests to measure the effectiveness of the new insulin in reducing the blood glucose level of healthy people and their immune response to it should be complete in a few weeks. By the autumn, tests should begin on diabetics. It is expected that human insulin will be tolerated without the production of antibodies. Some diabetics do produce antibodies to insulin derived from pigs and cattle. One possible advantage of human insulin is that it will minimize or eliminate the risk to middle-aged diabetics of eye and liver damage.

The techniques Eli Lilly are using are those developed by Genentech (which will get a cut of the profits) whereby synthetic genes for the A and B insulin chains are put into an *Escherichia coli* plasmid. The bacteria expressing the two genes are fermented separately, killed and broken up to extract the A and B chains. The chains are then chemically combined to produce human insulin. So far, no method of getting genetically engineered bacteria to excrete their products has been found, but Eli Lilly claims that its method of extraction has produced pure insulin free from bacterial fragments.

The production of human insulin from recombinant DNA is more complicated

0028-0836/80/310436-02$01.00

than the production of antibiotics, where bacteria excrete the product. Nevertheless, it should prove far less costly than the current methods of extracting porcine and beef insulin. The cost of human insulin to the consumer, however, will depend on its penetration into the market and competition from other companies. When costs will come down is still uncertain, especially since Lilly cannot even say yet when it will be in a position to start commercial production.

Judy Redfearn

Environmental protection

Bulgaria ahead

Bulgaria is to spend more than 1,000 million lev (£500 million) on environmental protection during the next five years, President Todor Zhivkov announced recently. He was addressing a meeting held to celebrate the 80th anniversary of the Bulgarian National Agricultural Union.

In Bulgaria, President Zhivkov said, the Constitution makes environmental protection a nationwide matter, dealt with by specially created bodies at all levels of state management. Ecological problems are a compulsory subject in higher educational establishments and throughout the educational system. Special organizations have been set up to deal with erosion and bring reclaimed or neglected soil back into use. Bulgaria, he said, is a world leader in reafforestation, planting 400–500 decares per year.

Zhivkov unequivocally rejected the view of "bourgeois ideologists" who maintain that the violation of the established ecological balance is the result of the modern scientific–technological revolution. On the contrary, he said, this revolution is essentially "our greatest ally in harmonizing relations between society and nature". Although the published data on natural resources are so "very alarming", Zhivkov reiterated that "being aware of the danger is a signal for action, not a cause for pessimism".

Bulgaria is not rich in natural resources, and before the Second World War it was the most backward but one of the European countries (Albania ranked last). Now, however, Zhivkov claimed his country is a "developed industrial agrarian country", with an agriculture capable of feeding "one and a half Bulgarias" and a target of "two Bulgarias" in 1985. Referring to his African tour of two years ago, Zhivkov suggested that if Nigeria, Angola, Ethiopia and Mozambique could apply Bulgarian-type organization and technology to their agriculture, they too would be producing surpluses. Ethiopia, in particular, he said, has especially good soil which could not only support the present population but also "feed a neighbouring state".

Vera Rich

One journal disowns plagiarism

Sir — Your recent article "An Outbreak of Piracy in the Literature" makes it apparent that the *Japanese Journal of Medical Science and Biology* (*JJMSB*) was a victim of an outbreak of paper piracy by a person called Dr A. Alsabti. I am writing this letter on behalf of the Editorial Board of *JJMSB* to make our position clear. Our unfortunate experience shows how difficult it is to be aware of dastardly and minutely planned piracy of papers.

We first received this manuscript entitled "Effect of Platinum Compounds on Murine Lymphocyte Mitogenesis" on 20 November 1978 from the stated address — Department of Developmental Therapeutics, M.D. Anderson Hospital and Tumor Institute, University of Texas System Cancer Center. After careful reviewing, the manuscript was sent back on 25 December 1978 with referees' comments to Dr Alsabti at his changed address (7520 Brompton Blvd, No. 736, Houston, Texas 77025). The revised manuscript was received in our editorial office on 16 January 1979, but it was still not satisfactory for publication and it was again sent back to him on 12 February. The final revision was received on 2 March, and the editorial board accepted it for publication on 12 April 1979. On 11 May 1979, a galley proof was sent to him and he asked us to send any further correspondence to his new address — 7511 Teal Run, Houston, Texas 77071. On 11 June 1979 the paper was finally published in the April issue of our journal (*Japan. J. med. Sci. Biol.* 32, 53–65, 1979).

The editing of Dr Alsabti's paper therefore followed quite a normal course. However, it may be important to add here that we received three other manuscripts from him at around the same time. These were:

(1) Effects of tumor cell culture supernatants from various tumor cell line and normal tissues on macrophages.

(2) Tumor dormancy established in DBA/2 mice with P815Y mastocytoma cell lines.

(3) Tumor dormant state established in DBA/2 mice by sinecomitant immunization and challenge with lymphoma cells: Role of endogenous viruses in its mechanism.

All these papers were rejected.

Almost one year later we received a shocking letter from Dr D. Wierda of the Chemical Industry Institute of Toxicology, North Carolina, USA. His letter told us an almost unbelievable fact, that the paper entitled "Suppression of Spleen Lymphocyte Mitogenesis in Mice Injected with Platinum Compounds" contributed by himself and Dr T.L. Pazdernik to the *European Journal of Cancer* (15, 1013-1023; 1979) is identical to Dr Alsabti's "Effect of Platinum Compounds on Murine Lymphocyte Mitogenesis" published in our journal. Dr Wierda enclosed copies of proofs demonstrating the authenticity of his work and suspected that their manuscript was probably pirated during the process of review for the *European Journal of Cancer*. He added that their manuscript was received on 10 October 1978, accepted for publication on 5 January 1979 and published in the August 1979 issue of *European Journal of Cancer*.

In urgent response to Dr Wierda's letter I wrote to Dr Alsabti on 9 June 1980 to ask for an explanation of this unusual situation, specifying a time limit of 15 July, 1980. This letter was sent to his last corresponding address. I also asked Dr Freireich, head of the Department of Developmental Therapeutics, M.D. Anderson Hospital and Tumor Institute, to forward my letter to Dr Alsabti.

On 30 June 1980 Dr Freireich wrote to tell me that he could not forward my letter to Dr Alsabti as his address was unknown. However, he proved that Dr Alsabti had never conducted any scientific research worthy of publication, either in the laboratory or clinic, during his 7 months' stay in his department, and suggested further that his large number of publications are all either outright plagiarisms or were totally imaginary.

We have so far received no reply from Dr Alsabti, although the deadline we gave him has already expired. Furthermore, Dr Wierda notified me on 21 July of the article "Jordanian Denies He Pirated Papers" (in the 11 July issue of *Science*) in which Dr Alsabti claimed that he had not published the paper in *JJMSB*. We therefore decided to retract Dr Alsabti's paper to protect the characters of Drs D. Wierda and T.L. Pazdernik. *Japanese Journal of Medical Science and Biology* hereby announces retraction of his paper from our journal. Our "Retraction Notice" will appear in the coming August issue of *Japan. J. med. Sci. Biol.* 33 (4), 1980 as follows:

> **The Editorial Board of the** ***Japanese Journal of Medical Sciences and Biology*** here announces retraction of the following paper from the Journal:
>
> "Effect of Platinum Compounds on Murine Lymphocyte Mitogenesis" by E.A.K. Alsabti, O.N. Ghalib, and M.H. Salem. *Japan. J. med. Sci. Biol.* 32(2), 53-65, 1979.
>
> Judging from several lines of evidence (1–5), this work must have been authentically carried out by Drs D. Wierda, and T.L. Pazdernik, whose paper was almost simultaneously published in the *Eur. J. Cancer* (15 (8), 1013-1023, 1979) under the title of "Suppression of Spleen Lymphocyte Mitogenesis in Mice Injected with Platinum Compounds".
>
> 1. Letters from Drs D. Wierda & T L. Pazdernik
> 2. Correspondence to the Head of Department of Developmental Therapeutics, M D. Anderson Hospital and Tumor Institute, the University of Texas System Cancer Center, with which Dr Alsabti was affiliated.

CORRESPONDENCE

Biologists mis-cite

SIR,—The importance of checking original sources is well recognized, but doing so becomes harder as the literature grows. I describe here an attempt at quantification of the reliability of citations.

Since familiarity with the cited literature is essential, I selected 28 of my own, not faultless, publications and 136 related publications by other authors. These deal mostly with snail physiology and with ionic and acid–base regulation in animals.

Errors found include misquotation of quantitative data, confusion of hypothesis with fact, of crustaceans with molluscs, of one species with another and of experimental variations with natural variations; also invention, simplification and statements contrary to what was demonstrated. Along with 33 such errors occurring in 29 citing publications are 11 instances of correct information being used with a wrong reference, or with none. Some of the correct citations were almost too simple to be capable of being wrong (such as "Recent investigations include that of. . ."). Such citations can be useful, but at least 12 citing publications include apparently pointless references to the cited publications or, more important, omit others known to the authors that are clearly of greater relevance.

There are 3 instances of references being given in the text, but not in the bibliography, and 4 mistakes of the opposite kind. Of the 205 entries in the 136 bibliographies, 14 contain mistakes that could hinder, though not prevent, the location of articles (wrong page number, year or publisher). Other, mostly trivial slips, including altered punctuation and omission of words or letters, occur in a further 55 references, sometimes several in each. 58 of the bibliographies contain at least one error. Most errors are in titles, which, in accordance with editorial policies, many of the other references do not include.

Fifty-six per cent of the citing publications contained at least one of the above faults. Especially in bibliographies, slips must often be due to hasty note-taking before citation is specifically envisaged; the original lack of care may then be forgotten during preparation of the manuscript. Blanchard[1], in a letter since misrepresented in print, has described (I think) how he found that, of 6 references to a particular paper in chemistry, 4 contained errors in volume or page number. The assessment concerning the appropriateness of some of the citations is subjective, but is a reminder that other factors may influence an author's choice of citations than the interests of the reader[2,3].

Chemical warfare

SIR, — Your leading article of 10 July makes the point that verification of an agreement to ban chemical weapons, which was never easy, becomes even more difficult in relation to production of the components of binary chemical munitions. An alternative approach, assuming that an agreement had been reached, might be to monitor the stockpiling and/or issue of protective clothing (especially gas masks) for military or civilian use, and any military exercises in such clothing. If the major powers had entered into the agreement in good faith there would be no need for clothing capable of protecting against nerve agents, and certainly not of military exercises by troops wearing it. It is very unlikely that a country intending to use chemical weapons could do so without making preparations to protect its own personnel on a scale which would escape detection by the intelligence organizations of the other countries which were party to the agreement. From an agreed date, after sufficient countries had ratified the agreement, all clothing for protection against nerve gases would go into bonded stores, and any military exercises involving such clothing would be forbidden.

If the argument is valid, such an indirect monitoring should suffice to detect any intention to infringe the agreement — even though the most important factor remains confidence that in no country do chemical weapons serve its people's real interests.

Budapest disclaimer

SIR,—Your article by Vera Rich (5 June) refers to an interview with me at the Budapest International Fair. Having studied the contents of the article, I must state with the utmost regret that it lacks the desired accuracy. I therefore feel it appropriate to correct the article at some points.

At the beginning of our talk I conveyed to Miss Rich that as the Hungarian Academy of Sciences was not a participant at the 1980 Budapest International Fair, academic research was not being presented at this event. I explained that at the exhibition, in accordance with Hungarian science policy, attention was drawn to scientific results serving practical benefits and achieved at universities and other institutes of higher education within the sphere of the Ministry of Education. Furthermore, I emphasized that great effort has been and is still exercised by the Ministry of Education towards putting research results into practice as soon as possible, thus promoting progress in our country. Universities agree with us in setting these goals, as was confirmed by the fair. I continued by emphasizing the importance of the demand made by users in connection with practical research, but I did not say "We make what foreigners want to buy".

In the course of the ensuing discussion, Miss Rich raised the question of how our scientists react to research being directed towards practical purposes. In answer, I said that the great majority seems to exercise the necessary goodwill in this respect but that not everybody is fit to fulfill the demands required by practical research.

In this sense, the statement attributed to me in the article that I do not agree with the pragmatic orientation of our research policy is incorrect; what I said was that the intention of the authorities of giving a pragmatic orientation to research policy causes some of our scientists anxiety. Accordingly I cannot accept, being myself also an advocate of emphasizing the need for practical research, the statement attributed to me that "It is a pragmatic solution to direct more scientists to industry and not good for research".

I do not know which facts led Miss Rich to the conclusion that we place less emphasis on the socialist virtue of the development of scientific research in Hungary. I am convinced that this could only be a misunderstanding.

GYÖRGY PÁRIS

Hungary

VERA RICH writes: I should feel most distressed if misunderstandings cloud Mr Paris's recollections of what I remember as a most friendly and open conversation. Although the Academy of Sciences was not, however, exhibiting this year, the pavilion was clearly marked on the official plan as housing, *inter alia*, the Academy. If, because of interpretation difficulties, I have inadvertently confused views that Mr Paris put forward on his own behalf with views he quoted from scientists who disagree with him, I would wish to point out, in tendering him my apologies, that it is by no means common to meet an official spokesman who is ready both to put his own view and to quote his opponents.

Adjectival concerns

SIR, — I suggest that we generalize the convention implicit in the naming of the Earth's year. We suffer from a surfeit of planetary adjectives — should one speak of the mercuric or mercurial year, the saturnian, saturnine or saturnalian? Can one, in a reputable journal, mention the venereal or uranal year? How much simpler to name the planetary years *ymer*, *yven*, *year*, *ymar*, *yjup*, *ysat*, *yura*, *ynep* and *yplu*! How fortunate that y is both vowel and consonant!

Unsplit infinitives

Dr Glascock from Reading's an erudite man,
Full of wit and grammatical zeal;
In *Nature*[1] this May, he asked for a ban
On the customary scientists' spiel.

Speak active, not passive, Dr Glascock
  advised;
Attach participles where they belong.
Above all be sure that you are apprised
Of how syntax matters in song.

Alas (and alack), as they say in some places,
The verses we liked but we shortened the
  missive.
One way and another, the result was red faces;
Nature had split one of Glascock's infinitives!

Much worse was to come, to readers' chagrin.
Good Garton noticed the error[2]
And promptly blamed Glascock, not *Nature*,
  for sin.
What anger, what shock and what horror!

Nature now tenders both Garston and
  Glascock
Regrets for its error and shame;
What verbs should be split is for authors to
  say
It is we who shoulder the blame.

The moral's quite clear, as we know too well.
The jargon leaves much to desire.
But do not rely upon rhymed doggerel
And to Belloc do not aspire.

NEWS AND VIEWS

Solar size variation

from David W. Hughes

Is the sun getting bigger, getting smaller or staying about the same size? Astronomers are divided as to the answer, some say it is shrinking, some say it remains constant.

John A. Eddy, of the High Altitude Observatory, Boulder, Colorado and Aram A. Boornazian, a mathematician with S. Ross and Co., Boston favour the shrinking Sun, and talk in terms of a contraction of about 0.1% per century. Their results were published in *The American Astronomical Society Bulletin* **11**, 437; 1979. A recent paper by Irwin Shapiro of the Massachusetts Institute of Technology contains results which disagree with those of Eddy and Boornazian. Shapiro concludes that the change is less than 0.03% per century.

Eddy and Boornazian used data obtained at the Royal Greenwich Observatory. At Greenwich the precise position of the centre of the Sun, with respect to the stars, was measured on every clear day at noon. The times at which the limbs of the Sun crossed a fixed meridian wire were recorded. Knowing the Earth's rotation rate and the Earth's orbit enables the time difference between the two crossings to be converted into a solar horizontal diameter. Values for this quantity are shown in Fig. 1.

The vertical solar diameter has also been measured since 1836 using a micrometer screw at the eyepiece. However inaccuracies in the mechanical screw and problems of atmospheric refraction make the vertical readings less accurate than the horizontal ones. The decrease in apparent Sun size as a function of time can be easily seen in the Greenwich data.

Sun transit measurements from the Naval Observatory, Washington, DC, were also analysed and the same decreasing trend was noticed. There was, though, a consistent difference between the two data sets, the Sun's horizontal diameter appearing to be 1 arc s larger from Washington, and the vertical diameter about 0.5 arc s smaller. (The Sun's diameter is about 1,917 arc s). This introduces one of the problems of the measuring technique. The results depend to an extent on the atmospheric transmission, a quantity that varies from place to place on the globe. The judgement of the time when the limb crosses a meridian wire is effected by irradiation, a physiological effect produced by the contrast between a bright object (the Sun in this case) and a dim one (the sky background). The Greenwich data shows for example a consistent difference between the apparent diameter of the Sun in winter and summer.

The Greenwich results indicate that the horizontal diameter is diminishing by 2.25 arc s per century and the vertical one by 0.75 arc s per century. The fact that the latter result suffers from atmospheric refraction makes the authors cautious about claiming that the Sun is changing its shape.

Now a constant shrinkage rate of 2.25 arc s per century for an object that is about 1,917 arc s in diameter means that the Sun shrinks to a point in 90,000 years time and was twice its present size 90,000 years ago. Both these are clearly ridiculous conclusions, the latter being completely unsupported by geological evidence, and Eddy and Boornazian are convinced that they are dealing with an oscillating Sun. The responsible agent could be thermal cycling in the convective zone or periodic variations in the convective efficiency, the period being hundreds of years, similar to the period between Maunder minima. The Kelvin-Helmholtz time scale of the convective envelope, the time it takes a photon to escape assuming that the photons movement is not assisted by convective motion, is also of the order of hundreds of years.

Before theoretical speculation gets out of hand let us consider the results of a more recent analysis that indicates that the Sun has been the same size for the last 250 years. The solar diameter can be easily obtained from an analysis of the observations of the transits of the planet Mercury in front of the Sun. These transits occur about 13 times per century, in May and November, when Earth and Mercury are nearly aligned, and have been carefully observed since 1677. The observations consist simply of the times of external and internal contact. Mercury has an apparent diameter of 10 arc seconds (1/200 that of the Sun) and takes about 5 hours to cross the Sun. The observed times of contact are affected by seeing conditions and the 'boiling' of the Sun's limb and are often uncertain by more than ten seconds.

Irwin I. Shapiro has published his analysis of the transit data in a recent edition of *Science* **208**, 51; 1980. His results are also shown in Fig. 1. The values obtained by the transit technique are free from any significant dependence on the variation in the rotation rate of the Earth and on our knowledge of the orbits of Earth and Mercury. The line through the

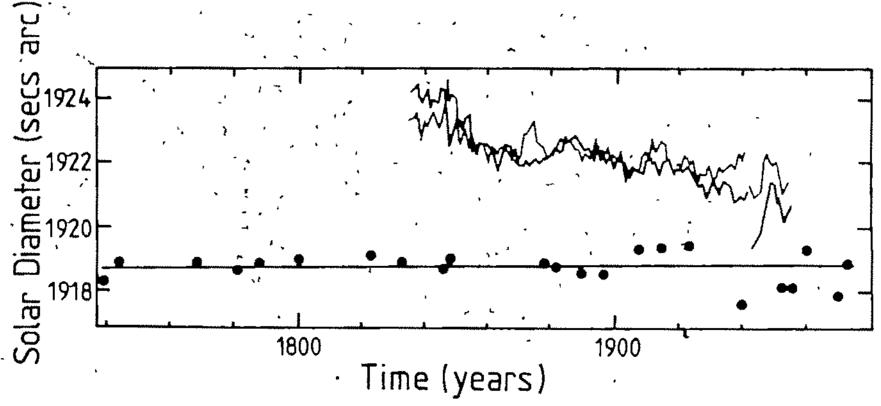

Fig. 1 The apparent diameters of the Sun as a function of time Upper graphs show the annual averages obtained by Eddy and Boornazian from the Royal Greenwich Observatory data (Thin line — vertical diameter, thick line — horizontal diameter). The dots represent the solar diameter as obtained from observations of the transit of Mercury by Shapiro

David W. Hughes is in the Department of Physics, University of Sheffield.

0028-0836/80/310439-02$01.00

data in Fig. 1 has a gradient of 0.05±0.10 arc s per century indicating that the Sun is possibly expanding but also that a conclusion that the Sun is of a constant size is entirely in keeping with the quoted uncertainties.

This result supports the findings of Sofia, O'Keefe, Lesh and Endal (*Science* **204**, 1306, 1979) who imply that changes in the solar constant (a measure of the energy output of the Sun) are directly related to the solar size. From the constancy of the solar constant Sofia *et al* conclude that the rate of change of solar diameter must be less than 0.6 arc s per century.

How do we explain Eddy's result? Firstly the difference shown in Fig. 1 between the solar diameter measured by Mercury transits and the diameter measured by meridianal transits is due to the irradiation effect caused by the solar disk — sky contrast. This can easily amount to the two s or so difference shown in Fig. 1. This irradiation is a function of atmospheric transparency and decreases as the transparency decreases. Greenwich being a suburb of London is obviously affected by the growth of London's population and the atmospheric effects of the increasing coal consumption between 1836 and 1950. Eddy and Boornazian find, however, that an unrealistic transmission decrease of at least 20% is required to explain their results. Irradiation effects also depend on the instrument, and the observing technique and the observer. The latter can be ruled out as over 100 different observers were responsible for the Greenwich data. In 1850 the instrument used was changed from the 5 inch transit to the 8 inch Airy transit circle. Also the means of recording the transit has varied. These changes complicate the interpretation.

So the mystery remains. Eddy and Boornazian are convinced that the sun is shrinking and claim that the fact that the 9 April 1567 solar eclipse was annular and not total indicates that the sun was bigger in the past. The situation is complicated by cyclic variations. Secchi and Rosa suggested in 1872 that the solar diameter varied with the 11 year sunspot cycle. Cimino (1945) and Giannuzzi (1955) found a 22 year period.

Looking to the future the SCLERA (Santa Catalina Laboratory for Experimental Relativity by Astrometry) f/100 photoelectric telescope could be used to measure the diameter to an accuracy of 0.01 arc s, a twenty-fold improvement in sensitivity, so the problem of size variation should be placed on a much sounder footing. The weather and sky transparency are better in Tucson, Arizona than in Greenwich or Washington and this should help too. □

Structure of bacteriophage Pf1

from R.A. Crowther

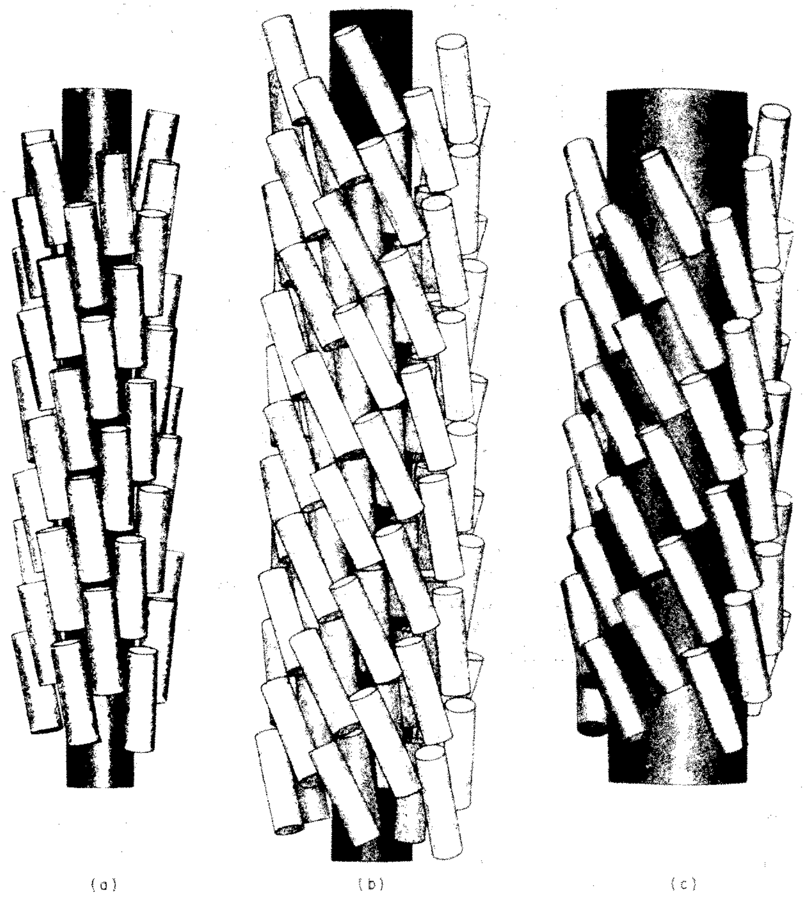
A NEW structural model for bacteriophage Pf1, differing in potentially important ways from that previously accepted, has just been proposed by Makowski, Caspar and Marvin (*J. molec. Biol.* **138**, 149; 1980).

Bacteriophage Pf1 is representative of a class of filamentous virus particles which infect gram-negative bacteria. The particles, which are about 1 μm long and 60 Å in diameter, contain a closed circular single-stranded DNA molecule of about 7,000 bases. The DNA is coated by many copies of a small protein of known sequence with a predominantly α-helical conformation. There is about 1 base of DNA per coat protein in Pf1, though the ratio is different in other phage, suggesting that interactions between DNA and coat may not be very specific. The ability to package single-stranded DNA molecules of arbitrary size makes filamentous phage, particularly M13, attractive as vectors for DNA cloning and sequencing.

An elongated structure built from a repeated unit would be expected to have helical symmetry and the X-ray diffraction patterns obtained from Pf1 confirm this. The detailed interpretation of the X-ray pattern has however been more controversial. Marvin and Wachtel (*Nature* **253**, 19; 1975) proposed a model for Pf1 assuming a helical repeat containing 22 coat protein molecules in 5 turns of a 15Å pitch helix. The model represented the coat subunit as a single α-helix coiled into a segment of a left handed concho-spiral. This interpretation was questioned by Makowski and Caspar (In *The single stranded DNA phages* eds. Denhardt, Dressler & Ray, p.627; 1978), who presented evidence favouring a subunit repeat of 27 units in 5 turns of a 15 Å pitch helix. The new model proposed jointly by the two groups is based on the latter assignment of helical symmetry, although the local structure is not much affected.

The X-ray diffraction pattern provides only part of the information needed to compute a map of the structure. Although the intensity of the various parts of the pattern is recorded the relative phase

Fig: The arrangement of α-helical segments in the virus particle. Two axial repeats of the inner layer of rod segments are shown in (a), two repeats of the outer layer in (c) and 2.5 repeats of both layers in (b). The α-helical segments in the virus protein subunit are represented as cylinders around the central core, occupied by DNA in the virus particle.



R.A. Crowther is in the MRC Laboratory of Molecular Biology, Cambridge.

0028-0836/80/310440-02$01.00

information is lost and must be regenerated by indirect means, such as introducing heavy atoms into the structure. This has not yet been possible for Pf1, so a more circuitous approach has been adopted by Makowski *et al.*, involving cycles of model building and iterative phase refinement. The stereochemical constraint of α-helical structure and the geometrical 'box' constraint of a particle of limited radius, within which all the scattering material must be confined, combine to produce what the authors claim is a unique structural solution consistent with the X-ray intensities to spacings of about 7 Å.

The picture that emerges of the coat protein (see figure) is of a segmented structure. One set of α-helical segments lies almost parallel to the particle axis at a radius of about 15 Å, while the other set of α-helical segments lies at about 25 Å radius and is tilted by about 25° to the particle axis. The resulting tightly packed and intricately interlocked structure conforms with accepted models for packing of α-helices and provides a stable 20 Å thick protein coat around the viral DNA. Unfortunately the model is not yet sufficiently detailed for the connectivity of the segments to be established. An inner segment might connect to an outer segment lying further along the virus giving an elongated though kinked subunit, reminiscent of the single α-helix of Marvin & Wachtel. More intriguingly the connectivity might be such that an inner segment joins to the outer segment overlying it at larger radius, giving a hair-pin fold to the molecule. The latter would produce a very compact coat protein, resembling the double α-helical hair-pin proposed as the primitive ancestor of the present day tobacco mosaic virus coat protein (McLachlan *et al. J. molec. Biol.* **136**, 203; 1980). More detailed studies are needed to choose between these possibilities but the outcome will clearly provide an important constraint on the molecular mechanisms proposed for viral morphogenesis. □

Plant opportunists

from Peter D. Moore

ADAPTABILITY is a valuable asset for an opportunist. The maxim applies as well to the struggling weed as to the business entrepreneur, as an increasing number of studies of the genetics and population biology of plant pest species is showing. Much of the interest in this area of botany stemmed from Bradshaw's work on variation within grasses such as *Argrostis tenuis* (see for example, *New Phytol.* **59**, 92; 1960) in response to intense selective pressures operating over limited spatial distances. In particular, it was the study of heavy metal pollution in areas disturbed by mining and dumping which led him and his students to an awareness of the genetical mosaic found in the plant cover as a response to such soil stresses (Jain & Bradshaw *Heredity* **21**, 407; 1966). In some cases it was possible to pinpoint the precise physiological adaptation involved in the provision of selective advantages, as in the case of Snaydon and Bradshaw's work (*New Phytol.* **60**, 219; 1961) on ecotypic variation in the grass *Festuca ovina* on alkaline and acid soils. Here, membrane selectivity (between sodium and potasium) was shown to be closely correlated with the environmental pH.

Complex variations and patterns in the micro-environment are frequently associated with human activity, as in the case of mine spoil, and consequently one might reasonably expect to find genetic diversification and intense local selection within those plant species which are especially dependent on man's activity, namely the weeds. This has indeed proved to be the case, for example, the work of Gadgil and Solbrig (*Am. Nat.* **106**, 14; 1972) on dandelions in North America, showed that these plants form a patchwork of genetically uniform populations, each of which has characters of growth, reproductive rate and seed size which could be regarded as adaptive responses to their varying local environment, such as degree of disturbance and frequency of mowing. (see *Nature* **252**, 191; 1974, **269**, 375; 1977).

But dandelions are somewhat peculiar in that they are apomictic and also can regenerate very effectively by vegetative means. Both of these characteristics lead to the conservation of a uniform genetic make-up within populations. Much interest has therefore been generated in the degree of variation and adaptation in other common weed species. An interesting series of papers concerning the genecology of a number of weeds has been published by Warwick and Briggs, who have been particularly interested in lawn plants. In the annual meadow grass, *Poa annua*, they found that some plants were prostrate and others erect, and that this growth habit was genetically determined (*New Phytol.* **81**, 711; 1978). The prostrate types were better able to withstand defoliation and were well adapted to lawn conditions, which is where they were generally located. The erect forms were associated with habitats in which catastrophes were common, such as disturbed soils, and devoted a greater proportion of their energy to reproduction. The erect types can therefore be regarded as r-selected with respect to the prostrate types.

A subsequent analysis of populations of the broad-leaved plantain, *Plantago major*, has demonstrated some similarities to and some differences from the meadow grass (*New Phytol.* **85**, 289; 1980). Populations were examined from regularly mowed lawns and from waste ground beside roads and canals. Again, there was a differentiation into populations with flattened, prostrate rosettes of leaves (found on lawns) and those with erect, tall shoots and leaves (found on roadsides). Naturally, when exposed to a régime of regular clipping at a height of 2 cm above ground level, the erect form suffered far more severe damage than the prostrate form. In this respect the plantains resembled the meadow grass. A consideration of Warwick and Briggs' data concerning the accumulation of vegetative and reproductive dry weight over the 14 weeks of the experiment, reveals some interesting contrasts to the meadow grass observations. Under control (unclipped) conditions, the reproductive structures (flower and fruiting spikes plus their scapes) of the lawn plantains account for between 62% and 65% of the total plant dry weight. The roadside populations, however, have a generally lower and more variable reproductive component, between 28% and 47% (based on population means). Thus, under control conditions, the prostrate form exhibits a greater degree of energy diversion to reproduction than the erect population, and this character is normally an indication of r-selection. Under clipped conditions, as one might reasonably predict, this difference is further exaggerated, for the shorter, less erect spikes of the lawn type are far more successful. After 14 weeks growth under a weekly mowing regime, the lawn population had a 52% to 54% investment in reproductive structures and the roadside plants were reduced to 13% to 17%.

Such clear indications of ecotypic variations have not, however, been found in all the lawn weeds examined by Warwick and Briggs. In the daisy, *Bellis perennis* (*New Phytol* **85**, 289; 1980), there was a great deal of variation within populations from grasslands of differing mowing and grazing histories. Transplantation into a regularly cut lawn did not necessarily diminish the reproductive vigour of some individuals from grazed habitats, but, in the case of the daisy, the importance of vegetative reproduction in the overall success of the plant is much greater than for either the plantain or the meadow grass. One cannot measure the full potential of a weed simply by its commitment to sexual reproduction. □

New developments in iron-sulphur proteins

from R. Cammack

A NOVEL kind of iron-sulphur cluster has been found in a ferredoxin from the nitrogen-fixing bacterium *Azobacter vinelandii*. The cluster is unusual in that it contains a ring of three iron atoms linked by labile sulphide atoms. The iron-sulphur proteins are a class of proteins that contain clusters of iron atoms bound to cysteine and sulphide sulphur. They are an important group of biological electron transfer agents. For example, more than a dozen different types of iron-sulphur clusters have been detected in mitochondria where they are concerned with energy metabolism. Two years ago, the possibility that iron-sulphur clusters can have other functions was raised when F. J. Ruzicka and H. Beinert (*J. Biol. Chem* **253**, 2514; 1978) found that aconitase is an iron-sulphur protein. This enzyme of the Krebs tricarboxylic acid cycle of mitochondria has no known electron transfer function. It now seems likely that the iron-sulphur cluster in this enzyme is unusual in another respect, in that it may be a new type of three-iron cluster, similar to those recently proposed in certain bacterial proteins.

In the early 1970's it became established, by a combination of X-ray crystallography, spectroscopy and synthesis of chemical analogues, that all the iron-sulphur proteins contained either 1-iron, (Rd), 2-iron [2Fe-2S] or 4-iron [4Fe-4S] clusters (see figure). The 1-iron centres are found only in the rubredoxins of certain bacteria but the [2Fe-2S] and [4Fe-4S] clusters, in which iron is attached to sulphide sulphur and cysteine sulphur from the protein, has been found in many electron-transferring systems and enzymes. The iron-sulphur proteins are often described by the low-temperature electron-paramagnetic-resonance (EPR) spectra, since this is a good way of detecting them in biological systems. The [2Fe-2S] clusters and some of the [4Fe-4S] clusters give EPR signals in the reduced state at $g = 1.94$. Other [4Fe-4S] clusters give EPR signals around $g = 2.01$. However recent results suggest that a novel type of cluster may also give a $g = 2.01$ signal.

The centre of attention is a ferredoxin from *Azotobacter vinelandii*. This protein contains two iron-sulphur clusters with widely different redox potentials, +320mV and −424mV. Both give EPR signals at $g = 2.01$. The first cluster seems to be a conventional [4Fe-4S] type. The second one, however, seems to be different. Chemical analysis (which is, admittedly, notoriously difficult with these proteins) indicates that it contains fewer than four iron atoms. Preliminary X-ray crystallography of the ferredoxin at 4 Å resolution by C. D. Stout of the University of Pittsburgh showed that this cluster was smaller than the other and last year it was proposed (Stout *Nature* **279**, 83; 1979) that it might be a two-iron cluster. A clearer picture of the cluster has now emerged from an electron density map at 2.5 Å resolution (Stout, Ghosh, Pattabni & Robbins *J. Biol. Chem.* **255**; 19797; 1980).

A model (see figure) has now been fitted to the X-ray data and can be considered as a two-iron cluster which has opened at one side to introduce a third iron atom (numbered 3) and sulphide atom. Unlike all other iron atoms in iron-sulphur clusters, atom 3 does not have tetrahedral symmetry but appears to be almost square planar. Also, the ligands from the protein could not all be cysteine sulphurs as there are insufficient residues of this amino acid available.

The results of the X-ray analysis are still preliminary. Refinement of the full structure of the protein is not expected before the end of this year. However support for the existence of a three-iron cluster is provided by a totally different technique, ^{57}Fe Mössbauer spectroscopy. A paper from groups in Wisconsin and Minnesota (Emptage, Kent, Huynh, Rawlings, Orme-Johnson & Münck *J. Biol. Chem.* **255**, 17973; 1980) looks at the iron atoms in *A. vinelandii* ferredoxin. After subtracting the spectrum of the [4Fe-4S] cluster, the second cluster appears to contain two types of iron atom, in the ratio 2 : 1. As in other iron-sulphur clusters, the iron atoms are antiferromagnetically coupled together. The observation that the cluster gives the EPR signal at $g = 2.01$ in the oxidized form, but is non-magnetic in the reduced state, can readily be explained by a three-iron cluster. (This was a difficulty with the previously proposed two-iron cluster). The valence states of the iron atoms would correspond to $3Fe^{3+}$ in the oxidized state, and $2Fe^{3+}$ and Fe^{2+} in the reduced state, giving net charges for the cluster of +3 and +2, respectively.

If the existence of three-iron clusters is confirmed, there are already a number of proteins known that may also contain them. All of these given the EPR signal at $g = 2.01$. Mossbauer spectra of ferredoxin II from *Desulfovibrio gigas* indicate that it contains a [3Fe-3S] cluster on each polypeptide chain. Since the protein is a tetramer it appears to contain four such clusters (Interestingly ferredoxin I from the same organism contains [4Fe-4S] clusters in a trimeric unit of exactly the same polypeptide). Other, more complex proteins, may also contain the cluster. Emptage *et. al.* report that they have observed similar Mossbauer spectra from the enzyme glutamate synthase of *A. vinelandii* and from aconitase of beef heart mitochondria.

The presence of this iron-sulphur cluster in aconitase is intriguing. The cluster does not appear to participate in the enzyme reaction directly, but the enzyme is inactive unless the cluster is first reduced. It has therefore been suggested that the cluster somehow regulates the activity of the enzyme. If this idea becomes accepted, there are other examples known. Glutamine amidoribosyl transferase is an enzyme concerned with nucleic acid synthesis. The enzyme, both from human tissue and from *Bacillus subtilis* has been found to contain an iron-sulphur cluster (possibly of the [4Fe-4S] type). Again this has no obvious role in catalysis, but the enzyme is only active when the cluster is reduced.

It seems, as more types of iron-sulphur proteins continue to be discovered, that we have much to learn about the versatility of iron-sulphur clusters. □

NEW SCHEME FOR DIRECTING BALLOONS

M. Gabriel Yon, one of the directors of the great Giffard captive balloon, and Mr. E.A. Pearse of Bristol, have each published a pamphlet on the direction of aërostats. The balloon of each inventor is to be elongated according to the principles of the experiments tried by Giffard in 1852 and by Dupuy de Lome in 1871. The propeller is to be moved by a gas-engine in the Pearse balloon, and by a steam-engine in the Yon balloon. M. Yon proposes to use the gas of the balloon as fuel, but only in proportion to loss of weight produced either by uncondensed steam or by consumption of petroleum.

Nothing can be said to be really impracticable in the Pearse scheme, although Mr. Pearse lacks the aëronautical training which distinguishes M. Yon, an aëronaut who ascended with M. Giffard in 1854, and has witnessed all his experiments. The only essential difference between M. Giffard's scheme and the new system is the place given to the fan, which M. Giffard attaches to the car. Practice will only decide whether the alteration projected is an improvement or otherwise. The reason alleged for the change is the bringing of the fan nearer to the centre of resistance. But it obliges the aëronaut to give to his fans a very small diameter, which requires an immense number of rotations in a second, and consequently represents a loss of power.

The calculations appear to have been made with care by M. Yon and Mr. Pearse. A trial would be greatly desirable, although it is impossible to suppose that the aërial carriage of Mr. Pearse or the directing balloon of M. Yon can possibly bring aëronauts to the North Pole for their inaugural trip, they may be instrumental in eliciting useful facts. We may add to the peculiarities of M. Yon's scheme that he uses a small globe inclosed in the lower part of the aërostat called a compensation sphere, and connected by a pipe with a ventilator, for keeping intact the form of his aërial machine. Mr. Pearse does not appear to be convinced of the urgent necessity of abstaining in any aërial construction from every complication which can be avoided at any cost, and he suggests the adoption of some accessory organs which, although designed to help aëronauts, would tax too much the lifting power or the attention of the aërial sailor. Mr. Pearse supposes that he will be able to navigate the air with an excess of weight, and does not pay attention to the intensity of motive power required to counteract gravitation even in a partial manner. He should certainly take advantage of the pamphlet written by his French competitor, who deals mostly with facts belonging to the public, and on which nobody can, in the present state of science, raise any claim as being his own property.

Both these pamphlets are greatly in advance of similar productions, and are creditable to their writers. Mr. Pearse's pamphlet has been only published for private publication. M. Yon's is printed with a number of plates representing many details; but a directing balloon is so complex a matter that this part of the publication can hardly be said to be complete.

Having been the builder of M. Depuy de Lome's balloon and one of his crew, M. Yon may be said to have witnessed all the great aeronautical constructions of the age. Next to M. Henry Giffard, of whom he claims to be the pupil, he is the most completely qualified aëronaut to work out the solution of the great problem to which a recent success in photography has given unexpectedly in some respects a practical result.

The mechanism of two-nucleon transfer reactions

from P.E. Hodgson

SOME recent calculations made by Da Hsuan Feng *et al.* (*Phys. Rev. Lett.* **44**, 1037; 1980) greatly clarify the interpretation of two-nucleon transfer reactions. These reactions, particularly the (*p*,*t*) and the inverse (*t*,*p*) reactions, are extensively used to study nuclear structure but the interpretation of the experimental results has been hindered by lack of knowledge of the reaction mechanism. The distorted wave calculations of the reaction cross-sections tend to give the shapes of the angular distributions rather well, but the absolute magnitudes are very often much smaller than the experimental values. The situation compares unfavourably with that for the corresponding one-nucleon transfer reactions, which can usually be accounted for both in angular distribution and in absolute magnitude using the distorted wave theory.

Attempts to improve the calculations of the cross-section of the two-nucleon transfer reactions fall into two categories, those that concentrate on the nuclear reaction and those that concentrate on the nuclear structure. It has been found that the inclusion of additional reaction mechanisms — for example a two-stage process through an intermediate nucleus — gives additional contributions to the cross-section that brings it into closer accord with the experimental values. Another line of research is to include more detailed wavefunctions for the initial and final nuclear states, and these also tend to increase the calculated cross-section. There still remains, however, much uncertainty about the reaction mechanisms that have to be included, and the importance of higher-order nuclear configurations.

Da Hsuan Feng *et al.* use realistic triton and nuclear wave functions and succeed in fitting the experimental cross-sections both in magnitude and in angular distribution. The reaction was assumed to take place by the direct pickup of the two nucleons from the target nucleus by the incident proton to give the outgoing triton. The wavefunction of the proton and the triton are generated by the appropriate optical potentials, and the reaction matrix element is evaluated without making the assumption that the interaction potential has zero range, an assumption that is known to give good results for one-nucleon transfer reactions but not for two-nucleon transfer reactions.

The improved form of the triton wave function is an important feature of the new calculations. Most of the previous calculations included only the predominant spatially symmetric *S* state. But now the mixed-symmetry *S*′ and *D* states are included as well. This alters the selection rules and allows transitions to unnatural parity states to take place by a one-step process. The overlap integral between the wavefunctions of the initial and final nuclei satisfies a Schroedinger equation for two interacting particles in an external potential, and this was solved by an extended-basis shell model method. Overall, these new calculations are the first that use realistic transfer potentials, triton wavefunction and nuclear overlap functions and are thus the first detailed test of the validity of the distorted wave method as applied to two-nucleon transfer reactions.

To evaluate the success of this formulation, it was applied to the ^{18}O(p,t)^{16}O reaction at 20 MeV., the ^{48}Ca(t,p)^{50}Ca reaction at 12.08 MeV. and the ^{90}Zr(t,p)^{92}Zr reaction at 11.89 and 20 MeV., and the results for the first two of these reactions are compared with the experimental data in the figure. In both cases, and also for the third reaction, the

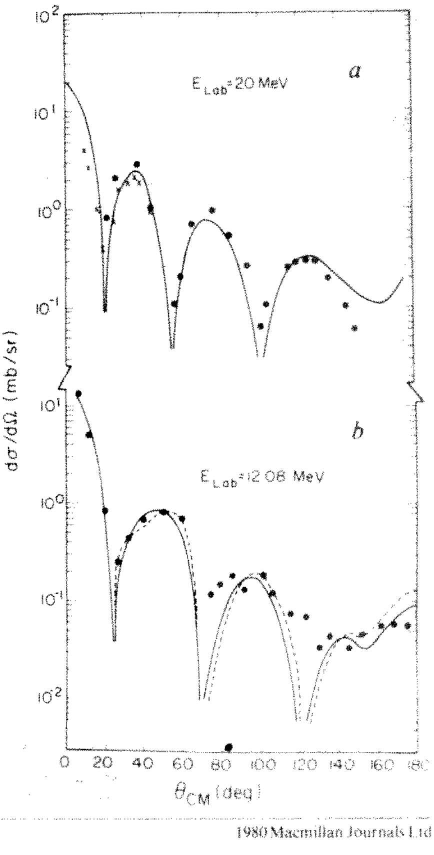

Figure: (a) Differential cross-section for the ^{18}O(p,t)^{16}O reaction compared with distorted wave calculations. (b) A similar comparison for the ^{48}Ca(t,p)^{50}Ca reaction. The dashed curve shows the result of using a different way of calculating the wavefunctions of the transferred nucleons.

P.E. Hodgson is in the Department of Nuclear Physics, University of Oxford.

0028-0836/80/310443-02$01.00

agreement is good both for the absolute magnitude of the cross-section and also for its angular variation. Since the optical potentials are obtained from the analysis of elastic scattering cross-sections, and the parameters of the nuclear structure part of the calculation are fixed in advance, there are no adjustable parameters in the calculations. The excellent fit to the data for different reactions at two energies for different nuclei shows that the essential features of the reaction have been included in the calculation. In particular, the results provide no evidence in favour of the suggestion that two-stage processes contribute appreciably to the cross-section.

Further work remains to be done to test these calculations against a wider range of data, and also to improve the method still further. In particular, the validity of the distorted wave method needs to be examined in more detail, and account needs to be taken of the possibility of exchanges between the ingoing proton and the target nucleus. However even in its present form the calculation is a significant advance on previous work, and should provide a powerful tool for nuclear structure studies.

Evolution and gaps in the fossil record

from Mark Ridley

CHARLES Darwin's theory of evolution differed from most of its alternatives in postulating that new parts evolved in many tiny stages from previously existing parts. Unfortunately, the intermediate stages hardly ever seemed to exist in the fossil record (Huxley's later trumpeting about *Archaeopteryx* notwithstanding). Darwin himself followed Lyell in blaming the fossil record — it was incomplete, unhistorical and misleading, so it did not count against this theory. If taken to an extreme the two ideas (that the fossil record is incomplete and that evolution proceeds at a fairly constant rate) can form an irrefutable system in which gradual temporal change in fossils is interpreted literally, but sudden jumps between species are attributed to gaps in the record. All the evidence is then consistent with a constant tempo of evolution.

A few years ago Eldredge (*Evolution* **25**, 156; 1971) and then Eldredge and Gould (*Models in Paleobiology* ed. J. W. Schopf; Freeman, San Francisco, 1972; *Paleobiology* **3**, 115; 1977), following on suggestions by Mayr, Simpson and others, argued that the gaps in the fossil record might be more real than apparent. They put forward a version of the theory of allopatric speciation that would automatically generate gaps in the fossil record. According to their theory: (1) the intermediates between species existed in small populations, and small populations are less likely to leave a record than large ones (2) evolution is rapid in the small isolated population, and (3) the intermediates did not exist in the same place as (and so are unlikely to be preserved with) their ancestor. Evolution, therefore, is not gradual and of constant tempo. There are short periods of rapid change at speciation, separated by longer periods in which there is no change. Eldredge and Gould christened this the 'punctuated equilibrium' model of evolution, and its alternative 'phyletic gradualism'.

Eldredge and Gould's forceful essay has inspired two controversies. One is over whether the fossil record does, in fact, show one pattern or the other, and the second concerns the validity of Eldredge and Gould's explanation of punctuated equilibria. Even if it is established that evolution is punctuated, Eldredge and Gould's theory of speciation is only one of a variety of possible explanations.

Biometrical studies, in which the range of variation is described for each interval within a continuous sedimentary unit, are essential for a test between phyletic gradualism and punctuated equilibria. Incompleteness of the record and typological taxonomy (in which each specimen is named by its similarity to a type specimen) will otherwise be confounding factors. A study of geographical variation is also desirable. If the samples contain specimens from the ancestral species pooled with increasing (as time passes) numbers from the allopatrically derived species, then gradual evolution can appear as an artefact even if the actual evolution was punctuated. Such pooling is less likely to occur if geographic variation is studied separately.

Gingerich has published several biometrical studies of mammal evolution, though his studies lack information about geographical variation (*Am. J. Sci.* **276**, 1; 1976; *Pap. Paleont. Mus, Paleont. Univ. Mich.* **15**, 1; 1976; *J. Paleont.* **53**, 153; 1979; Gingerich & Symons *Contr. Mus. Paleont. Univ. Mich.* **24**, 245; 1977). His most abundant data are for the condylarth *Hyopsodus* in the early Eocene (*Am. J. Sci.* **276**, 1; 1976), which looks as if it evoved gradually. Gould and Eldredge (*Paleobiology* **3**, 115; 1977) said that the rate of evolution in *Hyopsodus* was too slow to be important. However, the rate of change within a *Hyopsodus* species is similar to that at speciation. This is manifest phyletic gradualism even if only on small scale. More recently, West (*Paleobiology* **5**, 252; 1979) followed the descendants of Gingerich's *Hyopsodus* through a middle Eocene formation of at least one million years, and found no evidence of evolutionary change. So even if *Hyopsodus* did evolve gradually in Gingerich's study site, they showed prolonged stasis soon afterwards. Gingerich's other papers document phyletic gradualism in other condylarths and in primates, and there is now a steady trickle of papers (see recent issues of *Paleobiology*) variously substantiating either gradual or punctuated change.

Eldredge and Gould's microevolutionary theory has also been criticized. The first problem is whether speciation occurs in small populations. Anderson and Evensen (*Syst. Zool.* **27**, 421; 1978) have compared the sizes of the geographic ranges of recently diverged pairs of species of North American terrestrial vertebrates and found that "more than half of the recently divergent species pairs have the range of the smaller species greater than 30 percent of that of the larger species". Although uncertainty exists about just how recently the pairs of species diverged and about the relation between range and population sizes, Anderson and Evensen's data does not support Eldredge and Gould's claim that speciating populations are very small. It can also be asked whether evolution is rapid in small populations. Smaller populations have lower total rates of mutation which can cause lower rates of evolution (e.g. Maynard Smith *Am. Nat.* **110**, 331; 1976).

The second problem is to reconcile punctuated evolution with natural selection and genetics. The rate of evolution might either be controlled by the extent of genetical variation, or by the intensity of selection. On the latter possibility, the pattern of evolution is directly controlled by rates of change of the environment. The *Gryphaea* studied by Hallam (*Paleobiology* **4**, 16; 1978), for example, speciate rapidly when their ranges are fragmented by a fall in sea level. When the sea rises *Gryphaea* gradually evolve increased size. The other hypothesis is that rapid evolution results from rare, large mutations; chromosomal changes are possible examples. Chromosomal differences between species are well-known in a variety of taxa, and several authors have broached chromosomal mechanisms for rapid speciation in small populations (reviewed by M.J.D. White *Modes of Speciation* W.H. Freeman, San Francisco; 1978), which would cause a 'punctuated' pattern of evolution. One suggested mechanism is a change in a chromosome (such as a translocation or an inversion) within one local population. Heterozygotes for the mutation would probably be selected against, so that if members of this population interbred with the ancestral species there would be intense selection for reproductive isolation. However, even given a correlation between chromosome

---

0028-0836/80/310444-02$01.00

differences and speciation, it is not obvious which is cause and which effect, and nor can we be sure that chromosomal speciation would necessarily produce punctuated evolution. In his latest essay on the subject, Gould (*Paleobiology* **6**, 119; 1980) argues that large mutations are the main cause of punctuated evolution.

A third and interesting possibility is that gradual environmental change could cause punctuated evolution. In their original paper, Eldredge and Gould mooted that a species' gene pool is so intricately co-adapted that change is only possible by a thorough revolution. By co-adapted it is meant that a change in one part of the system will not be favoured without simultaneous changes in other parts. Thus when evolution occurs it will be by a sudden leap, with changes in many parts; natural selection does not favour piecemeal tinkering.

Ironically, an objection to any model in which punctuated evolution occurs with gradual environmental change comes from the very facts that led to the formation of the theory to begin with: geographical variation. Stepped clines (discontinuous variation in space) are known that do not coincide with obvious environmental discontinuities, such as the enigmatic spotting pattern of the butterfly *Maniola jurtina*, and these have been interpreted as quantum jumps between different co-adapted genetic systems (E.B. Ford *Ecological Genetics* Chapman & Hall, London; 4th edn, 1975, J.A. Endler *Geographic variation, speciation, and clines* Princeton University Press, 1977). However, continuous variation in space is commonly observed in many species and is difficult to reconcile with the theory that says that natural selection causes abrupt changes between different co-adapted states. Earlier this century gradual geographical variation was important in confuting the de Vriesian 'mutationist' theories of evolution. Gradual geographic variation probably evolves much too rapidly to be represented in the fossil record as gradual evolution, so the existence of gradual geographic variation is perfectly compatible with punctuated evolution over geological time. Gradual geographic variation, however, does not fit in well with the 'co-adaptation' theory of how natural selection brings this punctuated evolution about. □

Earthquake prediction

from David W. Simpson

In the early 1970s, principally because of observations of premonitory changes in velocity ratio and groundwater geochemistry in the USSR and crustal deformation studies in Japan, there was considerable optimism that earthquake prediction would soon become a reality. The intervening years have seen a greatly expanded program in earthquake prediction in the United States, but negative and conflicting results have dampened some of the initial enthusiasm, if not led to outright pessimism on the part of many US seismologists regarding the practical reality and imminence of reliable methods for predicting earthquakes. At a recent meeting* on a wide variety of topics related to earthquake prediction much of the original enthusiasm appeared to be re-emerging as it became clear that at least some earthquakes can be, and in fact have been, successfully predicted. It was also clear, however, that no universal panacea can be expected. Premonitory effects appear to vary widely with tectonic environment and earthquake magnitude. The premonitory signatures of large earthquakes in thrust regions of Soviet Central Asia, China and Japan appear to be clearer and to extend over a wider area than any such effects observed so far in strike-slip environments such as the San Andreas Fault of California.

On a time scale of tens of years, gaps in the occurrence of large earthquakes along major plate boundaries have proved to be one of the most successful methods for predicting the sites of future great shocks. Nishenko, McCann and Sykes (Lamont-Doherty Geological Observatory, Columbia) presented a map of the current 'seismic potential' of the circum-Pacific belt, in which they refined the idea of seismic 'gaps' by ascribing a high seismic potential to a gap only if historical or tectonic data indicate that it is a region capable of producing a large shock. Sykes *et al.* (Lamont-Doherty) used historical reports to extend the record of great earthquakes in the Alaska-Aleutian arc back to 1784 and showed repeat times of 50 to 100 years for great earthquakes in some regions. Large segments of this part of the plate boundary seem to rupture in temporally clustered sequences of large earthquakes (e.g., 1898-1907 and 1938-1965), separated by long periods of relative quiescence. Variations in seismicity in western Japan, and especially a south to north migration in the area to the west of the 1946 Nankaido earthquake were reported by Mogi (Tokyo University). He also showed how a recent model by Shimazaki and Nakata, in which rupture occurs at a constant ultimate stress (as opposed to a model of constant stress drop during an earthquake), can be used to explain the observation that the time interval between large earthquakes in western Japan is proportional to the stress drop in the preceding large earthquake. Takagi (Tōhoku University, Japan), in a detailed study of activity before and after the 1978 magnitude 7.4 Miyagi-oki earthquake, showed a migration of foreshocks towards the boundary between the oceanic slab and overriding plate, with aftershocks clustering along the boundary. Seismicity patterns in the Mexico-Central America segment of the circum-Pacific belt were described by McNally (California Institute of Technology), Ohtake *et al.* (National Research Center for Disaster Prevention, Japan) and Singh *et al.* (Instituto Geofisica, Mexico), who reviewed data which led to the successful prediction of the 1978 Oaxaca earthquake and showed repeat times of 30-40 years for this region. For at least 50 years following the 1906 San Francisco earthquake the level of seismicity in northern California was considerably lower than it had been in the preceding 50 years. Ellsworth *et al.* (US Geological Survey) suggested that a pair of magnitude 5.5 earthquakes in the San Francisco area in August 1979 and January 1980 show the activity to be returning to a more normal level. Pairs of earthquakes with similar temporal clustering have occurred a number of times in the area since 1836.

In continental areas, where the repeat times for large earthquakes are longer than for oceanic subduction zones and are usually beyond the range of instrumental or historical catalogues, geological data are being used to extend the record of occurrence of major earthquakes. Sieh (California Institute of Technology), Wallace (US Geological Survey) and Schwartz *et al.* (Woodward-Clyde consultants, San Francisco) showed how detailed mapping of displacement on major fault zones in the western US can be used to date past earthquakes to determine recurrence intervals and maximum magnitudes of prehistoric events. They showed a general increase in the recurrence interval from west to east: from tens to hundreds of years for large earthquakes along the San Andreas system to hundreds to thousands of years in Nevada and Utah.

Whereas most methods for long-term prediction are based on regularities and changes in the seismic cycle itself as revealed

Insect diapause — stability and change

from A.D. Lees

GEOGRAPHICAL strains of insects often differ substantially in their diapause characteristics. The critical photoperiod required for diapause induction, the interactions between day length and temperature and the intensity (duration) of dormancy are particularly variable. When the area of distribution extends continuously over a wide range of latitudes these characters form a north-south cline with critical photoperiod and intensity diminishing towards lower latitudes and diapause sometimes fading out entirely in the sub-tropics. Following the classical work of Danilevsky (*Ent. Obozr.* **36**, 6; 1957), this has been accepted as evidence that geographical strains are closely adapted in their phenology (date of entry into diapause, voltinism etc.) to their own part of the geographical range of the species. Since photoperiod and temperature, as the main agents controlling diapause, vary systematically with latitude, the insect would receive a false indication of season in other parts of the range. This is expected to limit spread along a north-south axis and might have severe initial effects on introduced species, although some later readjustment by natural selection might well be looked for. In this connection, crosses between different strains have shown that quantitative differences in diapause-related characters such as critical photoperiod and diapause intensity depend on polygenic inheritance. Nevertheless, as emphasised by Tauber and Tauber (*Evolution of Insect Migration and Diapause* p.53-71, Springer-Verlag, 1978), these features can sometimes be modified quite rapidly by directional selection in the laboratory.

Introduced pests that fail to gain a foothold usually escape notice. For this reason the diapause status of the more successful invaders is especially worthy of scrutiny. In this issue of *Nature* (p.489) Goldson and Emberson show that the Argentine grass stem weevil *Hyperodes bonariensis*, introduced into New Zealand more than 50 years ago, has a remarkably stable photoperiodically controlled adult diapause, populations collected in areas extending over 8° of latitude having much the same critical photoperiod. It seems that the beetle might have achieved multivoltinism (and even greater destructiveness?) if diapause had been eliminated by selection. The absence of diapause in most indigenous New Zealand insects suggests that this condition is not required for winter survival.

In contrast, the photoperiodically controlled winter diapause of the Colorado potato beetle is well suited to its new environment in continental Europe. Introduced into France in 1922, *Leptinotarsa* has since spread eastwards as far as the USSR, occupying only slightly wider latitudinal limits than in N. America. It seems likely that the dispause control mechanisms and the voltinism have again remained relatively stable (de Wilde, *Soc. exp. Biol. Symp.* **23**, 263; 1969). The pink bollworm *Pectinophora gossypiella*, originating in India, is a pest which has been transported by commerce to virtually every cotton growing area in the world, mainly during the present century. The geographical strains tested by Ankersmit and Adkisson (*J. Insect Physiol.* **13**, 553; 1967) were found to have very similar critical photoperiods for diapause induction even though the populations came from widely separated latitudes (for example, El Paso 32°N and Colombia 3°N). However, many fewer insects from lower latitudes entered diapause at all, even in short days. In this species adaptive changes are already far advanced. In the cornborer *Pyrausta nubilalis* the evidence suggests that changes in the diapause status are progressing rapidly. Introduced into N. America from Europe before 1920, there has been a strong tendency for the univoltinism of populations in the north to give way to a bi- or multivoltine life cycle in the warmer states of Kansas and Missouri. According to the analysis of Beck and Apple (*J. econ. Ent.* **54**, 550; 1961), these changes involve both photoperiod and temperature control of the inductive daylength as well as more indirect effects of temperature on the rate of larval development. From these few examples it is clear that the adaptive changes shown by different insects are liable to be varied and complex. ☐

A.D. Lees is Professor of Insect Physiology, Imperial College, London.

---

by seismicity data, many intermediate- and short-term predictions rely strongly on indirect indicators of the earthquake preparation process. Aki (Massachusetts Institute of Technology) presented a method by which information from various independent precursors can be combined to improve estimates of the probability of the occurrence of a large earthquake. Thatcher (US Geological Survey) showed how geodetic measurements have been useful, especially in Japan and California, in identifying areas of increased stress as the possible sites for future earthquakes. The importance of inhomogeneities in the stress distribution on fault zones and the role of asperities in controlling the release of stress were discussed by Kanamori and Lay (California Institute of Technology) and Wyss (Institute für Geophysik, Zurich). A model of time dependent failure due to stress corrosion, in which the growth of cracks is controlled by a 'stress intensity factor' and the presence of asperities, was presented by Scholz *et al.* (Lamont-Doherty).

In short-term predictions, water-related effects are especially common. A number of papers described the observation of changes in radon content in groundwater and deep wells. Fu (State Seismological Bureau, Peking) and Wakita (Tokyo University) reported a variety of short-term precursors preceding recent earthquakes greater than magnitude 7 in China and Japan, many of which may be closely related to groundwater (e.g., water level, geochemical and temperature changes in wells, resistivity variations). Sobolev (Institute of Physics of the Earth, Moscow), in a summary of studies in Soviet Central Asia, showed premonitory changes of water levels in wells as far as 650 km from earthquakes of magnitude 7.

Reviews were presented of the national programs in earthquake prediction in the US, USSR, China and Japan. As described by Mogi (Tokyo University) and Rikitake (Tokyo Institute of Technology) the Japanese program, which began in 1965, involves a closely integrated organization of universities and government agencies monitoring a wide spectrum of geophysical, geological, geodetic and geochemical parameters, with special emphasis on the Izu Peninsula and Tokai district. In addition to the high level of data gathering and research, the Japanese have also made significant advances in raising public awareness of earthquake hazards and in preparing the public for earthquake emergencies. Participants at the meeting were vividly reminded of the sociological and economic importance of earthquake prediction by a series of Japanese films on the disastrous effects of major earthquakes and a Chinese video-tape showing the destruction caused by the 1976 Tangshan earthquake.

Large earthquakes occur in cycles which are long compared to the instrumental records available of seismicity and related geophysical parameters. The seismic cycle appears even longer when viewed in terms of the relatively short time during which data have been gathered specifically for earthquake prediction purposes. Even within the limitations of existing data, however, the meeting clearly showed that consistent patterns are emerging. As data gathering and interpretation improve, the challenges of the next few years will be to identify the techniques which are the most reliable; to test the significance of predictions based on those methods; and to integrate various techniques into an increasingly reliable procedure for earthquake prediction. ☐

REVIEW ARTICLE

Biomolecular structure determination by mass spectrometry

Howard R. Morris

Department of Biochemistry, Imperial College of Science and Technology, London SW7 2AZ, UK

Mass spectrometry, conventionally used with smallish molecules (less than 1,000 daltons), has surprisingly emerged as a powerful technique for the determination of the amino acid sequences of proteins and the structure of glycopeptides as well as for the characterization of biologically active materials of unusual structure such as the peptidolipids. Further applications to biomedical problems are foreseen.

THE past decade has seen a considerable advancement both in the technical capabilities of mass spectrometry and in its application to problems in biochemistry and medicine. Perhaps most surprising, given that most conventional mass spectrometers perform optimally on volatile samples of mass less than 1,000 daltons, has been the successful extension of mass spectrometry to the elucidation of the structures of complex and polar substances such as proteins and carbohydrates. The great power of modern mass spectrometry stems from several fundamental principles peculiar to the technique, not all of which have yet been properly or completely exploited. These are all illustrated in the text that follows but a summary of the concepts will be useful at this stage: (1) sensitivity: mass spectrometry is the most sensitive of all general methods of structure elucidation or quantitation, being routinely applicable to sample sizes of microgrammes or less. In favourable cases picogramme sensitivity has been achieved[1], and progress in the physics of ion generation, mass analysis and detection may eventually lead to the ultimate in sensitivity-generation, analysis and detection of a single ion (detection is already a reality). (2) Specificity: because the method provides an exact physicochemical measurement (mass with an accuracy of five decimal places for example), its specificity is unequalled by other widely used 'structure probes' such as radioimmunoassay. (3) Sample purity: mass spectrometry has a unique advantage over classical chemical methods or true spectroscopic methods of structure elucidation in that it does not require a pure sample of the compound whose structure is to be determined. It is the intention of this review to illustrate the power and potential of mass spectrometry by examples of its recent role in the determination of protein, peptide, glycopeptide and peptidolipid structure.

Protein sequence analysis

The demand for protein sequence analysis is greater than ever despite recombinant DNA technology, not least because the positive identification of initiator, termination and intron coding sequences demands comparison with amino acid sequence data. The underlying trend in protein sequence analysis is towards the rapid generation of sequence data, not necessarily complete, but sufficient, for example, to combine with crystallographic data to

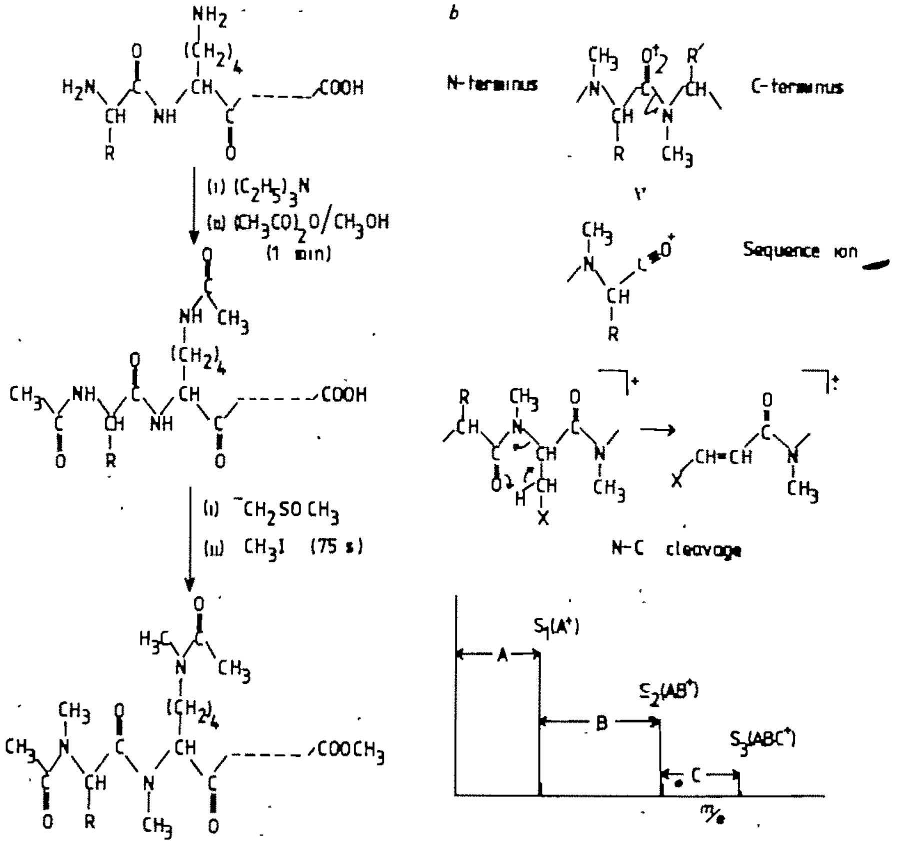

Fig. 1 *a*, General derivative-forming reactions applicable to 1–50 nmol of protein-derived peptides[10,11]. To be applicable to all common amino acids, the permethylation step must be restricted with respect to alkylation reaction time to prevent 'salt' formation[10]. Arginine-containing peptides require an additional mild hydrazinolysis step before acetylation. This reaction is carried out only on those peptides showing a positive stain test for arginine on the electrophoretogram[11] (see 'Strategy'). *b*, The formation of 'sequence ions' and N–C cleavage fragment ions from which the interpretation of the spectrum is made. N–C cleavage is only observed where 'X' corresponds to Phe, Tyr, His, Trp, Asn or Asp[13]. The schematic representation of a mass spectrum shows how the sequence is built up simply by counting mass differences (corresponding to the amino acids A, B and C) between sequence ions S_1, S_2 and S_3 (ref. 14).

0028-0836/80/310447—06$01.00

determine tertiary structure, to locate the protein coding in a DNA sequence, or to answer questions on the evolutionary divergence of enzymes. Partial sequence data, following chemical modification of the protein, can also be sufficient to reveal catalytic or binding sites.

It is now 20 years since studies on small synthetic peptides first indicated the possibility of sequence analysis by mass spectrometry[2,3], and 10 years since the mass spectrometric analysis of protein-derived peptides and peptide mixtures was first demonstrated[4]. Since then, considerable progress has been made, resulting in combined classical–mass spectrometric attack on total protein sequences, for example on ribitol dehydrogenase[5] and chloramphenicol transacetylase[6,7]. Only recently, however, was the first total protein sequence assignment made by mass spectrometry, independent of classical methodology, in work on dihydrofolate reductase[8,9]. Why has it been so difficult and taken so long to reach this stage? The short answer is that, as already mentioned, the mass spectrometer is not an obvious method of choice for the study of high molecular mass, complex polar molecules. The successful reconciliation of these apparently irreconcilable differences, to produce a methodology that has clear advantages over classical ones (whether manual or automated) has hinged upon the following developments in the areas of derivatization, fragmentation and strategy.

Derivatization and fragmentation

Several types of derivatives are currently in use, the choice depending very much upon the subsequent strategy, for example whether gas chromatography or direct probe insertion is to be used. In most of the protein studies reported to date, samples have been introduced directly via the probe, for which technique the *N*-acetyl, *N,O,S*-permethyl derivative[10] is preferred. Figure 1*a* summarises the method for obtaining volatile methylated derivatives.

The one feature of the early work that suggested that mass spectrometry might be useful for peptide sequencing was the observation of fragmentation at the peptide bond[2,3]. This 'sequence ion' formation, first observed for acyl peptide esters, is an even more pronounced fragmentation pathway when the amide bond is methylated, as in the permethylation reaction. Recognition of this important fragmentation pathway is not, however, sufficient for the successful interpretation of the mass spectrum; often the true molecular ion is not present, and other fragmentation pathways including radical or neutral losses from the molecular ion or other fragment ions[12] (Fig. 1*b*) must be recognized. The exact nuances of interpretation are too detailed for discussion here, but suffice it to say that current ideas on peptide sequence assignment go well beyond simple recognition of 'sequence ions', often to an understanding and recognition of every signal in the spectrum. This degree of sophistication has been generated by the study of hundreds of peptides in protein sequence analyses so that valuable sequence information can now be obtained from spectra, the interpretation of which might well have been abandoned 10 years ago because of 'ambiguous' assignments.

Strategy

Strategy is crucial to the ultimate success of mass spectrometric determination of biological structures. For example, should one use 'classical' enzymes, like trypsin, for an initial digestion of the protein followed by purification of all the peptides and redigestion of the larger ones? What purification methods will be compatible with mass spectrometry? Is it better to purify the peptides or their derivatives? And what derivatives should be made? Is it best to use high resolution, low resolution, electron impact or chemical ionization? Some of these questions are interrelated; for example, the initial choice of a dipeptidyl aminopeptidase (cathepsin) digest would exclude the production of derivatives by permethylation and would probably lead to gas chromatography–mass spectrometry (GC–MS) separation and identification of dipeptides. Such procedures have been developed[15] but have not yet been applied to proteins of unknown structure. Other GC–MS methods which have been developed include the examination of mixtures of small peptides as trifluoracetyl permethyl derivatives[16] or as polyamino alcohols[17,18].

The most widely applied mass spectrometric method used to date has been low resolution direct probe analysis of peptide mixtures[4,9]. The great advantage of this approach is that it can deal effectively with mixtures of all sizes of peptide from 2 to 15 residues and above. The ability to sequence unambiguously a mixture of peptides is unique to mass spectrometry[13], but the significance of this statement is only grasped when one realizes that the isolation and preparation of individual purified peptides is the rate determining step in any classical protein sequencing method; even when using an automated spinning cup sequencer, rarely more than 50–100 amino acids can be placed in sequence

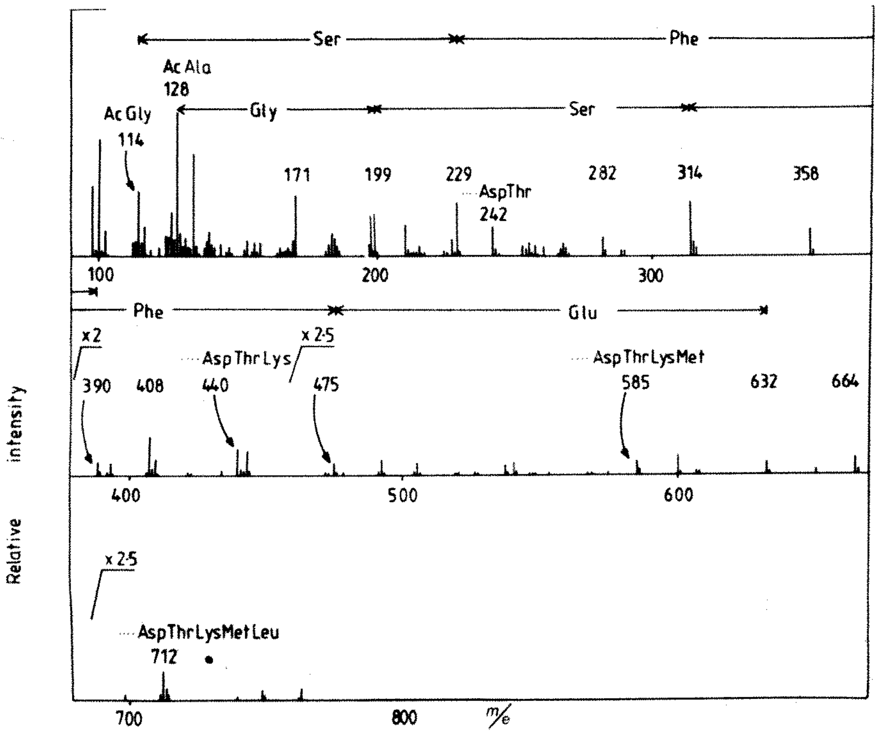

Fig. 2 A typical mass spectrum from the partially purified elastase digest of DHFR, at a source temperature of 240 °C. The assignment of major sequence ions is given, together with a sequence derived from N–C cleavage at aspartic acid. The latter assignment was made by working from high to low mass in the spectrum, looking for amino acid mass differences and expected losses (for example, methanol from Ser or Thr) until *m/e* 242. Since *m/e* 242 loses methanol to *m/e* 210, it must contain either a Ser or Thr. 242 minus serine (115 mass units) is 127—a meaningless N-terminal signal; however, 242 minus threonine (129 m.u.) is 113, which although not an abundant fragment (not well stabilized), is assigned to N–C cleavage at Asp, thus generating the sequence Asp-Thr-Lyr-Met-Leu. This, and the other sequences shown, were extended to higher mass at higher source temperatures[9].

by studying the intact protein. Mixture analysis provides a much needed way of bypassing this rate limiting step in the overall strategy. The principle is one of fractional distillation of the individual peptides from the mixture on the probe tip within the mass spectrometer, using either the probe or ion source heater[13,19]; the signals associated with any one peptide in the mass spectrum will rise and fall together at different rates to other components in the mixture, depending upon the separation achieved. The result is that each component can normally be sequenced unambiguously, the method being best suited to mixtures of two to five peptides.

To complete the strategy one needs a method of producing peptides of less than about 1,500 molecular mass. Cathepsins can be used[15], but they generate dipeptides, thus destroying the valuable 'overlap' information present in larger peptides. In contrast, trypsin or chymotrypsin may produce fragments too large for the mass spectrometer, and acid hydrolysis leads to loss of amides and other possible complications. It is best, therefore, to use nonspecific proteases, such as thermolysin[5], elastase[19] or subtilisin[20], which produce small peptides (2–15 residues) of ideal size for mass spectrometry.

The overall strategy developed is well illustrated by the study of the sequence of dihydrofolate reductase from methotrexate-resistant *Lactobacillus casei*. Here several digests were utilized, including elastase and subtilisin, and the large cyanogen bromide fragments isolated, to overlap and place the many peptides produced into a final sequence[8,9].

Peptide digests are separated by only one cation exchange column step, the effluent being screened analytically by high voltage paper electrophoresis before pooling of peptide mixture fractions, and derivatization. A typical spectrum from the elastase digest, together with its interpretation, is seen in Fig. 2.

Dihydrofolate reductase is the first protein of unknown structure to be fully sequenced by mass spectrometry without the aid of classical methods. Interestingly, with a molecular mass of 18,000 this must be the largest molecule ever to have had its structure determined by mass spectrometry[9].

New developments in computer automation of the interpretation of mass spectra—at present a skilled task—promise to reduce the time required to sequence a 20,000 dalton protein to about two man months. That, combined with the fact that in experienced hands one needs only 5–30 nmol of a peptide to sequence it, makes mass spectrometry both a complementary approach and a highly competitive alternative to classical techniques of protein sequencing, regardless of whether one chooses the GC–MS method[16–18] or the direct probe analysis method[4,5].

Glycopeptide analysis

Although glycopeptides are increasingly being recognized as an important group of substances, the determination of their structures has proven to be an especially difficult problem. It is difficult in that the structures are complex, demanding information on (1) protein sequence, (2) carbohydrate sequence, (3) nature of protein–carbohydrate linkage, for example O-glycosidic to serine, (4) nature of saccharide–saccharide linkage, for example 1–4, 1–3, and (5) configuration of linkage(s). In seeking such information, mass spectrometry offers the great advantage that it does not suffer from restrictions of compound class as do chemical approaches to the structure; given the normal difficulties encountered with any polar molecule, mass spectrometry can provide information on both the carbohydrate and protein structure from the same experiment. For example, it was necessary to study only two derivatives of AF8, an 'antifreeze' glycopeptide isolated from Antarctic fish blood plasma[21], to obtain information on each of the first four points above.

The peptide sequence of AF8 was established by studying the electron impact (N-terminal) and chemical ionization (C-terminal) spectra of an acetyl permethyl derivative of the glycopeptide. The spectra showed evidence of heterogeneity in several positions of the 14-residue peptide sequence (Fig. 3*a*), and the points of attachment of carbohydrate were clearly visible by the assignment of dehydrothreonine, formed by β-

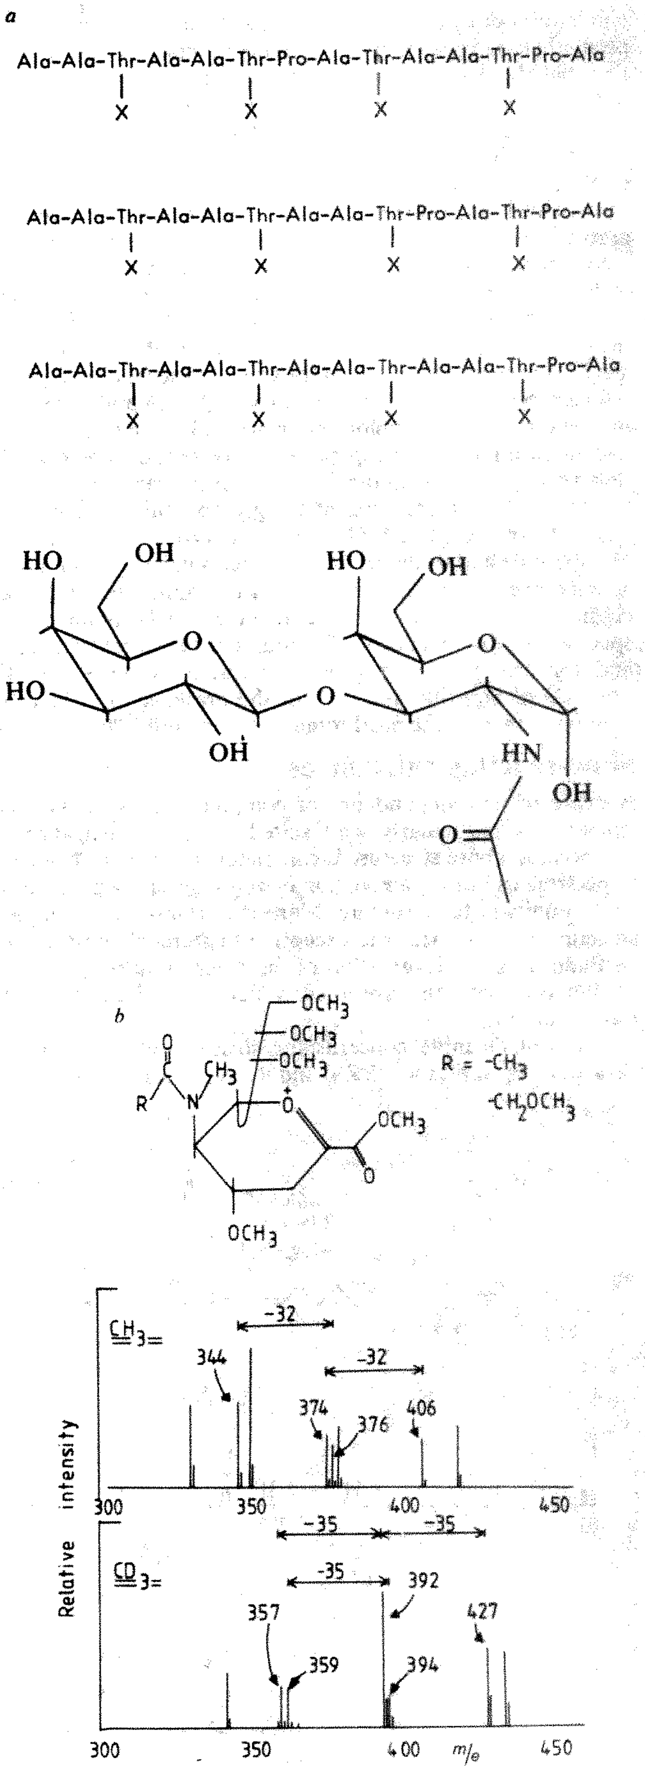

Fig. 3 *a*, The structure of the glycopeptide AF8 as deduced by electron impact, chemical ionization and field desorption mass spectrometry. *b*, The partial mass spectrum of a fragment of the glycoprotein prothrombin showing the presence of *N*-acetyl and *N*-glycolyl neuraminic acids. Sequence ions were confirmed by the stable isotope experiment shown.

elimination of carbohydrate during addition of the base in the permethylation reaction. Without any necessity for pre-separation, the eliminated permethyl carbohydrate was observed at a different source temperature (fractional distillation) and the sequence assigned as hexosyl-acetamidohexosamine. Interpretation of linkage between saccharides is normally based upon relative abundances of fragment ions which are much more pronounced in pertrimethylsilyl[22] rather than permethyl derivatives. In a separate experiment, the carbohydrate was eliminated from the peptide using sodium hydroxide, and again without any purification or separation, a trimethylsilyl derivative was prepared. Comparison of the spectra produced with those of standard 1–4 and 1–3 linked carbohydrates allowed an assignment of a 1–3 linkage in the amino disaccharide (Fig. 3*a*).

The potential of mass spectrometry in glycopeptide analysis is further illustrated by exploratory work on known structures[23,24] and on the unknown glycopeptide portion of the blood coagulation zymogen prothrombin[25]. Here, considerable information has been derived from one of the glycopeptides of molecular weight 4,500 (ref. 25). *N,O*-permethyl derivatives of the intact glycopeptide and its degradation products have been studied to characterize a number of sequences containing up to 10 saccharide units. Interestingly, several of the signals obtained in the spectra are very diagnostic of certain unusual saccharide units, and for example, have given conclusive evidence (via the presence of *m*/*e* 406 and 374) of the presence of *N*-glycolylneuraminic acid in the prothrombin glycopeptide[25] (see Fig. 3*b*).

Slow-reacting substances

Because of its independence of compound class, mass spectrometry is particularly well suited to the investigation of compounds whose structure is completely unknown. As long as a spectrum can be obtained, it may well suggest the presence of certain units in the structure. More importantly, the complete structure (usually with the exception of stereochemistry) may be deduced by interpretation of the fragmentation pattern in conjunction with the observed molecular weight (from the molecular ion).

A recent example concerns the structure elucidation of a slow-reacting substance (SRS) and its close relative, slow reacting substance of anaphylaxis, SRS-A[26], which is a mediator released from lung on antigen challenge, and believed to give rise to allergic bronchospasm (asthma) in man.

The structures of these pharmacologically similar substances have remained unknown since their discovery some 40 years ago[27]. Chemical clues have been uncovered (for example the probable incorporation of arachidonic acid and cysteine by radio-labelling experiments[28]), but these have been unconvincing because of the lack of purity of the preparations, and attempts to define the structures of SRSs have relied upon degradative experiments which are inevitably open to question[29]. Recently, following the earlier development of an HPLC purification procedure for SRS-A and the demonstration of its UV spectrum[30], the structures of SRS and SRS-A have been determined, based on the first mass spectra of derivatives of the intact molecules[31,32]. The SRS spectrum is shown in Fig. 4*a*. Definitive statements about the structure can now be made because of the exact physicochemical measurements available from the mass spectrum. For example, the molecular weight greatly reduces the number of structural possibilities, particularly since we can define this to five decimal places thus giving the atomic composition of this SRS. We can, however, go much further and use the fragmentation pattern of the molecule to define unambiguously the respective positions of certain structural features in the molecule. A detailed interpretation would not be appropriate here but some guidance is given in Fig. 4. In this way, we can show that SRSs form a novel class of 'peptidolipid'[31,32] and, in particular, SRS from rat basophil leukaemia cells and SRS-A from guinea pig lung are assigned the structure shown in Fig. 4*b*, and do not correspond to the recently revised structure of another SRS, termed leukotriene C[33]. Human lung SRS-A has previously been shown to co-chromatograph with guinea pig lung SRS-A[34], strongly suggesting that this also is the dipeptidyl structure shown in Fig. 4*b*.

Thus the mass spectrum can give a confidence of structural assignment on very small quantities of material (the above work was accomplished using less than 10 μg total material) in a manner unparalleled by any other physical or chemical technique. Importantly, the mass spectrum also shows what is *not* present in the structure; for example, we can say that neither the

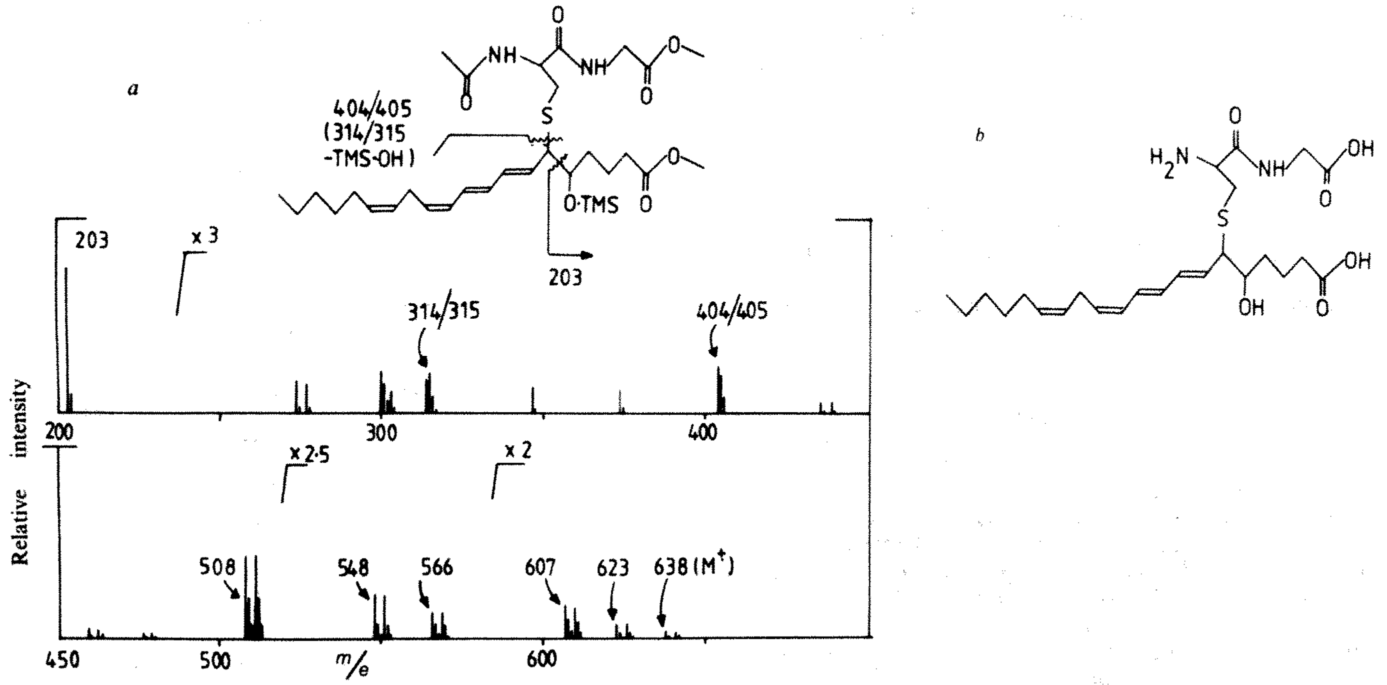

Fig. 4 *a*, The first mass spectrum of a slow reacting substance (SRS), as the trimethylsilyl ether of the *N*-acetyl, methyl ester derivative[31]. Analytical protein chemical data together with experiments on the destruction of biological activity had indicated the presence of a primary α-amino group in SRS and SRS-A[35]. The molecule was therefore located and differentiated from background by preparing the I:I ($^2H_3$:H_3) acetyl derivative of the unknown. The doublet signals found in the spectrum allowed unambiguous location of those ions corresponding to the unknown SRS, showing a molecular ion at *m*/*e* 638 and associated losses of CH_3 and OCH_3 at *m*/*e* 623 and 607 respectively. Signals at *m*/*e* 404, 405 and 314, 315 (loss of TMSOH) are diagnostic for the peptide attachment (C_6-S bond) and the arachidonate-derived portion of the molecule. *b*, The structure of the major SRS[31] from rat basophil leukaemia cells (RBL-1) and of SRS-A[32] from guinea pig lung, deduced from the above spectrum and associated data to be 5-hydroxy-6-cysteinyl-glycinyl-7,9,11,14-eicosatetraenoic acid. The mass spectrum does not define stereochemistry.

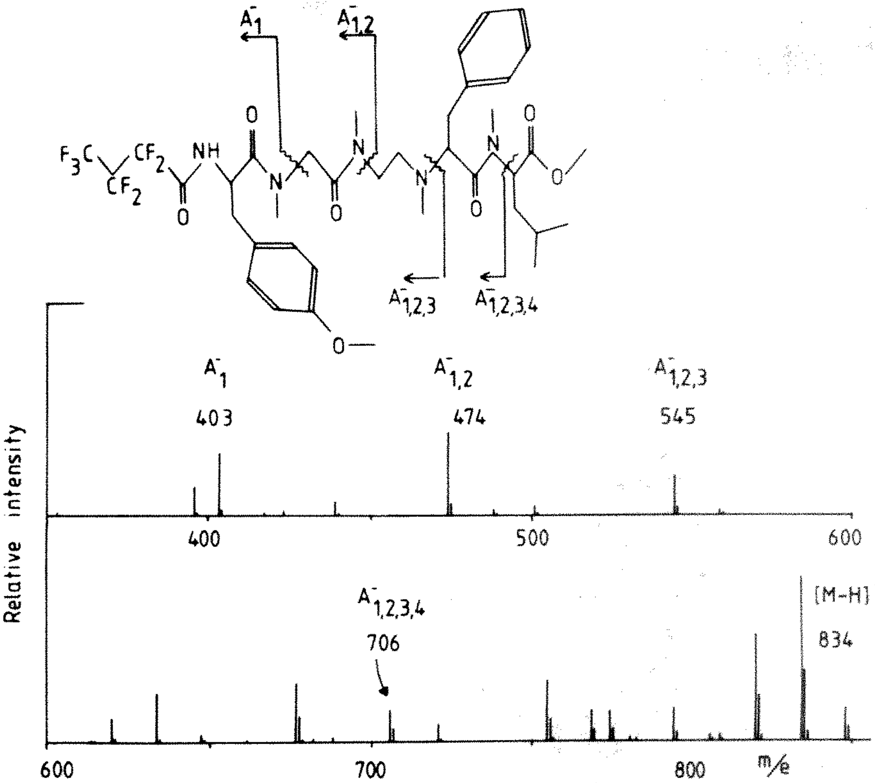

Fig. 5 The negative chemical ionization (NCI) spectrum of 1 nmol of leucine enkephalin as the *N*-heptafluorobutyryl permethyl derivative (A. Buko, D. F. Hunt, M. Judkins and H.R.M., unpublished work). The spectrum shows the increased relative abundance of high mass signals compared with typical EI or CI spectra (no amplification factors in drawing), together with retention of sequence ion information leading to structure (A_1, $A_{1,2}$ etc.) NCI spectra can be obtained routinely using this type of derivative at the 1 nmol level or less.

RBL-SRS nor the lung SRS-A contain a glycineamide or sulphoxide which would be difficult to discount by chemical or enzymatic methods. Similarly we can say that they do not contain a sulphate moiety, widely expected from the results of destruction of biological activity by aryl sulphatase, reported in the literature.

New and novel amino acids, and 'blocked' proteins

Another important area of biochemistry in which mass spectrometry is playing a significant role is in the study of enzymatic regulation and control in the blood coagulation system.

As with the SRS study above, perhaps the most obvious strength of the mass spectrometric method is in the area of new structures, where no reference compounds exist with which to make a classical interpretation. Just such a situation arose quite surprisingly in 1974 from a sequence study of one of the blood coagulation zymogens, prothrombin. The outcome of this work was the discovery of a new amino acid, γ-carboxyglutamic acid (Gla), and its sequence location in 10 positions in the N-terminal region of prothrombin[36–38]. This amino acid was missed in classical sequencing procedures (in fact it was assigned as ordinary glutamic acid) due to a ready decarboxylation during Edman degradation or hydrolysis in the dansyl procedure.

Since this discovery, there has been considerable interest in the function and occurrence of Gla. In the original work on the identification of Gla, two unique mass spectrometric signals and two unique mass differences were established. These are diagnostic for the new amino acid and the observation of these signals in a mass spectrum allows a definitive assignment not just of the presence of Gla in a peptide but also of its exact location in the sequence[38]. Thus a recent study of the N-terminal portions of factors X_1 and X_2 (derived by activation of the zymogen factor X) has shown each to contain 12 Gla residues and the two sequences to be identical[39].

It should be clear from an understanding of the methods discussed earlier, that the assignment of novel amino acids, such as *N*-methyl lysine, in a peptide sequence reduces to an almost trivial problem. The use of perdeutero-methyl iodide in the permethylation reaction will allow assignment of natural methyl groups simply by counting the mass spectrum (normal lysine would have a mass of 204 mass units, whereas *N*-Me lysine would have a mass of 201 mass units).

Deuterated reagents may also be used to define the presence (or absence) of blocking groups on proteins or peptides. There are now a number of examples in the literature[40–43], including a method for use on proteins[44], which obviates the necessity for isolation of the blocked N-terminal peptide.

Neurochemistry

Mass spectrometry is playing an increasingly important part in studies on neuropeptides isolated, inevitably in very small quantities, from the central nervous system. Not only the quantity but also the purity may be inadequate for classical structural determination and, furthermore, the confidence in sequence assignment normally associated with protein sequence studies is not available when the sample is not necessarily of protein origin, and, therefore, may have unusual amino acids, unusual linkages or even may not be a peptide at all.

Such a situation occurred in the study of enkephalin, where amino acid analysis, gel column and electrophoretic data did not correlate well with the partial sequence data obtained by the dansyl–Edman method, and an ultraviolet fluorescence measurement raised the further possibility of a 'modified' tryptophan in the molecule[45]. Using the mass spectrometric methods developed for protein sequence analysis, it proved possible to identify two enkephalin pentapeptides, Tyr-Gly-Gly-Phe-Met and Tyr-Gly-Gly-Phe-Leu[46]; once the mass spectrometric sequence assignment had been made, and the tryptophan analogue discounted, then the classical data were found to correlate reasonably well with this interpretation.

A number of biologically active neuropeptides have been shown to possess blocked structures, and these pose considerable problems for classical methodology, but fewer problems for mass spectrometry since free peptides would be 'blocked' before study by making derivatives. The difference in 'degree of difficulty' is really quite remarkable here when we consider that the pioneering work on the structure elucidation of thyrotropin releasing hormone (TRH)[47,48] took some 10 years, and even today the structure of this simple blocked tripeptide would pose very considerable problems for the protein chemist to define, as an unknown. By contrast, the presence of blocking groups actually assists in the mass spectrometric investigation since the formation of a derivative for such a small peptide is no longer necessary. Of course, larger blocked structures still require derivative formation to remove hydrogen bonding and a recent example of this type of problem is the study of adipokinetic hormone[49], isolated from locust and responsible for lipid mobilization during flight. The mass spectrum of a permethyl derivative of adipokinetic hormone showed a pyrrolidone carboxylate group (*m/e* 98 and 126) blocking the N-terminus, and a signal at *m/e* 428 was interpreted as arising from a C-terminal amide: ... Trp-Gly-Thr-NH_2. The total structure was assigned as a fully blocked decapeptide, PCA-Leu-Asn-Phe-Thr-Pro-Asn-Trp-Gly-Thr-NH_2, and was the first peptide hormone of insect neuroendocrine origin to be completely characterized.

New developments

Several new technical developments promise to improve the analytical value of mass spectrometry still more. Space does not permit a detailed discussion, but briefly the areas covered include ionization techniques giving molecular weight information on underivatized peptides and glycopeptide antibiotics[50,51] (field desorption), new approaches to improve sensitivity of detection based upon negative chemical ionization[1,52], and developments in magnet technology which have already led to a tripling of the effective mass range of the mass spectrometer at full sensitivity, to over *m/e* 3,000. The potential of negative chemical ionization in the neurochemical area is illustrated in Fig. 5 showing the spectrum of a Leu-enkephalin derivative, illustrating the derivation of full sequence information at the 1 nmol level.

Thus mass spectrometry is of growing value in the determination of the structure of compounds of biological interest. It is already the method of choice in some cases and is likely to become so in others as the technique develops. In combination with procedures such as high pressure liquid chromatography which can separate picomolar quantities of peptides[53,54], mass spectrometry promises to allow the solution of further important chemical and biochemical problems, only just beyond the scope of present technology.

ARTICLES

Evidence for differential intracellular localization of the *Acanthamoeba* myosin isoenzymes

Hana Gadasi & Edward D. Korn

Laboratory of Cell Biology, National Heart, Lung, and Blood Institute, Building 3, Room B1-20, National Institutes of Health, Bethesda, Maryland 20205

The three myosin isoenzymes of Acanthamoeba castellanii *coexist within a single cell and the native molecules probably have the same unusual polypeptide composition as the isolated enzymes. The two myosin I isoenzymes seem to be preferentially localized near the plasma membrane while myosin II seems to be much less concentrated near the plasma membrane than elsewhere in the cytoplasm.*

ACTIN and myosin provide the molecular basis for the diverse motility activities of eukaryotic cells[1]. Actins from muscle and non-muscle cells are very similar in structure and properties and almost all of the myosins are also structurally similar, containing a pair of heavy chains of molecular weight (MW) ~200,000 and two pairs of light chains with MWs of about 20,000 and 16,000. Because these non-muscle myosins can also self-assemble into bipolar filaments, it is widely, and not unreasonably, assumed

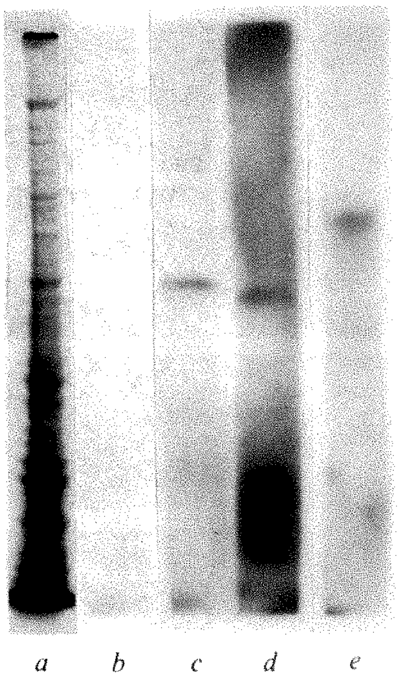

Fig. 1 Specificity of the reactions of the *Acanthamoeba* myosin heavy chain antibodies with polypeptides of whole amoebae. A centrifugal pellet of intact *Acanthamoeba castellanii* (0.1 ml) was boiled for 20 min in 3 ml sample buffer[8] containing 1% SDS, 5 mM EGTA, 5 mM EDTA, 0.5 mM phenylmethylsulphonyl fluoride and 0.1 mM pepstatin. Aliquots of 75 μl each were applied to multiple lanes of 5.6% polyacrylamide slab gels and electrophoresed according to Laemmli[8]. The polypeptides in one lane were stained with Coomassie blue and the polypeptides in the other lanes were transferred to diazobenzyloxymethyl paper as described in the text. The paper was cut into strips corresponding to individual lanes which were then exposed to one of four rabbit IgG fractions (1 : 50 dilution) and ^{125}I-labelled protein A (1×10^6 c.p.m. per lane) as described in the text. Autoradiographs were exposed for 18 h using Kodak no screen X-ray film NS 2T. Lane *a*, Coomassie blue stained polypeptides; lane *b*, non-immune IgG; lane *c*, anti-myosin IA heavy chain IgG; lane *d*, anti-myosin IB heavy chain IgG; lane *e*, anti-myosin II heavy chain IgG. The MWs of the radioactive bands in lanes *c*, *d* and *e* are 130,000, 125,000 and 170,000, respectively, relative to standards applied to the same gels, and their electrophoretic mobilities were identical to those of the heavy chains of the corresponding purified myosins on the same gels. Broad smears of apparent labelling (as in lane *d*) are common but irreproducible occurrences[9,11]. Occasionally, minor degradation products of the heavy chains were detected.

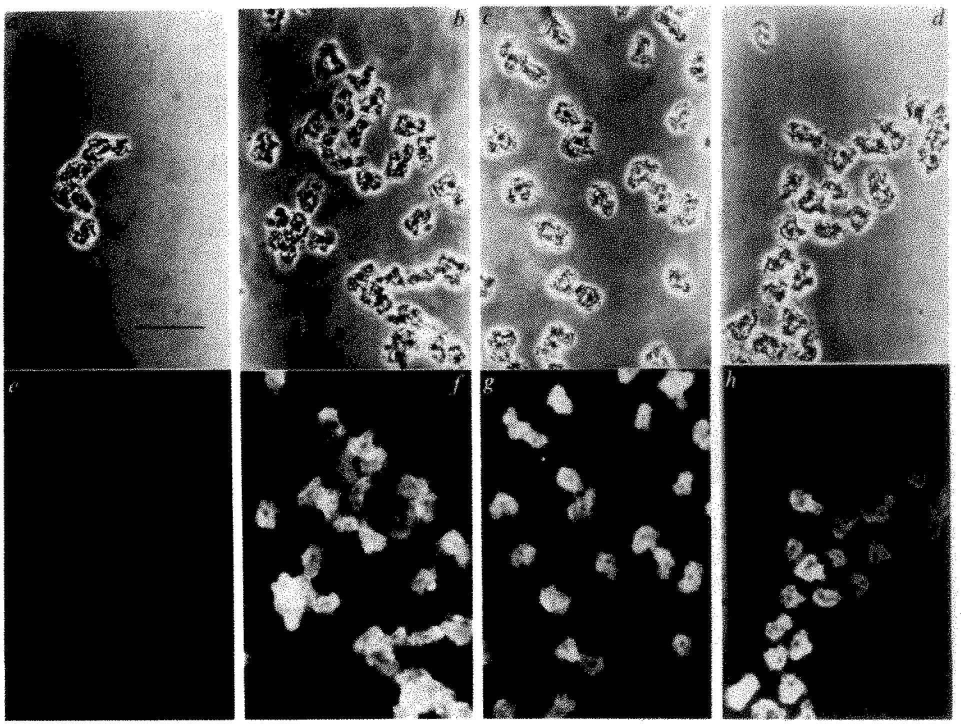

Fig. 2 Indirect immunofluorescence assay of the reaction of *Acanthamoeba castellanii* (Neff strain) with myosin heavy chain antibodies. Cells were allowed to adhere to clean glass slides and were fixed with 5% formaldehyde in phosphate-buffered saline (PBS) for 30 min and then treated with cold (−20 °C) acetone for 5 min. They were then sequentially treated with non-immune IgG in PBS, one of the specific antisera (1:200 dilution in PBS containing 1% bovine serum albumin (BSA)) and rhodamine-labelled goat anti-rabbit IgG (1:200 dilution in PBS containing 1% BSA). The cells were washed in 1% BSA in PBS between each treatment. Cells were photographed under phase contrast and fluorescent microscopy at the same magnification. All fluorescent microscopy photographs were made with 30 s exposure and were printed identically. Frames *a–d* are phase contrast and *e–h* are fluorescent micrographs of cells reacted with: *a*, *e*, non-immune IgG; *b*, *f*, antimyosin IA heavy chain IgG; *c*, *g*, anti-myosin IB heavy chain IgG; *d*, *h*, anti-myosin II heavy chain IgG. Scale bar, 40 μm.

that a sliding filament mechanism analogous to that responsible for contraction of skeletal muscle is responsible for activities such as amoeboid movement, cell division and phagocytosis in non-muscle cells.

The three myosin isoenzymes isolated from *Acanthamoeba castellanii* (Neff strain) are the only known apparent exceptions. As isolated, *Acanthamoeba* myosins IA and IB[2–5] are both single-headed enzymes of MW about 150,000–180,000. Myosin IA contains a heavy chain of ~130,000 MW and light chains with MWs of about 17,000 and 14,000, while myosin IB contains a heavy chain of ~125,000 MW and light chains with MWs of ~27,000 and 14,000. Both enzymes seem unable to form bipolar filaments[2]. A third myosin isoenzyme, *Acanthamoeba* myosin II, is structurally more conventional[6,7] and can form bipolar filaments *in vitro*[7]. It is a double-headed molecule with a pair of heavy chains of about 170,000 MW and two pairs of light chains of about 17,500 and 16,000 MWs, for a native MW of about 400,000. We have shown by peptide mapping[4] and immunochemical analysis[5] that the three *Acanthamoeba* myosin isoenzymes are products of different genes.

Because of the unusual structure of two of the *Acanthamoeba* myosin isoenzymes and because no other non-muscle cell has yet been shown to contain more than one species of myosin, we thought it important to establish: (1) if the isolated enzymes are in their native forms; (2) if the isoenzymes coexist in a single cell; and (3) whether the myosin isoenzymes are differentially localized within the cell. We have now obtained affirmative answers to all three questions through the use of specific antibodies raised against the isolated heavy chains of the three myosin isoenzymes. The differential localizations of the isoenzymes raise the interesting possibility that the different myosin species serve specific and different motility functions, and the unusual

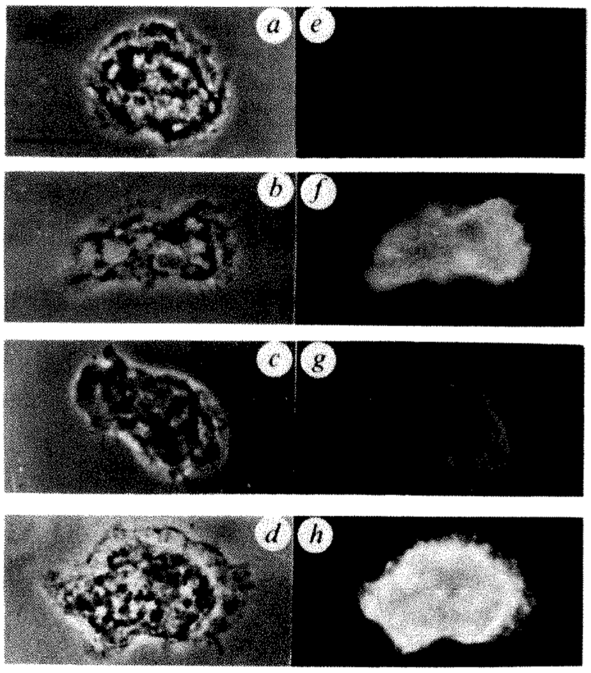

Fig. 3 Differential localization of myosin isoenzymes by indirect immunofluorescence. This experiment was identical to that described in Fig. 2. Frames *a–d*, phase contrast; *e–h*, fluorescence; *a, e*, non-immune IgG; *b, f*, anti-myosin IA heavy chain IgG; *c, g*, anti-myosin IB heavy chain IgG; *d, h*, anti-myosin II heavy chain IgG. Scale bar, 10 μm.

physical properties of the myosin I isoenzymes suggest that some of these functions might not involve the classical sliding filament mechanism.

Preparation of heavy chain antibodies

Previously[5], we had raised antibodies against the isolated myosins. Although the enzymes were highly purified, they were contaminated by small amounts of other amoeba proteins, which might also have elicited sufficient antibodies to make those antisera inappropriate for cytochemistry. Therefore, monospecific myosin heavy chain antibodies were prepared as follows. Highly enriched preparations of *Acanthamoeba* myosins IA, IB and II were obtained by direct immunoprecipitation with the appropriate antibodies previously raised against the isolated enzymes. The immunoprecipitates were separated by electrophoresis[8] on SDS-5.6% polyacrylamide slab gels and the gels were stained lightly with Coomassie blue. In each case[5], only a single major band, corresponding in mobility to the 130,000, 125,000 and 170,000-MW heavy chains of myosin IA, IB and II, respectively, was present above the dye front. These bands were cut out, washed, sonicated and injected into rabbits to elicit specific antibodies against each of the three heavy chains. Prepared in this way, the only possible contaminating antigens from the amoebae would be molecules which were precipitated from the amoeba extract by the antibody raised against the whole myosin and which also co-migrated electrophoretically with the myosin heavy chain. Such coincidence is unlikely. Immune and non-immune sera were precipitated with 45% ammonium sulphate and the IgG fractions were dissolved in phosphate buffered saline.

Specificity of heavy chain antibodies

We tested, in the same experiment, both the specificity of the three myosin heavy chain antisera and the possibility that higher molecular weight forms of the heavy chains might exist in the amoebae. Whole amoebae were boiled in 1% SDS containing several inhibitors of proteolytic enzymes and multiple identical samples were separated by SDS-polyacrylamide slab gel electrophoresis. One lane was excised and stained for polypeptides with Coomassie blue while the polypeptides in the duplicate lanes were transferred to diazobenzyloxymethyl paper[9]. The paper was cut into individual lanes which were incubated with a large excess of either non-immune sera or one of the specific myosin heavy chain antibodies followed by ^{125}I-protein A (ref. 10) and the positions of the bound antibodies were located by autoradiography.

The antibodies raised against the isolated heavy chains of myosin IA, IB and II reacted exclusively (Fig. 1) with polypeptides of molecular weights corresponding exactly to those of the heavy chains of the purified enzymes: 130,000, 125,000 and 170,000, respectively. Similar results have been obtained in 15 to 20 experiments including some in which the polypeptides were reacted with the antisera on the polyacrylamide gel without transfer to the paper. Occasionally, minor degradation products of the myosin heavy chains were detected but never a polypeptide of higher molecular weight than that of the heavy chains of the purified myosins. Degradation products were never detected when extracts of amoeba, rather than whole cells, were analysed, probably because the lysosomal proteases were removed before addition of SDS. To demonstrate that, if it were present in the amoebae, a polypeptide of the size typical of the heavy chains of other myosins would have been detected, we mixed pure chicken pectoralis muscle myosin with a sample of the amoebae just before they were added to the SDS solution. The undegraded 200,000-MW heavy chain of the chicken myosin was readily detected using its specific antibody. These experiments, therefore, provide strong evidence that the cells do not contain immunologically cross-reactive higher molecular weight forms of the heavy chains of *Acanthamoeba* myosins IA, IB and II.

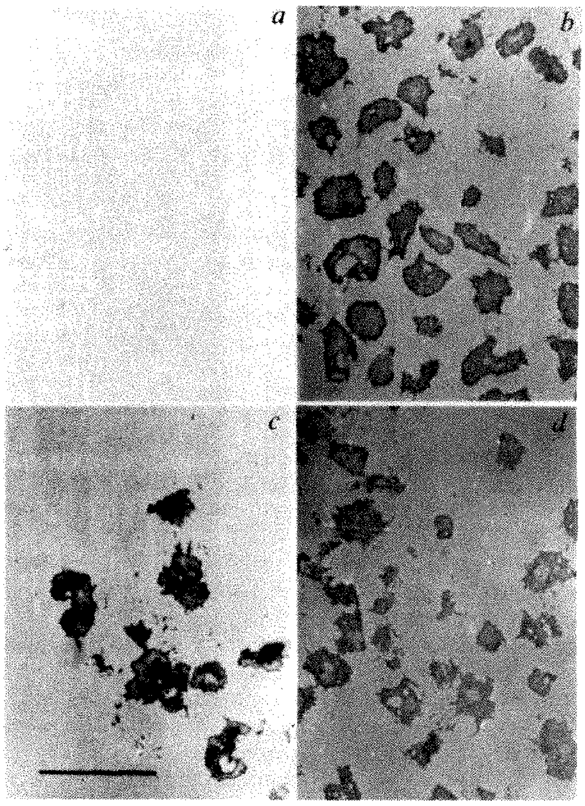

Fig. 4 Immunocytochemical localization of myosin isoenzymes. Sections (1 μm) were reacted with specific antisera (1 : 250 dilution) and subsequently with the peroxidase–anti-peroxidase system as described in the text. All micrographs were photographed and printed under identical exposures. Frame *a*, non-immune IgG; *b*, anti-myosin IA heavy chain IgG; *c*, anti-myosin IB heavy chain IgG; *d*, anti-myosin II heavy chain IgG. Scale bar, 40 μm.

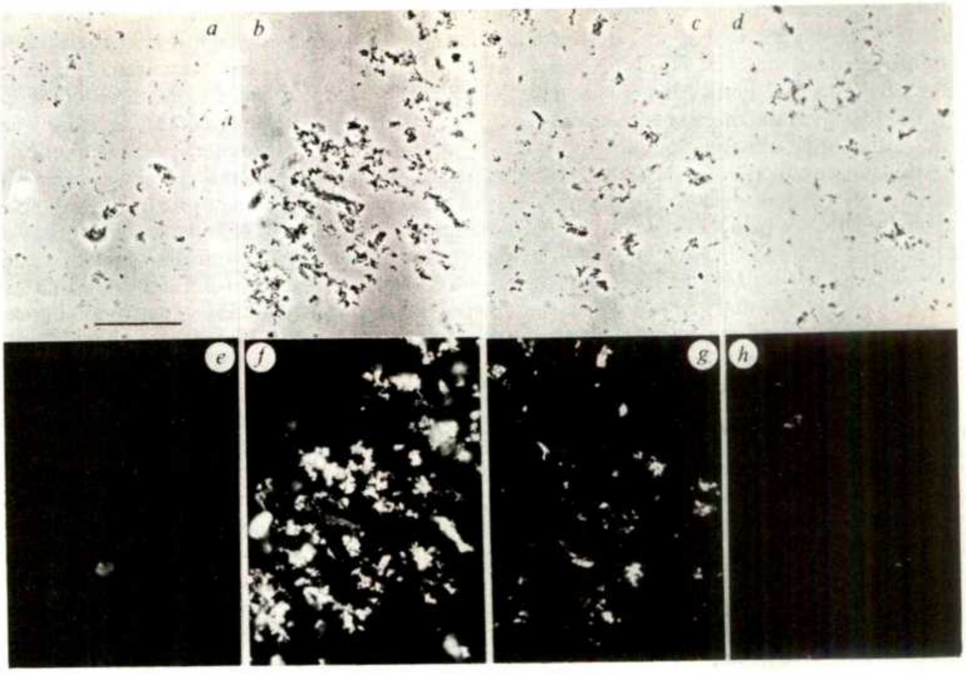

Fig. 5 Indirect immunofluorescence assay of isolated plasma membranes. Suspensions of purified plasma membranes[16] were fixed for 30 min with 3.7% formaldehyde and then reacted with specific antisera (1:50 dilution) followed by rhodamine-labelled goat anti-rabbit IgG (1:200 dilution). The membranes were then applied to slides and the same fields were photographed under phase contrast (*a*–*d*) and fluorescence (*e*–*h*). Exposure time was 20 s and all the fluorescent micrographs were printed under identical exposures. Non-immune IgG (*a*, *e*); anti-myosin IA heavy chain IgG (*b*, *f*) anti-myosin IB heavy chain IgG (*c*, *g*); anti-myosin II heavy chain IgG (*d*, *h*). Scale bar, 40 μm.

Myosin isoenzymes occur in the same cells

The data shown in Fig. 1 demonstrate that the antibodies to the myosin heavy chains could be used in cytochemical experiments to detect myosin II and the two myosin I isoenzymes in the presence of each other and without interference by other amoeba proteins. Although the antibodies to myosin IA and IB heavy chains also did not seem to cross-react (Fig. 1, lanes *c*, *d*), we were not certain that we could selectively detect myosin IA or IB in the presence of the other because previous antisera to the purified intact myosins IA and IB did cross-react[5] and because direct inspection of some of the autoradiograms obtained with antibody to myosin IA heavy chain indicated slight reaction with the 125,000-MW heavy chain of myosin IB.

We used the indirect immunofluorescence method to determine if each of the *Acanthamoeba* myosin isoenzymes occurs in every cell. Amoebae were allowed to crawl on clean glass slides[12]. The cells that adhered were fixed with formaldehyde and made permeable to antibodies by treatment with cold acetone. Cells were then exposed to antibodies to either myosin IA heavy chain, myosin IB heavy chain or myosin II heavy chain followed by rhodamine-labelled goat anti-rabbit immunoglobulin[13]. The same fields of cells were photographed at low magnification (×160) under phase contrast (Fig. 2*a*–*d*) or fluorescence (Fig. 2*e*–*h*) microscopy. As every cell on all of the slides was fluorescent irrespective of which of the three specific antisera was used, all the cells must have contained myosin II and at least one, but probably both, of the myosin I isoenzymes.

Intracellular localization of myosin isoenzymes

In Fig. 2, the fluorescent image of every cell exposed to the antibodies to myosin IA and myosin IB heavy chains is the same size as the corresponding phase contrast image (Fig. 2, *f* compared with *b* and *g* compared with *c*), whereas the fluorescent image of every cell exposed to the antibodies to myosin II heavy chain is smaller than the corresponding phase contrast image (Fig. 2, *h* compared with *d*). The reason for this difference can be seen at higher magnification, as in Fig. 3. Antibodies to myosin IA and IB heavy chains were bound more intensely at, or near, the plasma membrane than elsewhere in the cell (Fig. 3*f*, *g*) and, therefore, the fluorescent images of the cells have the same overall dimensions as the phase contrast images (Fig. 3*b*, *c*). On the other hand, the periphery of the cell and the cytoplasmic region adjacent to the plasma membrane reacted much less well with antibodies to myosin II heavy chain than did the rest of the cytoplasm (Fig. 3*h*). As a result, the fluorescent image of the cell is smaller than the corresponding phase contrast image (Fig. 3*d*). Therefore, the myosin I isoenzymes seem to be more concentrated at or near the plasma membrane, from where myosin II is mostly excluded. No reaction was detected with any antisera unless the cells were made permeable; none of the antigenic sites, therefore, is on the external surface of the amoeba.

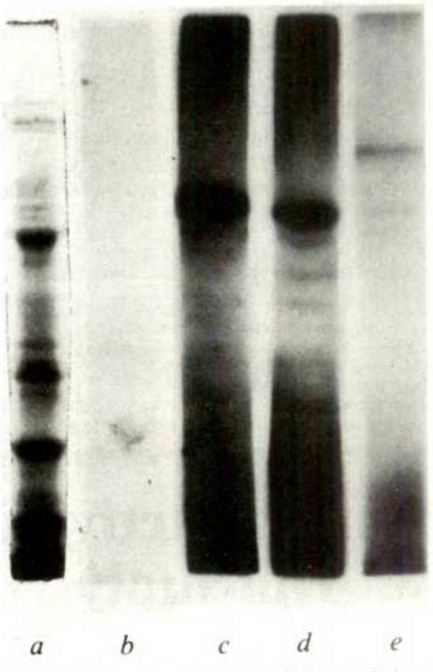

Fig. 6 Reaction of *Acanthamoeba* myosin heavy chain antibodies with plasma membrane polypeptides. Isolated plasma membranes of *Acanthamoeba castellanii* (Neff) were analysed identically as described for whole cells except that 7.5% polyacrylamide gels were used. Lane *a*, Coomassie blue stained polypeptides; lane *b*, non-immune IgG; lane *c*, anti-myosin IA heavy chain IgG; lane *d*, anti-myosin IB heavy chain. The autoradiograms (lanes *b* and *d*) were overexposed to detect the very low reaction with myosin II heavy chain and, therefore, minor degradation products of some of the heavy chains and nonspecific smears, may be detected in addition to the major bands. The major bands in lanes *c*, *d* and *e* are at the exact positions of the heavy chains of the respective purified myosins which were applied as standards to the same slab gel.

Additional evidence for the differential localization of *Acanthamoeba* myosins I and II was obtained by an independent immunochemical method. Transverse sections of cells fixed in glutaraldehyde and embedded in polyethylene glycol[14] were exposed to one of the three specific antisera and incubated with goat anti-rabbit immunoglobulin followed by rabbit anti-peroxidase immunoglobulin coupled to horseradish peroxidase[15]. The position of the bound peroxidase was determined cytochemically by incubation for 30 min with the peroxidase substrates, diaminobenzidine and hydrogen peroxide. When antibodies to myosin IA and IB heavy chains were used (Fig. 4*b*, *c*), the cell boundary was intensely stained with brown reaction product, and the cytoplasm was diffusely stained, the antibodies to myosin II heavy chain resulting in only diffuse staining of the cytoplasm (Fig. 4*d*).

Myosins of isolated plasma membranes

By indirect immunofluorescence, isolated plasma membranes[16] were found to react with antibodies to myosin IA and IB heavy chains (Fig. 5*f*, *g*) but not with antibodies to myosin II heavy chain (Fig. 5*h*). Myosin IA and myosin IB were also concentrated in the isolated plasma membranes as determined by specific staining of SDS-polyacrylamide electrophoretic gels. The intensity of the radioactive labelling of the 130,000- and 125,000-MW polypeptides of myosin IA and IB was very much greater than the barely detectable labelling of the 170,000-MW myosin II heavy chain (Fig. 6), in contrast to the essentially equivalent labelling of the three polypeptides in electrophoretic gels of the whole amoebae (Fig. 1). Also, the absolute intensity of labelling of the 130,000- and 125,000-MW peptides was very much greater for the plasma membranes (Fig. 6) than for whole amoebae (Fig. 1), although the same amounts of protein were applied. Both myosin I isoenzymes, therefore, were enriched in the isolated plasma membranes in comparison with myosin II and also relative to their own concentrations in the whole amoebae.

Conclusions

From the data in this and previous papers from our laboratory, we conclude that *Acanthamoeba castellanii* (Neff) contains three myosin isoenzymes: single-headed myosins IA and IB and double-headed myosin II having heavy chains of the unusually low MWs of 130,000, 125,000 and 170,000, respectively. The myosin I isoenzymes seem to be preferentially localized at or near the plasma membrane while myosin II seems to occur mainly, if not exlusively, deeper in the cytoplasm. We do not know if the myosin I isoenzymes are bound directly to the isolated plasma membrane or are associated with the actin filaments that lie immediately under the plasma membrane[17] and co-purify with the plasma membranes[18,19].

We must consider, of course, the possibility that the experimental data do not accurately reflect the distributions of the myosin isoenzymes in the living amoebae. When cells are fixed, soluble myosins might precipitate, or attach to actin filaments, in places where they do not normally occur, or myosins might be lost from cells during the subsequent steps of the cytochemical procedures. Similarly, myosin isoenzymes might differentially redistribute during the isolation of plasma membranes.

However, although none of these possible sources of errors has been unequivocally eliminated, we think it unlikely that three entirely independent methods, fixation by formaldehyde, fixation by glutaraldehyde and isolation of plasma membranes, would have given the same misleading result. Moreover, myosin II is larger and less soluble than myosin IA and IB and all three purified myosins bind tightly to F-actin, which greatly stimulates their Mg^{2+}-ATPase activities. There is no reason to suppose, therefore, that myosin II would be preferentially extracted from, or that myosins IA and IB would selectively and artefactually bind to, just that region of the cell which is particularly enriched in actin filaments. Nonetheless, it is important that the observations in this paper be confirmed by independent methods.

Finally, if the myosin I and II isoenzymes are, as we suggest, differentially localized, it is likely that they function in different cellular activities with the myosin I isoenzymes being involved in processes, possibly such as endocytosis, that occur at or near the cell surface. Because of the unusual physical properties of myosin IA and IB, their functions may involve actomyosin interactions of a type not previously proposed.

We thank Dr Susan Lowey for chicken pectoralis muscle myosin and its antibody, Dr Blair Bowers for guidance in the immunocytochemical procedures, Dr Michael Bustin for help with the immunofluorescence studies, and Mr Thomas Olszewski and Mrs Margaret Clark for technical assistance.

Surface activation of blood coagulation, fibrinolysis and kinin formation

Ronald L. Heimark, Kotoku Kurachi, Kazuo Fujikawa & Earl W. Davie
Department of Biochemistry, University of Washington, Seattle, Washington 98195

The activation of plasma prekallikrein by single-chain factor XII has been studied in the presence of high molecular weight kininogen and kaolin. The data indicate that factor XII can initiate blood coagulation, fibrinolysis or kinin generation in the presence of kaolin and does so by converting prekallikrein to kallikrein. An enzyme cascade is then generated leading to the formation of fibrin, plasmin or bradykinin in three closely related physiological events.

THE initiation of the contact phase of blood coagulation by a surface, such as glass or kaolin, leads to an enzyme cascade resulting in fibrin formation[1–3]. A similar enzyme cascade occurs during the formation of plasmin in the surface-activated fibrinolytic system and the generation of kinin in the presence of a surface.

0028–0836/80/310456—05$01.00

The molecular basis for the initiation of these three closely related processes has been difficult to explain as two of the proteins involved in the surface activation reaction, factor XII (Hageman factor, ref. 4) and prekallikrein[5,6] (Fletcher factor), are present in plasma as zymogens to serine proteases. Furthermore, these two proteins have an unusual relationship to each other in that factor XII$_a$ converts prekallikrein to kallikrein[6–10], and kallikrein converts factor XII to factor XII$_a$ (refs 9, 11–16). Thus, it has been difficult to determine whether factor XII$_a$, kallikrein or some other protein is responsible for initiating these cascade reactions. A third plasma protein, high molecular weight kininogen[17–20] (HMW kininogen), stimulates the activation of prekallikrein by factor XII$_a$ and the activation of factor XII by kallikrein[21–26]. HMW kininogen seems to function as a cofactor in these reactions.

The role of factor XII and factor XII$_a$

Considerable attention has been directed towards factor XII as the principal protein involved in the surface activation of blood coagulation, fibrinolysis and kinin formation. Bovine and human factor XII are single-chain glycoproteins with molecular weights of about 74,000 (refs 27–29). The bovine preparation has no detectable esterase or amidase activity in the absence or presence of a surface, such as kaolin, dextran sulphate, or sulphatide[26,30]. Furthermore, it shows very little reactivity towards serine protease inhibitors, such as diisopropyl fluorophosphate or antithrombin III and heparin, in the absence or presence of a surface. Bovine factor XII$_a$ is composed of a heavy chain (MW 46,000) and a light chain (MW 28,000), and these two chains are held together by a disulphide bond(s)[30]. The two-chain protein has substantial esterase and amidase activity and readily activates prekallikrein[31] and factor XI$_a$ (ref. 32) by the cleavage of a specific internal peptide bond(s) in each of these proteins. Bovine factor XII$_a$ is also readily inhibited by diisopropyl fluorophosphate or antithrombin III and heparin[30]. In contrast, single-chain human factor XII possesses amidase activity when previously exposed to ellagic acid–Sepharose[33]. Human factor XII, however, reacts about 600 times more slowly with diisopropyl fluorophosphate than factor XII$_a$ in the presence or absence of kaolin[34]. Accordingly, it has been suggested that factor XII may participate in the initiation of blood coagulation as a weakly active zymogen[34]. In whole plasma, radiolabelled human factor XII was shown to be converted to factor XII$_a$ during the coagulation process[35]. It was not established, however, whether the activation of factor XII was an initial or a secondary event in the contact activation reaction. Furthermore, it has not been clear from the various studies on human and bovine factor XII whether the single-chain molecule or the two-chain factor XII$_a$ participates as a catalyst in the initial reactions involving prekallikrein and HMW kininogen.

Involvement of factor XII in factor XI activation

Recently, Saito[24] reported the activation of human factor XI (plasma thromboplastin antecedent) by factor XII in the presence of HMW kininogen and ellagic acid. No evidence was obtained to indicate that human factor XII was converted into lower molecular weight fragments during the reaction. We have studied the activation of bovine factor XI by single-chain bovine factor XII in the presence of sulphatide, dextran sulphate or kaolin plus HMW kininogen[32]. In the latter experiments, factor XI (MW 124,000) was converted to factor XI$_a$ (MW 124,000) by the cleavage of an internal peptide bond in each of the two nearly identical chains of the precursor molecule. The bovine factor XII was converted to factor XII$_a$ in the latter portion of this reaction, however, by the newly generated factor XI$_a$ (ref. 32). Homogeneous preparations of bovine factor XI (ref. 36), factor XII (ref. 27) and HMW kininogen[26] were used in these studies. The activation of factor XI by factor XII provided direct evidence to support the concept that single-chain factor XII can act as a catalyst, but only in the presence of a highly specific substrate and a negatively charged surface.

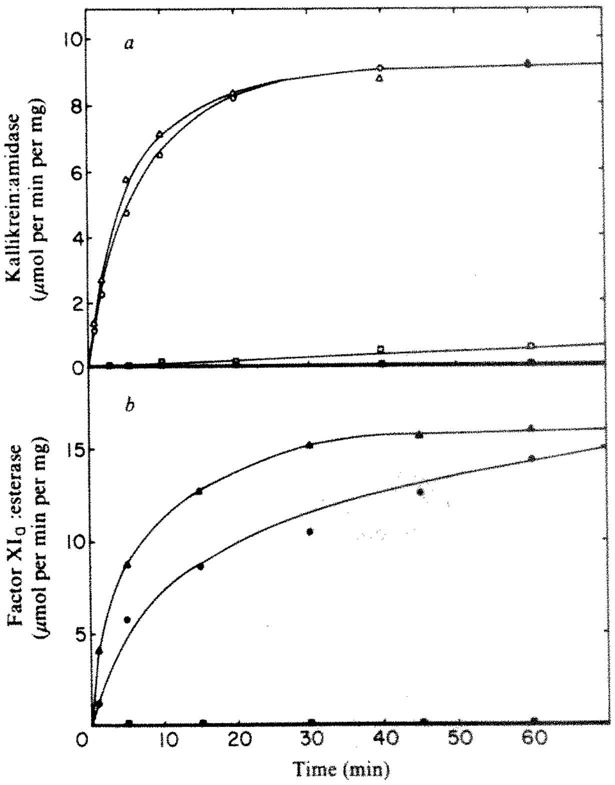

Fig. 1 Time course for the activation of *a*, plasma prekallikrein and *b*, factor XI by factor XII or factor XII$_a$ in the presence of HMW kininogen and kaolin. Factor XII or factor XII$_a$ (0.14 μg) was preincubated with HMW kininogen (0.4 μg) and kaolin (20 μg) for 5 min at 37 °C in 0.05 M Tris–HCl, *p*H 7.5, containing 0.1 M NaCl. Reactions were initiated by the addition of prekallikrein (9 μg) or factor XI (9 μg). Incubations were carried out in siliconized glass tubes in a final volume of 0.1 ml. Aliquots (10 μl) were removed at various times and assayed for kallikrein or factor XI$_a$. In the assay for kallikrein: amidase activity, the samples were added to 0.99 ml of 0.05 M Tris–HCl, *p*H 8.0, containing 0.15 M NaCl, 10 mg per ml polybrene, 50 μg lima bean trypsin inhibitor, and 0.1 ml of 1.5 mM benzoyl-Pro-Phe-Arg-*p*-nitroanilide. The initial rate of amide hydrolysis was followed at 37 °C by the change in absorbance at 405 nm using a Gilford recording spectrophotometer. For the factor XI$_a$: esterase activity, aliquots were added to a solution of factor XII antibody to stop the reaction and hydrolysis of tosyl-L-arginine- [^{3}H]-methyl ester was followed in a Beckman scintillation counter (SL-100C) as previously described[32]. The coagulation proteins were prepared from bovine plasma and all were homogeneous by SDS-polyacrylamide gel electrophoresis. Protein concentrations were determined by absorption at 280 nm using an $E_{280}^{1\%}$ of 10.9 for prekallikrein[37], 12.6 for factor XI (ref. 36), 14.2 for factor XII (ref. 27) and the same value for factor XII$_a$. Their specific activities in a clotting assay with their respective deficient plasmas were as follows: factor XII (180 u per mg), factor XII$_a$ (280 u per mg), HMW kininogen (11 u per mg), plasma prekallikrein (60 u per mg), and factor XI (280 u per mg). Factor XII was treated with diisopropyl fluorophosphate (1 mM) at 37 °C for 60 min to remove any traces of factor XII$_a$, and the diisopropyl fluorophosphate was removed by dialysis against the reaction buffer. *a*: ○, prekallikrein plus factor XII, HMW kininogen and kaolin; △, prekallikrein plus factor XII$_a$, HMW kininogen and kaolin; ■, prekallikrein plus HMW kininogen and kaolin; □, prekallikrein plus factor XII. *b*: ●, factor XI plus factor XII, HMW kininogen and kaolin; ▲, factor XI plus factor XII$_a$, HMW kininogen and kaolin; ■, factor XI plus HMW kininogen and kaolin.

Activation of prekallikrein by factor XII and/or factor XII$_a$

In the present report, we describe the activation of bovine plasma prekallikrein by single-chain factor XII as well as factor XII$_a$ in the presence of HMW kininogen and kaolin. In these experiments, a homogeneous preparation of single-chain plasma prekallikrein (MW 82,000)[37] was used as substrate. This preparation of prekallikrein contained no detectable kallikrein or factor XII activity. Bovine factor XII or factor XII$_a$ was added to optimum amounts of HMW kininogen and kaolin, and the activation reaction was initiated by the addition of prekallikrein. The factor XII or factor XII$_a$-to-prekallikrein weight ratio was 1:65. In these conditions, prekallikrein was rapidly converted to kallikrein (Fig. 1*a*). The generation of kallikrein was measured by its amidase activity towards benzoyl-L-prolyl-L-phenylalanyl-L-arginine-*p*-nitroanilide. The initial rate of kallikrein generation was almost the same with either factor XII (open circles) or factor XII$_a$ (open triangles). No lag phase or sigmoidal curve was observed for the activation of prekallikrein by factor XII. A lag phase would be expected, however, if the conversion of factor XII to factor XII$_a$ were essential in this reaction. No activation of prekallikrein occurred in the absence of factor XII or factor XII$_a$ (solid squares). A small amount of activation occurred in the absence of kaolin (open squares). When prekallikrein was omitted from the reaction, no amidase activity was generated.

To test for the possibility of an extremely rapid conversion of factor XII to factor XII$_a$ by kallikrein early in the activation reaction, the conversion of prekallikrein to kallikrein was studied using ^{3}H-labelled factor XII as the enzyme. These experiments are important because kallikrein readily converts factor XII to factor XII$_a$, and this reaction could greatly reduce any lag phase in the reaction if the activation of prekallikrein were catalysed only by factor XII$_a$. The ^{3}H-factor XII was prepared by reductive alkylation by the procedure of Means and Feeney[38] using ^{3}H-NaBH$_4$ and formaldehyde. The ^{3}H-factor XII had the same clotting activity as the unlabelled protein and contained approximately 143,000 c.p.m. per µg. Furthermore, when a catalytic amount of kallikrein was used to activate ^{3}H-factor XII in the presence of kaolin, the generation of factor XII$_a$ esterase activity occurred in parallel with the disappearance of single-chain factor XII and the appearance of two-chain factor XII$_a$. This was shown by SDS polyacrylamide gel electrophoresis of the reaction products in reducing conditions (data not shown).

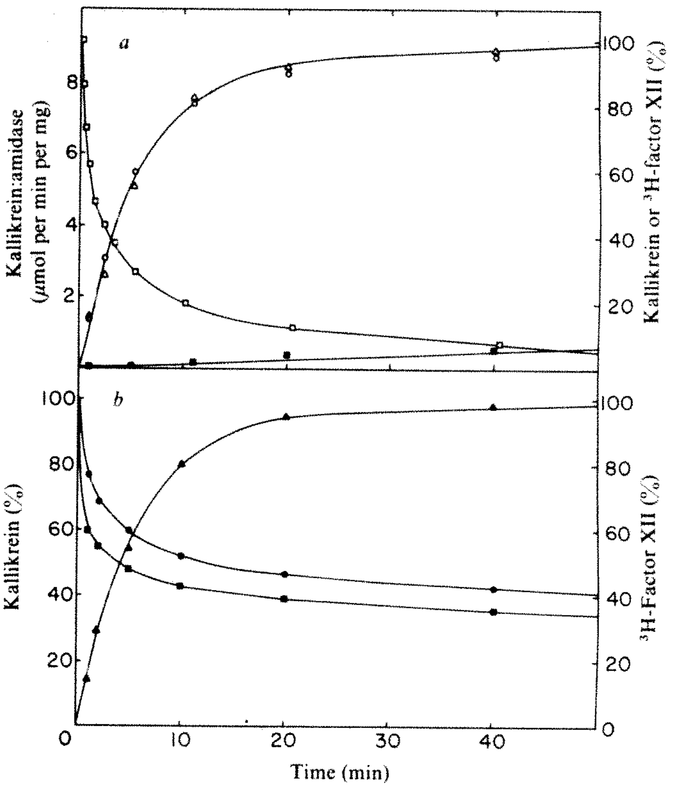

Fig. 2 *a*, Time course for the activation of plasma prekallikrein by ^{3}H-factor XII in the presence of HMW kininogen and kaolin. *b*, The reaction in the presence of RVV inhibitor II, a serine protease inhibitor from Russell's viper venom. ^{3}H-factor XII (0.84 µg) was preincubated with HMW kininogen (2.4 µg) and kaolin (120 µg) for 5 min at 37 °C in 0.05 M Tris-HCl, *p*H 7.5, containing 0.1 M NaCl. Reactions were then initiated by the addition of prekallikrein (55 µg) to give a final volume of 0.6 ml. Aliquots (10 µl) were removed at various times and assayed for kallikrein: amidase activity for the experiments shown in *a*. Samples (50 µl) were also subjected to SDS-polyacrylamide gel electrophoresis[39] in the presence of 5% 2-mercaptoethanol. The samples for electrophoresis were immediately added to sample buffer, boiled for 1 min, and then analysed on a 10% polyacrylamide slab gel. After staining (Coomassie brilliant blue R) and destaining, the gel was scanned with a Joyce-Loebl densitometer and the amount of kallikrein was determined from the tracings. To determine the amount of ^{3}H-factor XII, the gel was prepared for fluorography[40]. After developing the fluorogram, the band of ^{3}H-factor XII was sliced from the dried gel and the amount of radioactivity was determined by dissolving the gel slices in 30% H_2O_2 (99 vol:1 vol NH_4OH) followed by counting in Aquasol (NEN). The counting efficiency was 30%. *a*: ○, generation of kallikrein: amidase activity in the complete reaction mixture; ■, kallikrein: amidase activity in the absence of kaolin; △, generation of kallikrein as determined by densitometry of the stained gels; □, per cent ^{3}H-factor XII. *b*: ▲, generation of kallikrein in the complete reaction mixture plus RVV inhibitor II (114 µg), determined by densitometry of the stained gels; ■, per cent ^{3}H-factor XII in the reaction mixture containing 23 µg of RVV inhibition II; ●, per cent ^{3}H-factor XII in the reaction mixture containing 114 µg of RVV inhibitor II.

Activation of prekallikrein by factor XII

A time course for the activation of prekallikrein by ^{3}H-factor XII in the presence of HMW kininogen and kaolin is shown in Fig. 2*a*. The rate of formation of kallikrein (open circles) was very similar to that shown in Fig. 1*a*, and no lag phase was observed. The activation of prekallikrein was also followed by SDS-polyacrylamide gel electrophoresis on a slab gel using the method of Laemmli[39]. In these experiments, samples were removed at various times during the activation reaction by factor XII and examined in the presence and absence of 2-mercaptoethanol. In the absence of reducing agent, prekallikrein appeared as a band of MW 82,000. This indicated that little, if any, change in the molecular weight of prekallikrein occurred during its conversion to kallikrein. A difference in the SDS-polyacrylamide gel electrophoresis pattern of the prekallikrein was observed, however, after reduction of the samples with 2-mercaptoethanol. At zero time, prekallikrein appeared as a 82,000-MW band. During the first few minutes of the activation reaction, three new, faster-moving bands appeared, including a heavy chain (apparent MW 52,000) and a light chain (apparent MW 38,000 or 33,000). The appearance of these bands as measured by densitometry (Fig. 2*a*, open triangles) occurred in parallel with the formation of kallikrein as measured by its amidase activity (Fig. 2*a*, open circles). These data indicate that bovine prekallikrein was converted to kallikrein by the hydrolysis of an internal peptide bond in the single-chain precursor molecule in the presence of HMW kininogen and kaolin. The cleavage of bovine prekallikrein by factor XII is very similar to that reported earlier for human prekallikrein activated by human factor XII$_a$ fragments (ref. 10). The SDS-polyacrylamide slab gel was then prepared for fluorography[40] and the amount of radioactivity present in ^{3}H-factor XII was determined. At zero time, the radiolabelled protein migrated as a single band (approximate MW 74,000) on SDS-polyacrylamide gel electrophoresis in the presence of 2-mercaptoethanol. As the ^{3}H-factor XII was converted to ^{3}H-factor XII$_a$ by the newly generated kallikrein, the ^{3}H-factor XII$_a$ appeared as a heavy chain (MW 46,000) and a light chain (MW 28,000) in the presence of 2-mercaptoethanol. After 2.5 min, 35% of the prekallikrein was converted to kallikrein (Fig. 2*a*, open circles), while 40% of the factor XII was still present as a single-chain molecule (Fig. 2*a*, open squares). After 5 min, 60% of the prekallikrein was converted to kallikrein, while only 30% of the factor XII was still in the single-chain form. After 5 min, the weight ratio of kallikrein-to-factor XII was nearly 40 : 1, and the conversion of factor XII to factor XII$_a$ was occurring very rapidly. These data indicate that single-chain factor XII converts prekallikrein to kallikrein in the initial phase of the activation reaction in the presence of HMW kininogen and kaolin. This conclusion is further supported by the fact that the initial rate of prekallikrein activation by either factor XII or factor XII$_a$ was nearly identical (Fig. 1*a*), and this would not be the case if the prior conversion of factor XII to factor XII$_a$ were required. These experiments also demonstrate that the latter part of the prekallikrein activation reaction is catalysed primarily by factor XII$_a$ which is rapidly generated after the formation of kallikrein.

The activation of prekallikrein by single-chain ^{3}H-factor XII was further examined in the presence of an excess of RVV inhibitor II, a low molecular weight serine protease inhibitor from Russell's viper venom. This protein inhibits bovine plasma kallikrein with a K_i of 0.29 nM (ref. 41) but has no effect on factor XII or factor XII$_a$. Thus, it is useful to restrict the effect of kallikrein on the activation of factor XII. The conversion of prekallikrein to kallikrein in the presence of a 5-M and a 25-M excess of the RVV inhibitor II relative to prekallikrein is shown in Fig. 2*b*. The weight ratio of ^{3}H-factor XII-to-prekallikrein was 1:65. The formation of kallikrein was measured by SDS-polyacrylamide gel electrophoresis in the presence of 2-mercaptoethanol as described for Fig. 2*a*. In these experiments, the rate of generation of kallikrein (Fig. 2*b*, solid triangles) in the presence of either a 5-M or a 25-M excess of kallikrein inhibitor was the same as that in the absence of the kallikrein inhibitor (Fig. 2*a*, open triangles). As before, no lag phase was observed. The conversion of factor XII to factor XII$_a$, however, was substantially reduced in the presence of the kallikrein inhibitor. With a 5-M excess of RVV inhibitor II, 35% of the prekallikrein was converted to kallikrein in 2.5 min, while 55% of the factor XII was in the single-chain form (Fig. 2*b*, solid squares). With a 25-M excess of RVV inhibitor II, 35% of the prekallikrein was converted to kallikrein in 2.5 min, while 70% of the factor XII was still in the single-chain form (Fig. 2*b*, solid circles). If the conversion of factor XII to factor XII$_a$ were an absolute requirement for this reaction, then a lag phase would have been readily detected in these experiments and the inital rate would have been much slower than that found for an equivalent amount of factor XII$_a$. These data strongly suggest that single-chain factor XII converts prekallikrein to kallikrein in the presence of HMW kininogen and kaolin and does so at a very rapid rate.

Activation of factor XI by factors XII or XII$_a$

Similar experiments were then carried out for the activation of bovine factor XI by factor XII or factor XII$_a$ in the same reaction conditions used in Fig. 1*a*, except that factor XI was substituted for prekallikrein. Factor XII readily activated factor XI in the presence of HMW kininogen and kaolin (Fig. 1*b*, solid circles). In these experiments, factor XI$_a$ was measured by its esterase activity towards tosyl-L-arginine methyl ester. The initial rate of activation of factor XI by factor XII was 2–4 times slower than that of factor XII$_a$ (Fig. 1*b*, solid triangles). The rate of activation of factor XI by factor XII$_a$, however, was almost the same as the activation of prekallikrein by factor XII$_a$ or factor XII (Fig. 1*a*). As factor XII$_a$ is a more effective catalyst than factor XII in the activation of factor XI, the generation of factor XII$_a$ by kallikrein is required for the rapid activation of factor XI and the eventual formation of fibrin in whole plasma.

The cascade mechanism is initiated by factor XII

These data strongly suggest that the initial event in the activation of the intrinsic pathway of blood coagulation involves a substrate-induced catalysis by single-chain factor XII (Fig. 3). In this reaction, factor XII, bound to the kaolin surface, converts prekallikrein to kallikrein. The kallikrein thus generated converts the kaolin-bound factor XII to factor XII$_a$, which in turn converts factor XI to factor XI$_a$. Each of these three reactions is stimulated by HMW kininogen or kinin-free HMW kininogen. Human kinin-free HMW kininogen and bradykinin are formed after the generation of the kallikrein in the initial reaction. In the presence of calcium, factor XI$_a$ then converts factor IX to factor IX$_a$. Eventually, thrombin is formed and this leads to the conversion of fibrinogen to fibrin[1]. Although the present experiments were carried out with clotting factors from bovine plasma, similar data have been obtained in preliminary experiments with purified clotting factors from human plasma. Thus, the mechanism shown in Fig. 3 seems applicable to other mammalian plasmas.

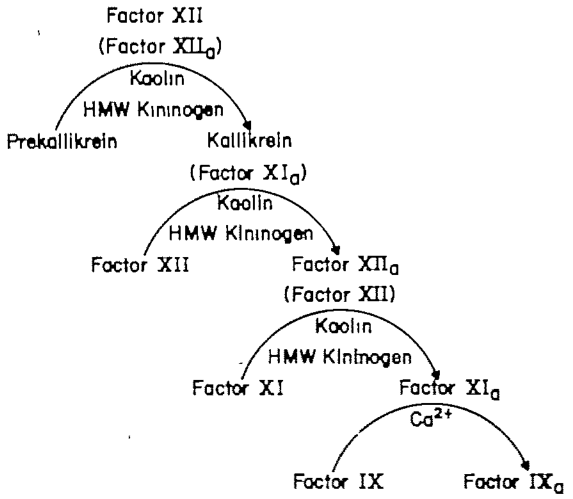

Fig. 3 A tentative mechanism for the surface activation of blood coagulation in the presence of kaolin.

Factor XII$_a$ will also activate prekallikrein after it is generated in the initial reactions. The activation of prekallikrein is not catalysed by kallikrein, factor XI$_a$ or prekallikrein. Factor XI$_a$ will activate factor XII when it is generated by factor XII$_a$ (Fig. 3). We have not observed, however, an activation of human or bovine factor XII by factor XI$_a$. Recently, Wiggins and Cochrane[42] have reported the cleavage of rabbit factor XII by factor XI$_a$. In whole plasma, the activation of factor XII is probably catalysed primarily by kallikrein rather than factor XI$_a$, as kallikrein is generated first and it is about four times more active in the activation reaction than factor XI$_a$ (ref. 26). Thus, factor XI$_a$ probably has only a minor role in the activation of factor XII. Factor XII will also activate factor XI in the presence of kaolin and HMW kininogen, although the rate is slower than that catalysed by factor XII$_a$. Thus, the initiation of blood coagulation by kaolin occurs at a faster rate in the presence of prekallikrein which is converted to kallikrein, and this in turn leads to the formation of factor XII$_a$. When plasma deficient in prekallikrein is preincubated with kaolin for approximately 10 min before the addition of calcium, it has a normal clotting time[22]. In these conditions, optimal levels of factor XI$_a$ are probably generated by single-chain factor XII and the formation of factor XII$_a$ via kallikrein is not required[32]. The correction of the kaolin clotting time of prekallikrein-deficient plasma by factor XII (refs 17, 27) can also be explained by the fact that elevation of the level of this protein will lead to the direct activation of factor XI and bypass the requirement for prekallikrein in these conditions.

Consequences of our studies

The present data provide a mechanism for the initiation of blood coagulation, as well as fibrinolysis, and kinin generation by single-chain factor XII in the presence of a surface, such as kaolin. By this mechanism, a trace of factor XII$_a$, kallikrein or some other plasma or cellular protease as previously suggested[3,21], is not required to initiate the reactions. Also, it is not necessary to postulate the participation of factor XII or prekallikrein as weakly active zymogens as suggested by Griffin and Cochrane[34], as factor XII is as active as factor XII$_a$ in the activation of prekallikrein in the presence of kaolin and HMW kininogen. Whether or not this mechanism will be applicable for other negatively charged surfaces is not clear. The physiological importance of the surface activation reaction is evident when blood comes in contact with a foreign surface *in vivo*. This occurs following the implantation of artificial heart valves where the incidence of thrombosis on the valve is 20–25% (ref. 43). Similar problems are encountered when patients with kidney failure are subjected to haemodialysis, when fibrin formation often occurs in the shunt.

This work was supported in part by grant HL 16919 from the NIH. K.K. is a recipient of a Research Career Development Award HL 00404 from the NIH. The nomenclature for the various coagulation factors is that recommended by an International Nomenclature Committee[44]. We thank Dr W. Kisiel for supplying the highly purified RVV inhibitor II.

Distinctive sequence of human mitochondrial ribosomal RNA genes

I. C. Eperon, S. Anderson & D. P. Nierlich*
MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH, UK

The nucleotide sequence spanning the ribosomal RNA (rRNA) genes of cloned human mitochondrial DNA reveals an extremely compact genome organization wherein the putative tRNA genes are probably 'butt-jointed' around the two rRNA genes. The sequences of the rRNA genes are significantly homologous in some regions to eukaryotic and prokaryotic sequences, but distinctive; the tRNA genes also have unusual nucleotide sequences. It seems that human mitochondria did not originate from recognizable relatives of present day organisms.

HUMAN mitochondrial DNA comprises a duplex closed circle of molecular weight 10×10^6, which has been shown to code for several proteins[1] and RNA species[2]. Two RNAs (12S and 16S) are conspicuous by their stability, methylation and equimolar synthesis[3,4], being the RNA components in 60S mitochondrial ribosomes[5,6]. These unique genes[7] are adjacent[8], and were mapped relative to the 4S RNA genes[9] and the *Hpa*II cleavage points in mitochondrial (mt) DNA[2,10].

It has been suggested that mitochondria are derived by endosymbiosis from prokaryotes, based on the sensitivity of ribosomes to antibiotics[11] and initiation of polypeptides with formylmethionine[12]. However, mammalian mitochondrial ribosomes and rRNAs are unusually small, and all but plant mitochondria also lack a 5S rRNA [13]. The rRNA sequences, being the only identified large genes with nuclear and prokaryotic counterparts, should clarify phylogenetic relatedness (for example, in chloroplasts the 16S rRNA gene[14] has shown near identity to that from *Escherichia coli*). This comparison should also clarify the sequences necessary for the function of these small rRNAs.

Most of the *Mbo*I fragments from human placental mt DNA have been mapped and cloned in the *Bam*HI site of the plasmid pBR322 (ref. 15); these have been used to determine the rRNA gene sequences presented here.

DNA sequence analysis

Figure 1 shows the map established for the restriction enzymes *Mbo*I (ref. 11) and *Hpa*II (ref. 10). The cloned *Mbo*I fragments 7, 14, 12, 3a, 18, 19 and 9 were sequenced using the dideoxy chain-termination method[16]. Single-stranded template was prepared by cleavage of the pBR322 moiety of the recombinant plasmid at the single sites for the enzymes *Hin*dIII or *Sal*I, followed by exonclease III digestion[17] which results in degradation of each strand from the 3′ end, exposing different strands in each case. An example is given in Fig. 2, which shows the sequence of the tRNA$^{\mathrm{Val}}$ gene and the 3′ end of the 12S rRNA gene.

Small inserts were sequenced using adjacent pBR322 restriction fragments as primers; larger inserts required the use of restriction fragments purified from the insert, which were often pretreated with exonuclease III to give sequence information within the region complementary to the restriction fragment[18]. Where the internal fragments were large, ribosubstitution of the 3′ end of the fragment was used to generate a new 5′ end for the extended chains on cleavage with alkali or ribonuclease. The published technique[19] was modified to allow direct ribosubstitution of the fragments before addition of the template:

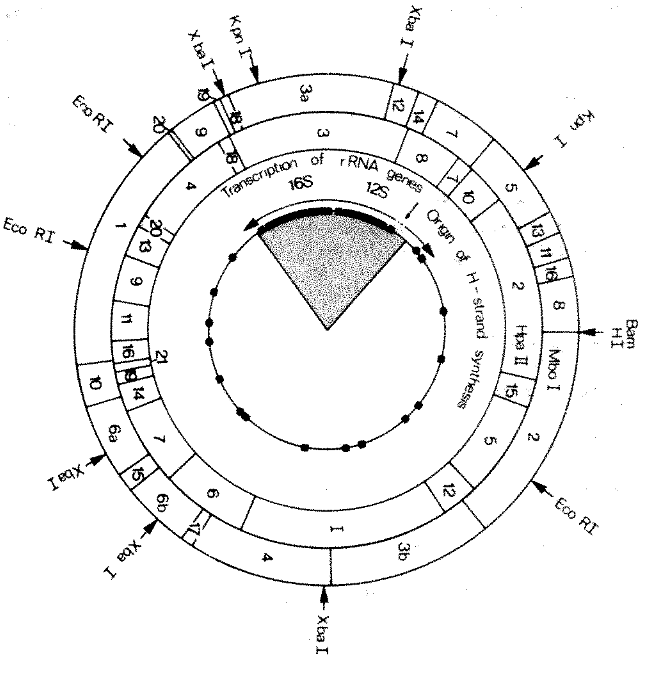

Fig. 1 The *Mbo*I restriction enzyme map of human mt DNA[11] is correlated with that of *Hpa*II[10], based on their alignments with some of the other enzyme cleavage sites marked and corrected according to the sequence in the region published here, which is shaded. The rRNAs are marked, as are the L-strand (■) and H-strand (●) sequence 4S RNAs[10]. The origin and direction of H-strand synthesis are shown.

incubation of the fragment with a ribonucleotide triphosphate and the Klenow fragment of DNA polymerase I at 37 °C allowed exchange of the 3′-terminal deoxyribonucleotide or 'filling-in' of the restriction fragment with the ribonucleotide. This eliminated the possibility that the overlapping ends of the exonuclease-degraded template could be substituted. EDTA was used to chelate Mn^{2+} during the reaction to prevent ribonucleotide incorporation during extension with deoxy- and dideoxynucleotides without recourse to column separation steps (I.C.E., unpublished).

Single-stranded template DNA prepared by exonuclease digestion can give a relatively high background and two other techniques were also used. One involved the separation of complete plasmid strands on alkaline RPC-5 columns (ref. 20 and B.A. Roe, manuscript in preparation) after cleavage of the closed circular duplex at a unique restriction enzyme site. This was most satisfactory where the pBR322 vector contained large inserts that were asymmetric with respect to the base compositions of the two strands, although recovery was variable. The second technique involved recloning of the isolated insert into the *Bam*HI site of the double-stranded form (RFI) of a derivative of the single-stranded bacteriophage M13 mp2 (refs 21–23).

To establish the orientation of the *Mbo*I fragments, and to ascertain whether very small fragments might have been missed in the mapping experiments, fragments prepared from the pBR322 clones were used for priming on HeLa mt DNA that had been digested by exonuclease III from the *Bam*HI, *Eco*RI or *Xba*I sites. The sequences obtained thus overlapped the *Mbo*I sites. Further confirmation was provided by sequence analysis of *Alu*I fragments (A. R. Coulson and F. Sanger, personal communication). The sequence obtained is shown in Fig. 3, with the *Mbo*I sites and extent of the probable genes indicated.

Organization of the genome

The tRNA genes have been assigned to the sequences shown (Figs 3, 4) by detection of likely clover-leaf structures (using the computer program TRNASU: R. Staden, unpublished) and features of the sequence that are common to all previously identified tRNAs[24,25]. The assignments correlate well with the map positions identified by electron microscopy of HeLa 4S RNA–mt DNA hybrids. No further likely tRNA genes were found when the possibility of insertions in the anticodon loop, analogous to those found elsewhere[26–28], was allowed.

The rRNAs were exactly located by the accurate homology with short sequences from the 5′ ends of the HeLa rRNAs[2], and found to abut tRNA genes at these termini (Fig. 3). The 3′ ends cannot be identified at present, although the extensive sequence homology to known small subunit rRNA sequences to within approximately 12 nucleotides from their 3′ termini (Figs 5, 6*a*) suggests that the 12S 3′ terminus is very close to the $tRNA^{Val}$ gene. This proximity agrees with mapping by electron microscopy, which has shown that the gap between the two rRNA genes is less than 500 base pairs[8] and that a 4S RNA maps between the two[9]. This closeness may involve a conjunction of the 12S rRNA and $tRNA^{Val}$ genes as at the 5′ end of both rRNA genes.

The lack of an intergenic sequence at some junctions suggests that a large initial transcript will be produced: this would agree with the large sizes of the HeLa mitochondrial transcripts hybridizing to the heavy (H) strand, the largest of which (9.0×10^5 MW, equal to the sum of the rRNAs) is found polyadenylated and unpolyadenylated[2,29]. The polyadenylated species has a short halflife compared with some other discrete mitochondrial 'poly(A)-containing' RNAs and is notable among these for being present in the polysomal fraction to a very small extent, as expected for a rRNA precursor. Resistance of restriction fragment–rRNA hybrids to exo- and endonucleolytic enzymes demonstrated that neither of the rRNA genes is 'split' by an intervening sequence in HeLa mitochondria[2].

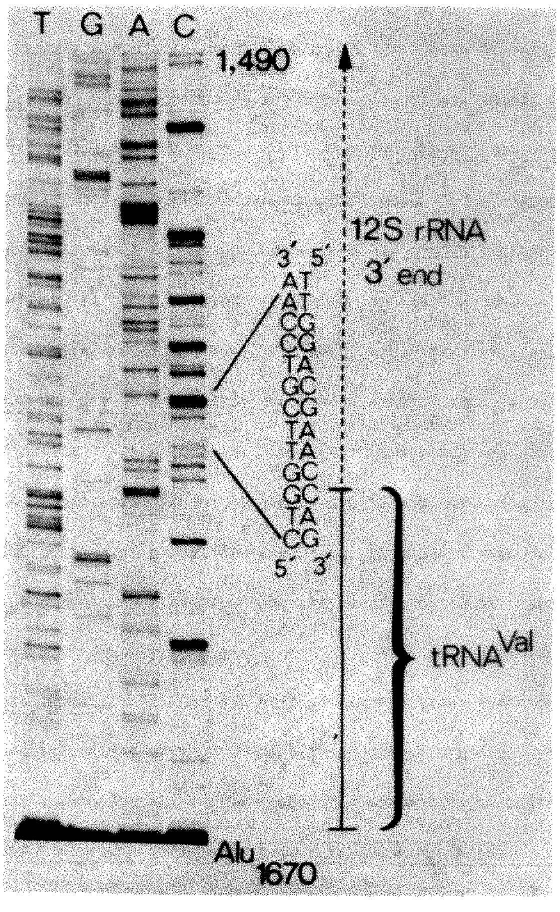

Fig. 2 A chain-termination sequencing gel showing the sequence through the $tRNA^{Val}$ gene and the 3′ end of the 12S rRNA, in the complementary sense. The primer is 223 bases long (the *Alu*I fragment from 1,671–1,894 of Fig. 3), and the resultant sequence from priming on exonuclease-treated template (*Ava*I digest of *Mbo*I fragment 3a cloned in pBR322) can be read from this 6% thin gel[86], run for 4 h, to a total polynucleotide length of 400 bases, that is, to 1,490 on Fig. 3. The sequence through the junction of the two genes is shown.

In *E. coli*, processing of the 16S rRNA probably involves initial cleavage by RNase III of a large inverted repeat that flanks the 16S gene[30], followed by at least RNase M16 cleavage to generate the mature 5′ terminus[31]. Eukaryotic nuclear rRNA transcripts also include large flanking sequences that are later removed[32,33], although the available sequence data do not suggest that these are inverted repeats (ref. 34 and K. G. Skryabin, personal communication). The 'butt-jointing' of mt tRNA genes at one or both end of the rRNAs implies a totally different processing mechanism, involving recognition of the structure or sequence of regions within mature transcripts and simple cleavages around the rRNA genes if both mature from the same transcript.

This mechanism implies a novel method for the production of the 3′ terminus of mature tRNAs, which in *E. coli* and *Bombyx mori* probably involves 3′,5′ exonuclease activity[35], as mitochondrial tRNA^{Phe} and tRNA^{Val} abut rRNA genes at their 3′ termini. However, single cleavage at the 5′ terminus of the tRNA genes would not be unusual: such a cleavage is catalysed in *E. coli* by RNase P, the rate being dependent on the secondary

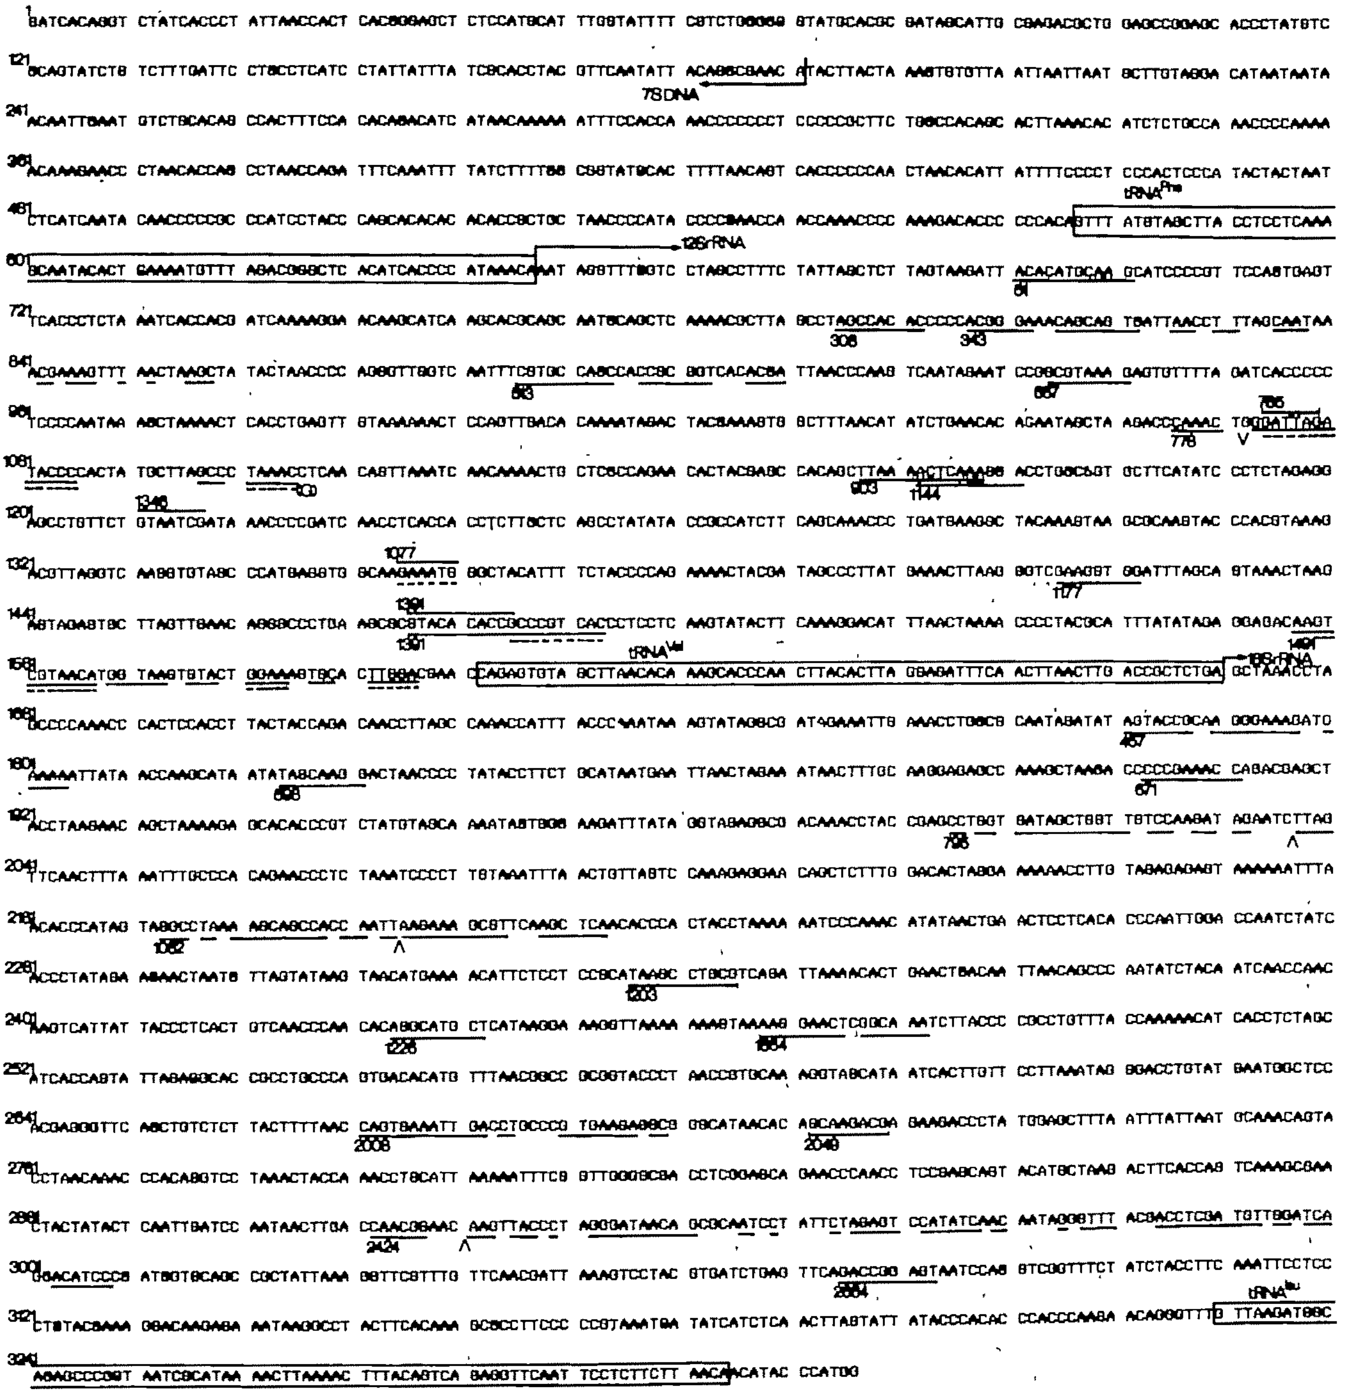

Fig. 3 The sequence of the region shaded in Fig. 1 is shown, with the tRNA genes boxed and the 5′ termini of the 12S and 16S rRNA genes shown; this is L-strand sequence, which corresponds to the RNA sequence. Numbers down the left-hand edge are those of this mt sequence, and those adjacent to underlining are those of the *E. coli* rRNAs. The 5′ terminus of 7S DNA, which is complementary to the strand shown, is also marked. Underlining shows regions of homology with the *E. coli* rRNAs ≥ 8 nucleotides, with surrounding smaller blocks in the same phase. Λ and V indicate that the *E. coli* rRNAs have one nucleotide more or less, respectively, in the areas of parallel sequence. Overlined regions are homologous to sequences (≥pentamers) identified by Woese *et al*[72] as universal among prokaryotes and kethoxal modifiable in 30S ribosomal subunits of *E. coli*. Broken underlining emphasizes those sequences that are identifiably homologous (assuming that sites would be in the same 5′–3′ order along the two rRNA sequences) to sites identified by Herr *et al.*[73] as those in 16S rRNA of *E. coli* that must be unmodified by kethoxal for 30S–50S subunit association.

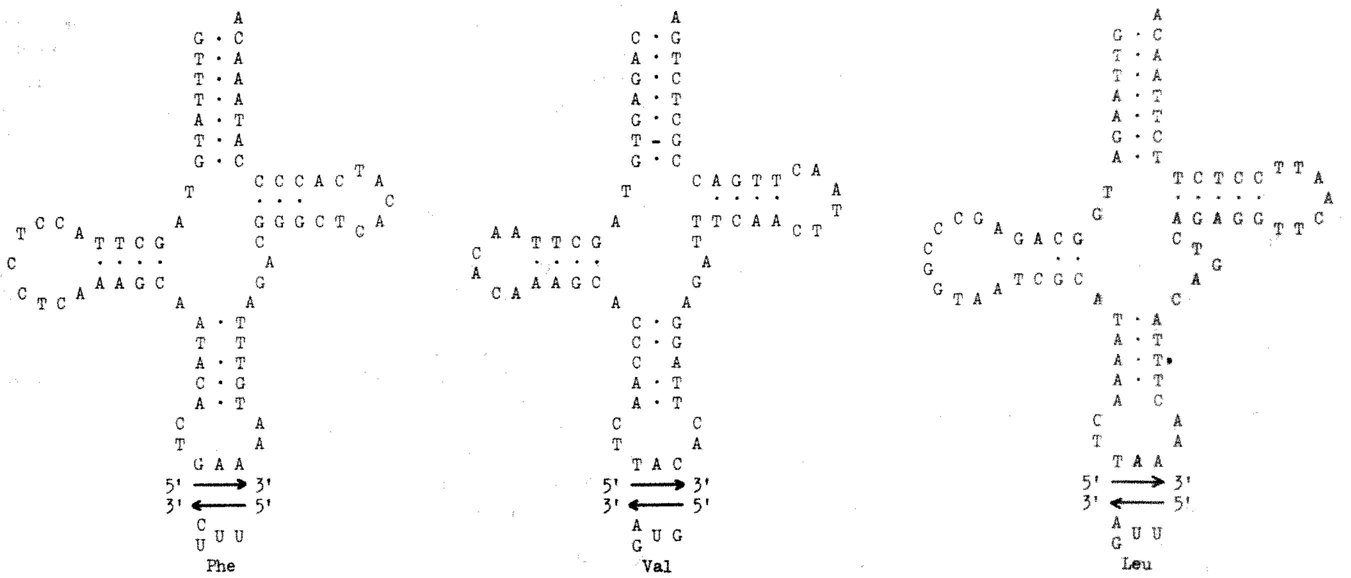

Fig. 4 A clover-leaf arrangement of the tRNA genes. The 3′ CCA sequence common to all other tRNAs is not encoded. G–U wobble is assumed in the codons recognized[46]. Loop I is the left-hand loop of this arrangement and often contains dihydrouridine, and loop IV is the right-hand loop which is usually characterized by the sequence G-T-pseudouridine-C.

or tertiary structure of the tRNA moiety of the substrate[36], and a similar *in vitro* activity has been isolated from the eukaryote, *B. mori*[35]. Cleavage around both termini of mt tRNA sequences in the primary transcripts by an analogous activity to RNase P is a possible general processing mechanism in human mitochondria, agreeing with the approximate correlation found between the length of mapped inter-tRNA sequences and the sizes of encoded proteins[2] and with the generally larger sizes of the polyadenylated RNA species.

The origin of H-strand replication of HeLa mt DNA was initially mapped by locating the D-loop within large restriction fragments by electron microscopy[37], and later by hybridization of the D-loop-forming 7S single-stranded DNA fragment to small restriction fragments with subsequent primed synthesis[38]. A sequence of the HeLa 7S DNA at its 5′ end and adjacent restriction fragment sequences have been published[39]. The placental sequence differs slightly from the HeLa sequence in that nucleotides 263–264 are A–C rather than just G, and there are three fewer Cs in the block 303–315.

The function of the region between the 5′ end of the 7S DNA (H-strand sequence) and the 5′ end of the first tRNA^{Phe} (light-strand sequence) seems likely to include that of initiating transcription of L-strand sense RNA, but there are no sequences resembling the initiation sequences found in *E. coli*[40] or those before the 5′ end of transcripts in eukaryotes. Further, there are no obvious repeated sequences analogous to the two or more promoters[41,42] or RNA polymerase binding sites[43] found before rRNA genes in *E. coli* and *Xenopus*[44] that have been postulated to play a part in the high level of transcription of these genes. The rRNAs in mitochondria are comparatively stable[4] and this, rather than a high frequency of transcription, may account for their predominance *in vivo*.

Sequences of tRNA genes

With the exception of those flanking the cytochrome oxidase subunit II gene in human mitochondria[45], previously published mt tRNA sequences have come from *Neurospora* or *Saccharomyces* and have shown most of the features common to prokaryotic and eukaryotic tRNAs. Only the initiator tRNA from *Neurospora crassa*[46], for example, seems to have radically altered those nucleotides identified [from X-ray crystallographic studies on yeast cytoplasmic tRNA^{Phe} (ref. 47)] as being involved in the loop I–loop IV tertiary interactions.

In contrast, the sequences presented here (Fig. 4, drawn on the assumption that stem lengths are conserved) differ considerably from other tRNA sequences. This is most noticeable in the lengths and sequences of loops I and IV, where many 'invariant' features are lacking, and in the poor base pairing in the stem to loop IV of tRNA^{Phe}. These changes may reflect altered possibilities of interaction between the two loops. The significance of the retained 'invariant' and common features cannot be assessed from so few sequences and will be discussed elsewhere.

Sequence analyses of the genes coding for the yeast ATPase subunit 9 (refs 48, 49) and cytochrome oxidase subunit II[45,50] (in human and yeast mitochondria) have recently shown, by comparison with the yeast and beef protein sequences respectively, that threonine (in yeast only) and tryptophan (and perhaps methionine in human mitochondria) are coded for by triplets which otherwise have different specificities in the 'universal' genetic code. The codons corresponding to the tRNAs published here, UUC(U), GUA(G) and UUA(G), do not seem to be anomalous in protein–DNA sequence comparison, and so probably do code for the amino acids shown (Fig. 4).

Like the sequences of yeast and *Neurospora* mt tRNAs[51], the human mt tRNA sequences published here show no greater homology to prokaryotes than to eukaryotes, seeming to form a rather distinct class. At some positions in tRNA sequences that are apparently characteristic of prokaryotes or eukaryotes, these genes frequently differ from both. The lack of agreement with a recent prokaryotic origin is emphasized by the inability of *E. coli* aminoacyl tRNA synthetases to charge mt tRNAs[52,53]. The HeLa cytoplasmic enzymes were partially successful in some cases[53] with HeLa mt tRNAs, one of which involved valine incorporation despite the fact that the human placental mt tRNA^{Val} has lost the conserved positions found in prokaryotic, eukaryotic and yeast mt tRNAs.

The 16S ribosomal RNA gene

Because relatively little is known about mitochondrial ribosomes, the significance of the sequence shown in Fig. 3 must be brought out by comparison with known sequences.

The homology of *E. coli* 23S rRNA[54] to this 16S rRNA does not extend to the 3′ end of the former sequence, resulting in some uncertainty about the length of the latter gene. Despite this and the considerable difference in probable lengths (2,904 to 1,559 nucleotides), there are regions of homology between the two. Regions with eight common nucleotides, with surrounding smaller blocks of homology in the same phase, have been shown in Fig. 3 where these regions occur in the same order in both sequences. The largest region of homology is found between nucleotides 2,910 and 3,010 of Fig. 3, corresponding to nucleotides 2,422–2,522 of the 23S rRNA. This is within the region that has been identified as involved in the interface between *E. coli* ribosomal subunits, the RNA being protected against kethoxal modification on 30S–50S association[55], although the exact sites of modification are not conserved. More extensive homology to this region of the 23S rRNA has been reported in a partial sequence of the yeast mt 21S rRNA gene[54]. Nucleotides 2,934 and 2,990 of Fig. 3 correspond to 21S rRNA nucleotides altered in chloramphenicol-resistant mutants of yeast and are therefore probably involved in binding the 3′ terminus of aminoacyl tRNAs. Only 2 of the 16 kethoxal-modifiable sites found in *E. coli* 50S subunits[54] occur within the underlined regions, suggesting a low level of conservation of exposed sequences in general.

The 12S ribosomal RNA gene

By contrast with the absence of sequences from cytoplasmic large rRNAs, some of the yeast small (18S) cytoplasmic rRNA sequence[6,7] is known, as is that of the *E. coli* 16S rRNA[56,57]. The involvement of the 3′ end of 16S rRNA in initiation of protein synthesis has led to the determination of short sequences at the 3′ ends of many small subunit rRNAs (Fig. 5).

The degree of complementarity[58] and binding[59] of the 3′-terminal sequence of *E. coli* 16S rRNA to a polypurine stretch before the initiation codons in bacteriophage RNA has been correlated with the level of translation of these RNAs. Complementarity alone, however, does not fully explain the level of binding, or the translational preferences of ribosomes from various bacterial species[60,61]. In contrast, eukaryotic ribosomes show comparatively little messenger discrimination; the 3′-terminal sequences of eukaryotic 18S rRNAs are highly conserved[62], and no region of complementarity has been identified in eukaryotic mRNAs that has any constant relationship to the initiation codon. The eukaryotic ribosome–Met tRNA$^{\mathrm{Met}}$ complex[63] may therefore not recognize internal regions of mRNA, but could 'scan' the mRNA for the first initiation codon[64], after binding near the 5′ end[65,66]; complex binding[65] and the monocistronic translation of prokaryotic mRNA are enhanced by a 'cap' (refs 67, 68).

The comparison shown in Fig. 6*a* clearly illustrates that the small subunit rRNA from human mitochondria lacks the polypurine-complementary sequence (CCUCC) found in prokaryotes. Although the exact 3′ end of the 12S rRNA has not been established, it is apparent (Fig. 6*b*) that any extended stem would be less stable than that of the analogous structure in *E. coli* if the rRNA gene does not overlap the tRNA$^{\mathrm{Val}}$ gene. This stability may be necessary for dissociation (after initiation) of the prokaryotic CCUCC sequence from the mRNA[59], and hence may be diagnostic of such a mode of initiation. No region of complementarity to the 3′ end of 12S rRNA has been found appropriately near the initiation codon for the cytochrome oxidase subunit II[46] or other structural genes (B.G. Barrell, personal communication).

The absence of these prokaryotic characteristics suggests that there is no sequence-specific binding of ribosomes and internal initiation, but rather that the long mitochondrial transcripts are processed to monocistronic units as in eukaryotes. If so, initiation seems likely to be dependent on the 5′ terminus *per se* or the first AUG codon for transcripts are not capped and in at least one case there would be no leader sequence (the AUG codon abuts a tRNA gene) unless translation preceded processing[46]. No eukaryotic transcripts are known where there is no leader sequence, although the cap structure does not seem to be invariably necessary for efficient translation, and the single prokaryotic example (λprm transcript[69]) is translated inefficiently. It is interesting, however, that the λprm transcript is translated; this suggests that initiation will occur at the AUG nearest to the 5′ end of mRNA, or that the 5′ end of mRNA is bound by the 30S–initiation factor complex. Mitochondria may represent a situation where there is no 12S–mRNA complementarity to favour internal initiation, nor a cap to enhance 5′-terminal binding, but a simpler mechanism underlying those developed elsewhere. If this is the case, the persistent failure of non-mitochondrial *in vitro* or *in vivo* systems to produce other than at best fragmentary translation products from mt RNA or DNA[70,71] may be ascribed to the use of the codon TGA (normally a terminator) to code for tryptophan[46,51], rather than a lack of initiation. One would, however, expect discrete products representing N-terminal peptides of proteins.

The 12S rRNA shows several other regions of homology to both *E. coli* and yeast small subunit rRNAs (Figs 3, 5, 6). The homology around the stem-loop structure near the 3′ end is

Fig. 5 The 3′ termini of mitochondrial *E. coli*[56,57] and yeast[34] small subunit rRNAs have been aligned to show the major blocks of homology, introducing gaps where appropriate. The scores for homologous nucleotides out of the total possible in this alignment are 45%, 57% and 45% for the pairs mitochondria·*E. coli*, *E. coli*·yeast and yeast·mitochondria, respectively. The mt DNA sequence has been extended for seven nucleotides into the tRNA$^{\mathrm{Val}}$ gene, illustrating the lack of homology there.

Fig. 6 *a*, The 3'-terminal sequences of small subunit rRNAs. The solid lines enclose regions of absolute homology in all previously determined sequences, including some prokaryotes not included here. Broken lines indicate incomplete sequences or a short 3' terminus. **Dictyostelium discoideum*. *b*, The small subsidiary loop proposed for *E. coli*[59] and the extended stem (of sequence GGAUCACCU) are unlikely to form in mitochondria unless the 12S gene overlaps the tRNA^{Val} gene.

broken, but differences from the other sequences are such as to retain the possibility of base pairing. The TG base pair and its flanking pairs are found in all the sequences known. The large block of homology in the region of nucleotides 1,476–1,495 (1,391–1,408 in the *E. coli* sequence, Fig. 5) is strongly conserved in mitochondria, eukaryotes and prokaryotes. Like the region just before the 3' stem-loop, there are important functional aspects to this sequence in *E. coli*, for part is a sequence that is universal among prokaryotes and accessible to modification by kethoxal in 30S subunits[72], and the remainder has been identified as crucial for 30S–50S subunit association[73]. Several other sequences are homologous to those found to be universal and accessible to modification in prokaryotes (Fig. 3), and 7 of the 14 kethoxal-modifiable sequences in *E. coli* 16S rRNA that are implicated in subunit association are recognizable in the 12S sequence. One of these is very similar to one of two sequences that might be involved in base pairing to 23S rRNA in *E. coli*[55,73], but there are no complementary sequences (>6 base pairs) in the mt 16S rRNA. The latter indeed has no regions absolutely homologous to the few association-protected oligonucleotides identified in *E. coli* 23S rRNA[55].

Evolution of human mt DNA

Although only one other small rRNA gene (16S rRNA of *E. coli*) has been sequenced, the sequences of the many small oligonucleotides produced by exhaustive ribonuclease T1 digestion of 16S rRNA have been used to deduce relatedness and highly conserved sequences among prokaryotes. Apart from obvious blocks of homology, comparisons of extensive rRNA sequences and judgements of similarity are hampered by the fact that the functional importance of the structure is not known in most regions. Unlike some proteins, it is not possible to draw conclusions as to similar chemical nature, structural role or frequency of substitution by the comparison of non-identical sequences. The use of 'catalogues' of oligonucleotides, each of which represents a phylogenetic character and is scored as absent or present, is therefore attractive, and does not require attempts at alignment of different sequences.

Previous evidence for an endosymbiotic origin of mitochondria has sought to demonstrate recent common ancestry with contemporary prokaryotic forms. However, these arguments have generally relied on features that are not due to mitochondrially coded components[74–76], and often the similarities are

Table 1 Degree of homology in small subunit rRNAs

Sequence	Oligonucleotide catalogue				
	E. coli	*R. spheroides*	*B. stearo-thermophilus*	*H. halobium*	Wheat mt 18S*
Human mt 12S rRNA gene	15(9.5)	34(11)	22–28‡(9)	30(12)	20(17)
E. coli 16S rRNA	†	167(17)	151(13)	53(19)	87(28)

Values given are the total number of nucleotides in ribonuclease T_1-generated oligonucleotides (⩾hexamers) that exactly match the two sequences, assuming a requirement for a G nucleotide before the oligonucleotide sequence. This stringency, together with the size requirements, reduces the number of *E. coli* oligonucleotides that match the 12S rRNA from 38 (see text) to 2 (a hexamer and a nonamer). The values in parentheses are the results expected when these catalogues are tested in this manner against randomly chosen sequences of the same length as the 12S or 16S rRNA (≏954 and 1,541 nucleotides, respectively). Oligonucleotides of unknown sequence were omitted.

* Wheat mt 18S and wheat cytosol 18S score 31, approximately the expected random level, when matched.

† As a test of the method, virtually all the oligonucleotides listed in ref. 72 matched the DNA sequence.

‡ Of the oligonucleotides which were shown with ambiguous sequences, one matched only when one of the two possible sequences was assumed.

more likely to have arisen by chance or convergence than are extensive sequence homologies.

The tRNA structures, unique genetic code and 3′-terminal sequence of the 12S rRNA suggest that mitochondria are less close to prokaryotes than the latter are to eukaryotes. This was further explored using oligonucleotide sequences from the published catalogues of small subunit rRNAs, which were fitted to the 12S rRNA gene sequence using the computer program SEQFIT[77]. Of the 114 oligonucleotides produced from *E. coli* 16S rRNA[72], only 38 matched the 12S rRNA, including 9 of the 29 'conserved' sequences but 14 of the 32 universal prokaryotic sequences[72]. With just 500 nucleotides known from the 5′ and 3′ termini of yeast cytoplasmic 18S rRNA (ref. 34 and K. G. Skryabin, personal communication), 29 *E. coli* oligonucleotides matched, 8 being conserved and 12 being universal sequences, suggesting (because the oligonucleotides do not all map at the ends of 16S rRNA) a far higher level of shared oligonucleotides (see Fig. 5) between prokaryotic and cytoplasmic rRNAs than either shares with mt rRNA.

To test evolutionary relatedness more stringently, hexanucleotides or larger from several catalogues were matched against the 12S mt rRNA and *E. coli* 16S sequences, and the total number of nucleotides in those oligonucleotides that matched was calculated (Table 1). These values are higher than those expected from matching unrelated sequences of the same lengths as those of the two rRNA genes to the individual catalogues. Table 1 shows that the Gram-negative bacterium *Rhodopseudomonas spheroides*[78] and the Gram-positive *Bacillus stearothermophilus*[79] are far more closely related to *E. coli* than either is to human mitochondria, contrary to conclusions from comparisons of respiratory chains[75] and from matrix-of-differences trees based on cytochrome *c* and 5S RNA homologies[76]. The close homology among all tested eubacterial rRNAs[79,80] confirms the distinctiveness of the mt 12S rRNA. Despite the molecular peculiarities of the 'archaebacterium' *Halobacter halobium*[81], it seems to be more closely related to eubacteria than to human mitochondria. The approximately equal homology of eukaryotes and eubacteria with Archaebacteria[80], together with the higher homology between the *E. coli* 16S rRNA and yeast cytoplasmic 18S rRNA (discussed above and shown in Fig. 5) than the homology of either with mt rRNA, suggests that the representatives tested from the major groups of organisms are more closely related to each other than to human mitochondria.

A catalogue from wheat mt rRNA has shown that, although not closely akin to prokaryotic sequences, it is nonetheless further removed from the wheat cytoplasmic rRNA[82]; it can be added from Table 1 that human mt rRNA is at least as distant. 5S rRNAs have only been found in plant mitochondria; if they are absent in other mitochondria the sequences of the larger rRNAs may differ for this reason. A difference between mt rRNAs from different organisms was expected, yeast mitochondria differing in rRNA methylation[83,84], arrangement of the genome[85] and genetic code from mammalian mitochondria, but the implied distance from wheat is surprising. Further work on the difference between cytoplasmic and mitochondrial rRNA from different organisms will be required to show the relative extents of divergence of these sequences and thus the patterns of selection and drift in mitochondria.

From the results presented here human mitochondria seem to represent a radical departure from previously examined organisms. The compact genome organization is probably linked to a requirement for processing so as to free the tRNAs and rRNAs, and perhaps to allow 5′-end recognition of mRNAs. Although there are conserved features, and perhaps functions, of these rRNA sequences, the extent of the differences from other rRNA genes has consequences for the mechanism of initiation of protein synthesis and argues, at least, for a more ancient origin of any endosymbiosis than 'recent common ancestry' (ref. 76) with prokaryotes or eukaryotes.

We thank Dr F. Sanger for encouragement and criticism, Dr B. G. Barrell and Mr R. Staden for advice on the computer techniques used, Dr B. A. Roe for strand separation on RPC-5, and Dr G. Attardi for the gift of HeLa mt DNA and for communicating results before publication. S.A. is a Research Fellow of the Cystic Fibrosis Foundation of America and D.P.N. was supported by a grant from the USPHS.

Note added in proof: The sequence of the region between nucleotides 324 and 933 of Fig. 3 has been determined in HeLa mt DNA; the 5′ sequence of the 12S rRNA differs only in being A at nucleotide 750 (ref. 87).

Discovery of a very distant supernova

M. R. S. Hawkins

Royal Observatory, Blackford Hill, Edinburgh EH9 3HJ, UK

The luminosity and rapid time variation of supernovae suggest that they could be powerful cosmological probes. The main obstacle to such use has been the difficulty of finding sufficient high-redshift examples in time to make the necessary observations of the light curve. Here a very distant ($z \simeq 0.5$) supernova is reported together with photometric observations of its light curve.

On a given night a deep UK 1.2-m Schmidt plate would be expected to show between one and ten supernovae depending on the supernova rate and the usable limiting magnitude. In the present observing programme one sky-limited plate was taken per night, clear of Moon, for 3 weeks between two lunations. The plates could then be compared and a light curve measured for any supernova discovered with maximum near the beginning of the series. This could then be compared with a measured or estimated redshift. The main run of observations was made during August 1978 with the UK 1.2-m Schmidt in Australia. The field was centred on 21 h 28 min, −45° (1950) at a galactic latitude of −47° chosen as a compromise between time available on the telescope and minimum distance from the South Galactic Pole; the plate material is described in Table 1.

A Zeiss blink comparator was used to search for supernovae. Initially two plates were selected; the early epoch J3653, and J4410, a plate of similar quality near the beginning of the run. This produced 36 candidates which were appreciably brighter on the later plate. These images were then blinked with J4458, taken a month after J4410. Six of the candidates were found to have dimmed to their original magnitudes, and three of these were too faint to measure photometrically. The remaining prime candidates—SN1, SN4 and SN6—were all ~2 mag above the plate limit at their brightest. SN4 and SN6 appeared to be stellar with no obviously associated galaxy, but SN1 was clearly resolved.

Table 1 UK 1.2-m Schmidt plates measured

Plate no.	Date UT	Exposure (min)	Seeing (arc s)
J3653	8.10.77	70	DL-1
J4381	25.7.78	45	2–3
J4394	27.7.78	70	DL
J4401	30.7.78	70	DL
J4410	31.7.78	70	1
J4416	3.8.78	65	4
J4425	4.8.78	75	4
J4436	9.8.78	70	3
J4458	23.8.78	70	1

Field centre 21 h 28 min–45° 00′ (1950); emulsion IIIaJ; filter GG395. DL, diffraction limited.

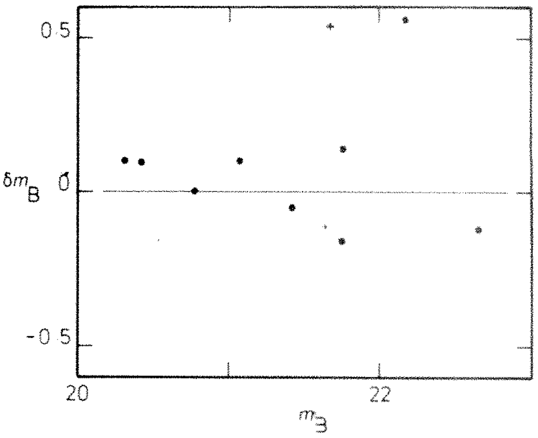

Fig. 1 Plot of residuals between mean magnitudes and magnitudes for plate J4394 against magnitude. +, The supernova image.

To obtain magnitudes three separate measurement procedures were used. A 'first look' was obtained by scanning in one dimension across the candidate image and four nearby comparison images spanning the full range of variation, using a Joyce-Loebl microdensitometer. The readings were converted to intensity using the step wedge calibration, and the area under the curves integrated to give relative magnitudes.

The magnitude scale was checked against photoelectric and electronographic standard magnitudes and no significant deviation from a slope of unity was found, even for brighter stars where saturation effects might be expected. Zero points were obtained by averaging the readings of each star and then plotting the measures for each plate against these mean magnitudes. A plot of relative magnitude of the candidate images against epoch revealed that SN4 and SN6 were not supernovae. They were both of more or less constant brightness on all plates except J4410, where they flared up by about one magnitude. Concentrating on SN1 an electronographic sequence was obtained of the field to fix the zero point of the mean magnitudes, which showed that at its brightest, the candidate image had $B = 21.4$ mag. The SN1 field was now remeasured on the Perkin–Elmer Data System (PDS) at the Royal Greenwich Observatory, including about eight comparison images comprising stars and galaxies, measured in square rasters. The images were analysed in two ways; first the volume under the images was integrated,

0028–0836/80/310467—03$01.00

and second a gaussian of variable height and radius was fitted to the image. These and the Joyce-Loebl measurements all gave substantially the same light curve, although they differed slightly over the measurement of individual images. The PDS integration method gave the smallest scatter and we use those measurements here.

Figure 1 shows residuals between plate J4394 and mean magnitude plotted against magnitude; the r.m.s. scatter of the residuals is 0.11 mag. The supernova candidate is shown by a cross, and the mean magnitude is taken from the early and late epoch plates; the cross is a 5σ point. Figure 2 shows magnitude plotted against epoch for SN1, the scatter being as expected, similar to that in Fig. 1. It is not usually possible to see the supernova as a distinct stellar image superimposed on an underlying galaxy on even the best plates. It looks more like a faint galaxy which suddenly becomes brighter and more star-like and then fades to its original form. The best early epoch plate (J3376) for SN1 shows a faint roughly circular galaxy with a rather compact centre. A positive classification of the galaxy type is not feasible for such a faint image but the general morphology is suggestive of an elliptical. J4381 is the first plate of the main series and here the image has become more point-like and distinctly brighter. On the next plate J4394, taken in very good seeing, the image is just resolved into a faint star-like object about 1 arc s west of the galaxy centroid. This is confirmed by positional measures from the PDS. For the other plates the image steadily fades as shown in Fig. 2, until it regains its early epoch magnitude. This object has all the properties expected of a distant supernova, and apart from some unlikely coincidences is hard to classify in any other way. Distinguishing a type I from a type II supernova is always difficult, even for nearby objects where spectroscopic information is available. Type II objects are, however, observed relatively infrequently, and if, as seems likely, the underlying galaxy is not a late-type spiral, a type II can be ruled out. To measure the decay time, the magnitudes in Fig. 2 must be modified by subtracting the flux from the underlying galaxy. The resulting light curve from the early and late epoch plates is shown in Fig. 3. A straight line was fitted to the readings to give the decay time, the best fit being

$$5.8 \pm 0.5 \text{ days mag}^{-1}$$

Repeating the fit after removing individual readings, and changing the value for the underlying galaxy by the standard error, still gave the best fit slope within the above error limits. Note that the last two observations, which after galaxy subtraction were the most uncertain, were not used. The resulting least-squares slope was 6.16 ± 0.67 days mag^{-1} which is not significantly different from the value given above. The r.m.s. difference of the stars about the best fit line was 0.19 mag, larger than the error in Figs 1 and 2. This is to be expected due to the effect of subtracting the underlying galaxy.

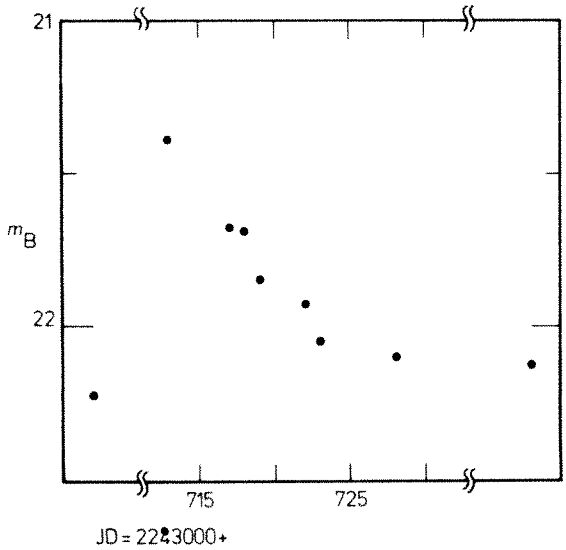

Fig. 2 Plot of magnitude against epoch for the supernova image.

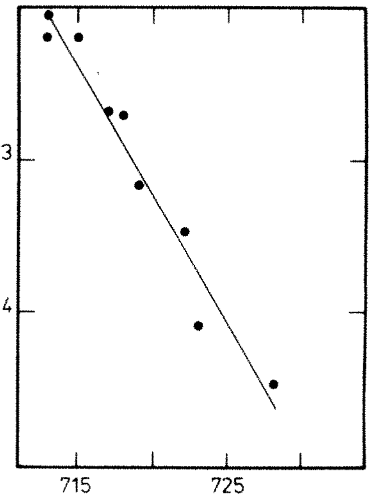

Fig. 3 Plot of magnitude against epoch for the supernova image after subtracting background galaxy flux. Also shown is the least-squares best fit straight line.

Rust[1] has found that the local value for the decay rate of a type I nearby supernova is 8.32 ± 1.95 days mag^{-1} which is compatible with the result found above, although SN1 is clearly not a local object. Unfortunately, we cannot yet obtain a redshift for the underlying galaxy due to its faint magnitude of $B = 22.23$. However, the brightest magnitude in Fig. 3 is $B = 22.06$ which sets a lower limit to the supernova brightness at maximum. Rust[1] found a mean absolute magnitude at maximum of $m_B = -19.53$ with a dispersion of 0.94 mag. The mean value gives a redshift of $z \simeq 0.6$ which in a Friedman cosmology would imply an increase of the decay time given by

$$T_0 = T_i(1+z) \qquad (1)$$

where T_i and T_0 are the intrinsic and observed decay rates respectively. Thus the expected decay rate at the redshift of 0.6 would be 13.3 ± 3.1 days mag^{-1}, which puts the observed value of 5.8 days mag^{-1} at 2.5σ, and in fact the slowest supernova known would have a decay rate of 7.2 days mag^{-1} at this redshift. Even if the absolute magnitude of the supernova were 2σ fainter than the mean value at $m_B = 17.6$, a redshift $z \simeq 0.3$ would be implied giving an expected decay rate of 10.8 ± 2.5 days mag^{-1}; this is still 2σ above the observed value. The most natural interpretation of these observations is that light from the supernova has not undergone a Doppler shift.

Another important effect must be taken into consideration. De Vaucouleurs and Pence[2] have pointed out that the change in the supernova spectral energy distribution as a function of time alters the observed decay rate in a particular bandpass with redshift—the observed magnitudes must be modified by a time-dependent k-correction. This makes supernovae appear to decay more quickly at high redshifts, and de Vaucouleurs and Pence give as the correction factor

$$T_0 = T(1+1.08z) \qquad (2)$$

where T is the observed decay time and T_0 is the decay time which would be observed were the passband redshifted to the rest frame of the supernova. The relation (2) is only claimed by de Vaucouleurs and Pence up to a redshift of $z = 0.15$; however, if this holds at the redshift of SN1 comparison of relations (1) and (2) shows that there will be essentially no observed change in the decay rate as a function of redshift in a Friedman cosmology, and that for a non-expanding universe the decay rate would actually become smaller. Applying the correction to the present observations puts the observed decay time within the bracket represented by the Friedman cosmology, and is evidence that the Universe is expanding; rejection of the correction implies a non-expanding Doppler cosmological redshift.

I thank the UK 1.2-m Schmidt Unit, Miss Faroos Saedi, Dr B. D. Kelly and Dr R. S. Stobie for assistance.

A 2.2-Hz modulation of auroral electrons imposed at the geomagnetic equator

D. R. Lepine, D. A. Bryant & D. S. Hall

SRC Rutherford and Appleton Laboratories, Ditton Park,
Slough SL3 9JX, UK

The direct observation of high frequency ~3 Hz modulation of electron intensities during pulsating aurora is comparatively recent although, from TV and photometric studies, modulation of the visual aurora at these frequencies has been recognized for over a decade. We report here 2.2 ± 0.5 Hz oscillations in the intensities of 4–25 keV electrons producing a pulsating aurora. The electrons were measured from a Petrel sounding rocket launched from Kiruna, Sweden on 25 January 1979. The oscillations like the slower 1–20 s pulsations, exhibit a marked velocity dispersion implying an equatorial origin for both forms of modulation. VLF—hiss observed at about the same time at the Satellite GEOS 2, operating in the same equatorial region, shows remarkable similarities to the modulation in the particle fluxes. A connection between VLF emissions and auroral pulsations has been suggested by Coriniti and Kennel who argue that low frequency, 5–300 s period, micropulsations modulate whistler-mode wave amplitudes leading to variations in the rate of pitch-angle scattering of electrons from the magnetosphere. The isotropic angular distributions reported here suggest that this mechanism acting alone cannot explain the modulation in the present case.

A Petrel rocket, designated P216 in the UK National Programme, was flown from Kiruna, Sweden, to compare electron intensities seen in pulsating aurora with related parameters at the magnetically-conjugate geostationary satellite GEOS 2. The rocket was launched at 21.07.33 UT on 25 January 1979 during the recovery phase of a magnetic substorm. A low-light television, operating down range, showed that for part of its flight the rocket was in the vicinity of patches of aurora that pulsed irregularly with durations of maximum brightness of between 1 and 20 s. Electron intensities at the rocket, measured with channel multipliers and electrostatic analysers, exhibited similar pulsations. We are concerned here with shorter-period (0.46 ± 0.05 s) oscillations that occur in 4–25 keV electron intensities, at several intervals during the rocket flight superimposed on the maxima of the slower pulsations[1]. Particle modulation in the 3 ± 1 Hz frequency range has been observed previously[2] at low energies (< 70 eV), and more recently at high energies[3] (> 25 keV). The present observations are significant in that particles within the 4–25 keV range carry sufficient energy to account for the observed light emission and, therefore, may cause a 2–3 Hz modulation in light intensity frequently observed during pulsating aurora[4,5]. During these particular oscillations, however, due to the combined effects of velocity dispersion and the narrow range of spectrum energies involved, the precipitated energy-flux variations amount to only ± 3% of the ~25 mW m^{-2} energy-flux at pulsation maximum. Because of the low auroral intensity (~2 kR at 427.8 nm), this level of modulation equals the noise level of the optical instrumentation and we cannot confirm that the particle modulation reported here leads to a modulation in the optical brightness.

Examples of the oscillations are contained in Fig. 1, an energy-time spectrogram of electron intensities for the flight-time interval 217–250 s. These intensities were measured at pitch-angles 20 ± 3.5° with a detector whose electrostatic analyser swept through the energy range 1.2–25 keV every 143 ms. In the interval shown the rocket altitude ranged from 170 to 180 km. Oscillations at 2.2 ± 0.2 Hz are strongest during intervals A and B in which it is very noticeable that intensity changes at higher energies precede the corresponding changes at lower energies. This effect can be readily explained as velocity dispersion due to a distant source of modulation. A dispersion in the times of occurrence of 1–20 s pulsations at different particle energies was discovered by Bryant *et al.*[6], confirmed on subsequent occasions[7,8], and indeed found to be the case in this event[1]. The present results are, we believe, the first indication of dispersion in shorter-period oscillations.

To test more closely the hypothesis of a distant source of modulation, we have examined the intensity changes recorded by other detectors operating continuously at energies 3.9, 7.7 and 11.5 keV. These constant-energy detectors were sampled every 0.5 ms as they scanned through the pitch-angle range 15–55° every 57 ms, all sampling the same pitch angle at the

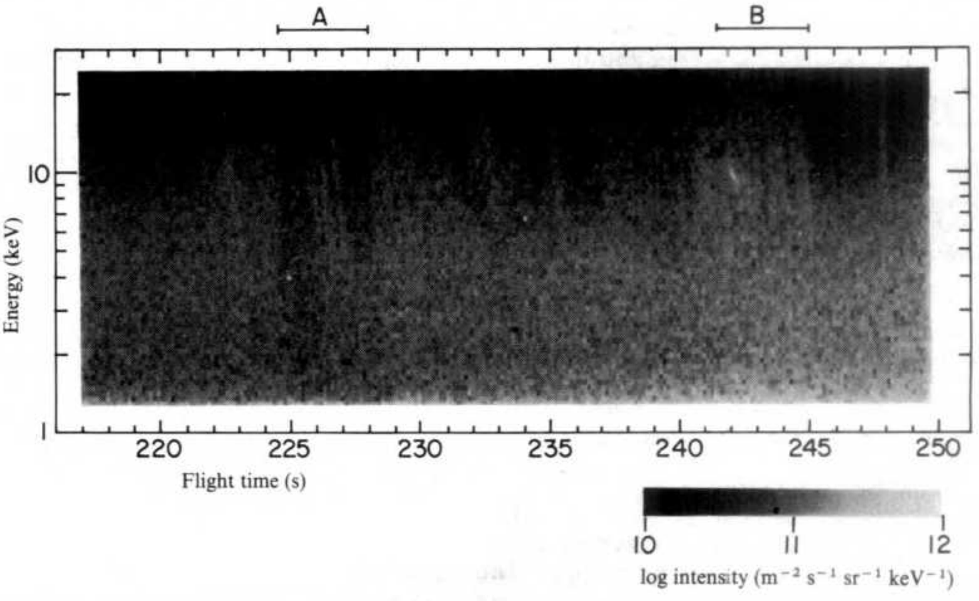

Fig. 1 Electron intensities measured at P216 during an interval of temporal changes. The intensities were measured at pitch angles 20 ± 3.5°. 2.2 Hz oscillations occurring during the intervals A and B are discussed in the text.

same time. In the intervals A and B intensities were found to be isotropic over the observed pitch-angle range at all three energies. Figure 2 shows intensity variations at the three energies in terms of fluctuations about a mean intensity at that energy. It is immediately apparent that the oscillations are quasi-periodic with a mean frequency of 2.2 Hz, and that the amplitude and phase are energy dependent. The oscillations are, when the time shift is taken into account, well correlated.

Because the vertical separation in Fig. 2 is proportional to reciprocal of velocity, sloping lines linking the oscillations provide clear evidence of velocity dispersion, if we assume that modulation is simultaneous at all energies and that particles travel with constant speed after modulation. The data clearly support the dispersion hypothesis, and point to a source distance of $42 \pm 5 \times 10^6$ m. The length of a particle trajectory from a rocket altitude to the geomagnetic equator ranges from, in the dipole approximation, 41 to 43×10^6 m for the pitch angles (15–55°) sampled here, so the analysis performed in Fig. 2 therefore suggests that the source of modulation is located in the equatorial region at a radial distance of about 5.4 R_E. The use of the dipole approximation requires justification, particularly when there is evidence for, on some occasions, a considerable stretching of field lines in the midnight sector of the magnetosphere. Using a comparison of plasma measurements made by the Vela satellites at 18 R_E, with satellite photographs of the auroral oval, Hones *et al.*[9] have deduced that the degree of stretching is variable, and that on some occasions field lines from approximately the latitude of Kiruna reach out to at least 18 R_E. Their result is consistent with the degree of stretching deduced from observations of variable dispersion[8], and therefore our present results indicate that, at the time of the rocket flight, the magnetic field was not severely stretched from its dipole-like configuration.

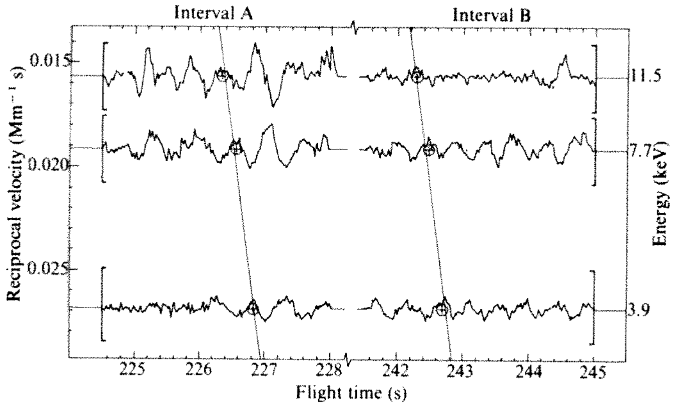

Fig. 2 Velocity dispersion of 2.2 Hz oscillations in the intervals A and B. Each trace shows electron intensity at a constant energy in terms of variations about a mean intensity at that energy. The encircled crosses indicate zero variation and an average time for the cycle on which they are drawn. The vertical separation of the traces is proportional to reciprocal velocity. The straight lines linking the oscillations provide clear evidence of dispersion, and correspond to a source distance of 42 Mm. [ ], Indicate ±25% variations. Random statistical errors are typically ±4%.

In view of the location of GEOS 2, close to the equatorial crossing point of magnetic field lines which at times connect with the area of Kiruna, measurements made at the satellite are well suited for comparison with those made at the rocket. An examination of particles of similar energy at GEOS 2, indicates that there are no changes, either inside or outside the loss-cone, corresponding to the longer-period pulsations. It is not yet clear whether 2.2 Hz oscillations in particle flux are detectable by the instruments on GEOS 2. However, VLF emissions measured at GEOS 2 during the rocket flight are noticeably modulated at a frequency close to that of the oscillations in electron intensities at the rocket. These emissions are strongest in a band centred on 500 Hz, and are of a type usually referred to as hiss. Figure 3 shows the amplitude of 500 Hz magnetic field fluctuations, measured by experiment S300 on GEOS 2, for the rocket flight interval 220–250 s. Oscillations at 2.8±0.6 Hz are very apparent between 221 and 225 s, and at 3.1±0.6 Hz between 241 and 243 s. Although these do not correspond exactly with events at the rocket they have a similar frequency and occur, like those at the rocket, in irregular bursts. A possible connection between the electron intensity oscillations and VLF activity is not entirely unexpected. Coroniti and Kennel[10] have argued that auroral pulsations are caused by a modulation of the rate of pitch-angle scattering in a diffusion region near the equator. In their model, electrons are scattered by resonance with whistler-mode electromagnetic waves whose growth rates depend on, among other parameters, the amplitude of magnetic micropulsations within the diffusion region. Although this is in many ways a promising explanation of auroral pulsations[11], there are

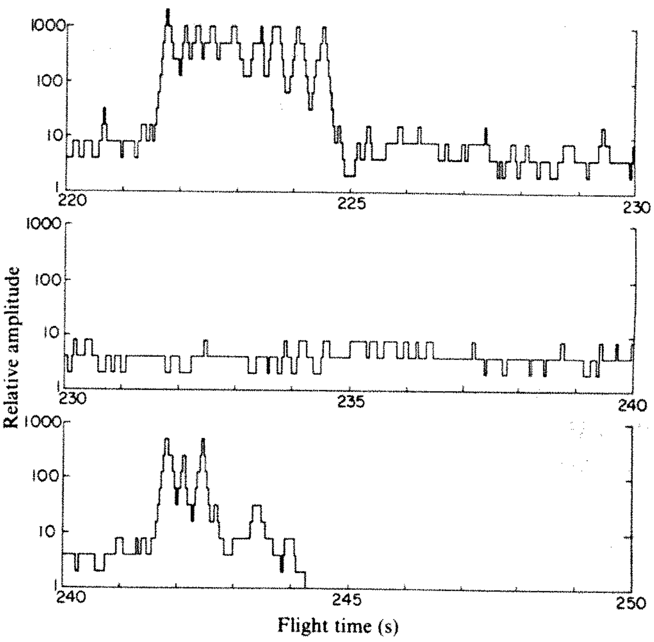

Fig. 3 Intensity of 500 Hz magnetic field fluctuations measured at GEOS 2 by the S300 wave experiment during the rocket flight interval 220–250 s. Oscillations at about 2.8 Hz can be seen between 221 and 225 s, and at about 3.2 Hz between 241 and 243 s.

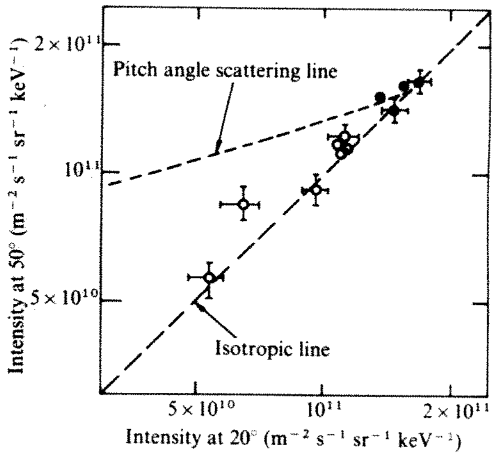

Fig. 4 Relation between intensities at pitch-angles of 50° and 20° for 11.5 keV electrons during interval A: ●, maxima; ○, minima intensities. The pitch-angle scattering line is calculated using a dipole approximation with $L = 5.4$ and a loss-cone of half-angle of 3.44° at the equator.

observations, as on earlier occasions[12], which create difficulties for this theory. Figure 4 shows the relationship between intensities at pitch-angles of 50° and 20° for 11.5 keV electrons during interval A. The broken line, marked pitch-angle scattering, indicates the expected degree of anisotropy for oscillations that are driven by changes in the rate of diffusion of trapped electrons from a reservoir of constant intensity of $1.6\times10^{11}\ \mathrm{m^{-2}\,s^{-1}\,sr^{-1}\,keV^{-1}}$ into a loss-cone created by atmospheric absorption. Although there is a suspicion that intensities at large pitch-angles exceed those at small pitch-angles, the observations follow more closely the isotropic line than the pitch-angle scattering one, indicating that variations in pitch-angle scattering are not the dominant feature controlling the oscillations. Intensities at other energies during intervals A and B follow closely the behaviour of the 11.5 keV electrons shown in Fig. 4, therefore pitch-angle scattering acting alone cannot explain their modulation. As the nature of the mechanism is unclear at this stage, the extent to which the similarity between the modulation seen at GEOS 2 and the modulation seen at the rocket indicates a real coupling between magnetospheric and ionospheric events remains to be evaluated.

We thank Drs H. Borg, P. Christiansen, P. Gough, A. D. Johnstone, A. Korth and G. Martelli for information and helpful discussions on GEOS 2 particle and wave measurements.

Observation of flaws in anodic films on aluminium

G. E. Thompson, K. Shimizu & G. C. Wood

Corrosion and Protection Centre, University of Manchester Institute of Science and Technology, PO Box 88, Manchester, M60 1QD UK

A thin compact oxide film forms naturally on aluminium in air and can be thickened by anodizing, to give widely used materials. However, highly localized processes can occur at flaws, which are always present in the films and they can lead to pit development[1] and influence the electrical properties[2] (dielectric breakdown and rectification). As awareness of the different behaviour at flaws increases, other interesting phenomena, such as electroluminescence[3], response to UV radiation[4] and electrolytic colouring[5], may be influenced by the activation of pre-existing flaws, or the generation of new flaws. Clearly, further knowledge of this kind is of fundamental and practical importance. Some of the more significant findings relating to the nature, shape and geometry of flaws observed after anodizing in ammonium pentaborate solution are outlined here.

Flaws or lighter regions ~73–200 nm in size, can be observed readily in the barrier films formed to various voltages at constant current density on as-received superpure aluminium (99.99 Al; 0.003 Cu; 0.002 Fe; 0.002 Si wt%) (Fig. 1). Stripped anodic films show that the pre-existing flaws are now 'decorated' by differently textured film, which spreads into the neighbouring featureless film in an approximately circular front (Fig. 1*a*, *b*) This texture changes further with increase in forming voltage and, at 200 V, the local islands have been identified as γ' alumina[3] (Fig. 1*c*). A change in the extent of crystallinity has also been suggested[6,7]. The corresponding ultramicrotomed sections show that the film formed to 50 V is relatively uniform, although occasional metal ridges protruding into the film from the metal–film interface are evident (Fig. 1*d*). Further thickening of the film has occurred at 100 V and distinct local regions of differently textured film are evident in approximately the outer half of the film (Fig. 1*e*). These apparently convex lens-shaped regions are sharply defined and are located above metal ridges at the metal/film interface. A more marked change in appearance is observed at 200 V, where the metal ridges are more clearly defined and the differently textured film is more extensive (Fig. 1*f*). The locally textured regions of film have spread laterally from their original position centred above the tip of the metal ridge. The islands of crystalline γ' alumina have become damaged during sectioning, but the micrograph suggests that they are thicker at their centres, and the thickness decreases progressively into the neighbouring barrier film. In addition, a narrow channel appears to be present in the barrier film above the crystalline island.

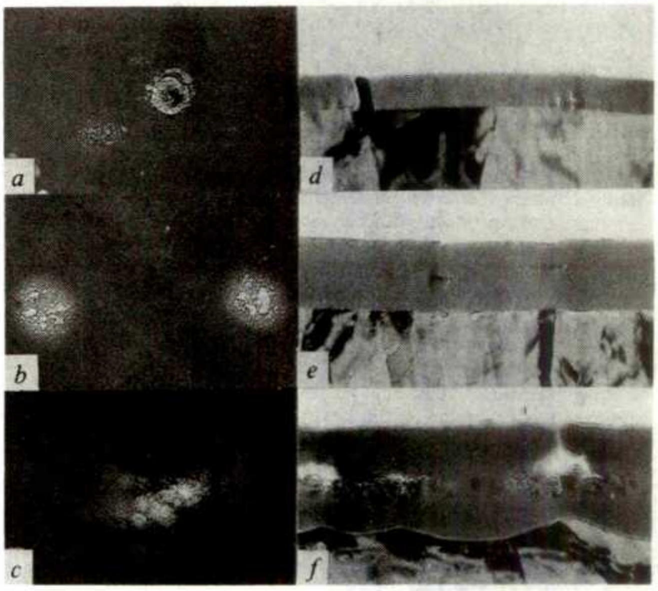

Fig. 1 Transmission electron micrographs of the films formed on as-received aluminium at $50\ \mathrm{A\,m^{-2}}$ in 0.1 M ammonium pentaborate solution at 298 K to various voltages. *a*, Stripped anodic film formed to 50 V, showing the decorated flaws. *b*, Stripped anodic film formed to 100 V showing the different textured appearance of the flaws. *c*, Stripped anodic film formed to 200 V, showing the island of crystalline γ' alumina. *d*, Ultramicrotomed section of the aluminium substrate and the film formed to 50 V. Occasional metal ridges can be seen at the metal–film interface. *e*, Ultramicrotomed section of the aluminium substrate and the film formed to 100 V, showing the sharply defined regions of differently textured film above metal ridges. *f*, Ultramicrotomed section of the aluminium substrate and the film formed to 200 V, showing the marked scalloping at the metal–film interface and the developing regions which have been identified as γ' alumina by electron diffraction[3]. Magnification ×78,000.

The number of the resultant islands of crystalline film is dependent on substrate preparation and cleaning or electropolishing markedly reduces their population density (from $2\times10^{12}\ \mathrm{m^{-2}}$ on as received specimens to about $10^9\ \mathrm{m^{-2}}$ after

0028–0836/80/310471—02$01.00

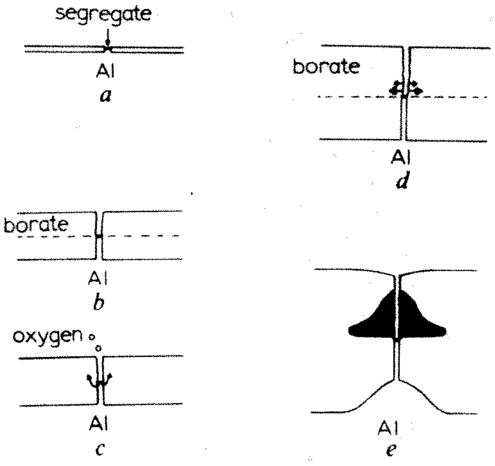

Fig. 2 The development of islands of crystalline film. *a*, An impurity segregate situated at the tip of a metal ridge protruding into the air-formed film. *b*, After anodizing, the segregate is located in the vicinity of the boundary between the borate-containing film material and the relatively pure alumina film. *c*, Gas evolution from the segregates proceeds during anodizing and high local field strengths may cause the aluminium ridge to be removed preferentially, thereby occluding the segregate in the film. *d*, Joule heating allows the development of local temperature rises in the solution-filled channel. The hotter region is situated just above the segregate, and direct heating of the film in this region causes the change in texture. *e*, Crystalline film develops as a result of direct heating and the original flaw passes through the centre of this material. Its development produces shielded regions, which hinder the development of the amorphous barrier film.

electropolishing). This suggests that they develop in the vicinity of surface impurity segregates rather than from effects in the depths of the metal, that is, second phase material, which may be revealed as the metal–film interface recedes during anodizing. Favoured sites for segregation of impurities, such as iron and copper, exist on rolled surfaces, that is, in the vicinity of metal ridges and troughs associated with rolling lines. Growth of the air-formed film, which is more voluminous than the aluminium consumed, then creates a distribution of flaws, comprised of metal segregates situated at the bottoms of channels in the film, which are located at the tips of metal ridges protruding into the film from the metal–film interface (Fig. 2*a*). A characteristic air-formed film is also likely to form over the segregates.

During anodizing, thickening of the air-formed film occurs by the usual growth processes involving ionic migration of Al^{3+} outwards and OH^- or O^{2-} ions inwards[8]. SIMS data (G.E.T. and G.C.W., unpublished work) suggest similar anion and cation transport numbers, leading to an inner relatively pure alumina film and deposition of an outer borate-containing film. However, film formation does not proceed directly above the segregates where an alternative anodic process, oxygen evolution occurs or in the shielded regions directly below the segregates. This manner of film growth results in the segregates being located at the tips of metal ridges protruding into about one-half of the total film thickness (Fig. 2*b*). Gas evolution from the segregates tends to maintain the channels above them open by mechanically disrupting the outer film, which attempts to bridge over them. Unless the shielding of the aluminium ridges is effective, high local field strengths may result in the consumption of this metal in lateral film growth, and the possible inclusion of some of the segregate into the film (Fig. 2*c*).

The areas of the bases of the segregates are extremely small compared with the macroscopic aluminium substrate and large effective current densities can be directed to these relatively low resistance pathways, with resultant large temperature rises due to local Joule heating effects. This is unlike the situation suggested to occur during pitting, at localized sites, where salt film formation proceeds rapidly and the temperature at the pit surface remains essentially unchanged[9]. As the film thickens further, more current is focused into these preferred regions, which is confirmed by the more ready observation of gas evolution at high cell voltages, with greater local heating effects. Heat is dissipated into the aluminium substrate and bulk solution, but because the segregates are located above the tips of relatively narrow metal ridges, it is likely that the rate of heat flow into the substrate is limited and the hottest zone in the solution-filled channel is situated just above the segregate (Fig. 2*d*).

Direct heating[10], or hydrothermal treatment[11], increases the extent of crystallinity of anodic films, at a rate dependent on their composition. Similar texture changes to those evident here initially have been observed during electron beam heating of anodic films[12], suggesting that they may be promoted by direct heating. However, there is presently little direct information about the magnitude of the local temperature rises. Figure 2*d* shows that the hot zone is adjacent to the borate-containing film material, which implies that this film material undergoes the more rapid change in texture and ultimate increase in crystallinity.

In the present situation the local heating is thought to develop continuously rather than in discrete bursts, which are more commonly associated with electron avalanching and dielectric breakdown. Direct heating promotes the increase in the extent of crystallinity of the material adjacent to the hotter regions of the channel and, as the barrier film thickens, the hot regions spreads up the channel resulting in an increase in the volume of the resultant crystalline island. The shape of the crystalline region is explained by the hotter region remaining just above the segregate, but with further barrier film thickening temperature rises adjacent to regions further up the channel promote local crystallization. The actual stage at which crystallinity appears is a compromise between the size and population density of the flaws and the film thickness, which govern the effective current density and local temperature rises generated. Anodizing in borate solution favours development of the islands[3], which suggests that the eventual crystallization process may be dependent on electrolyte conductivity and buffering capacity and/or film composition. Furthermore, it is not clear whether borate species incorporated in the film aid this process directly by reducing the crystallization temperature or migrate from the hotter regions during crystallization and whether borate species act as glass network formers or modifiers. However, the eventual development of these islands, which hinders the growth of the normal amorphous barrier film results in the development of scalloped metal regions at the metal–film interface (Fig. 2*e*).

Note also that electroluminescence is observed during the growth of these films in borate solutions. The significance of flaws, film composition and the development of crystalline film is in the stages of elucidation and will be reported elsewhere.

In conclusion, it is suggested that iron and/or copper impurities are responsible for the behaviour observed during anodizing in borate solution. They remain at the tips of metal ridges located at the bases of channels within the films and local temperature rises associated with Joule heating effects give rise to the development of crystalline film.

The structure and energetics of the conduction plane in Naβ Al$_2$O$_3$

J. R. Walker & C. R. A. Catlow

Department of Chemistry, University College London,
20 Gordon Street, London WC1H 0AJ, UK

An atomistic computer simulation study of the superionic conductor NaβAl$_2$O$_3$ is described here. This material is a layer structured compound in which highly mobile sodium ions are located in 'conduction planes' between spinel structured Al$_2$O$_3$ blocks[1]. Although we have investigated structural properties of the conduction plane, which have been widely studied by diffraction techniques, our results are also important to transport properties of the compound. We demonstrate that a very flat potential surface governs the distribution of Na$^+$ ions in the conduction plane. This finding is clearly compatible with superionic properties of the compound but also has consequences for analysis of structural data. Our calculations confirm that O^{2-} interstitials are stabilized by large relaxations of neighbouring lattice ions to give the cluster proposed earlier[2]. Defects in the conduction plane of β-Al$_2$O$_3$ are shown to be generally stabilized by large relaxations of surrounding ions, which favour defect formation in the compound, and which, therefore, cause the gross deviations from stoichiometry observed in β-Al$_2$O$_3$. Our results suggest a 'fluid' conduction plane structure (a fluidity which extends to the neighbouring spinel block ions) with only weak localization of the conduction ions into specific sites and strong stabilizing relaxations of conduction and spinel block ions around any defect species.

Two types of calculation are discussed. In the first, lattice energy calculations on stoichiometric NaβAl$_2$O$_3$ for a variety of sodium ion distributions, use the general lattice energy code, PLUTO[3], previously applied successfully to complex problems in the field of non-stoichiometry[4,5]. In the second, calculations of the energies of formation of defects within the conduction plane of stoichiometric NaβAl$_2$O$_3$ use another general computer code, the HADES III[4,6], which can be applied to all crystal symmetries. The HADES code is an improvement on earlier theoretical studies of Wong *et al.*, which omitted relaxation effects.

Both types of calculation require specification of the relevant interionic potentials. Shell model potentials (see refs 3, 6) are used. Thus to model NaβAl$_2$O$_3$ we take parameters from the lattice potential of Al$_2$O$_3$ (refs 4, 6) which are supplemented by a Na$^+$–O^{2-} potential obtained from a study of the crystal properties of Na$_2$O; for the shell parameters of the Na$^+$ ion we use the values reported in ref. 7. The present calculations were prompted by their successful application in other systems[5,6,8].

Three important cation sites in the conduction plane of NaβAl$_2$O$_3$, have been identified. Figure 1 shows the positions known as the Beevers–Ross, anti-Beevers–Ross and mid-oxygen sites. We have, therefore, performed three lattice energy calculations; in each case all the Na$^+$ ions were situated at one of the three sites. The Beevers–Ross configuration is found to have the lowest lattice energy. The other results are summarized in Table 1.

Table 1 Energies of Na$^+$ ion configurations

Configuration	Energy* (eV)
Mid oxygen	0.39
Anti-Beevers–Ross	0.15

* Energies are given per Na$^+$ ion and with respect to the Beevers–Ross configuration.

Several important consequences follow from these calculations. First, the Beevers–Ross sites are the most energetically favourable for the incorporation of Na$^+$ ions—a result in line with experimental observation[9]. But the differences between the energies of the Na$^+$ at this site and other configurations are very small—of the same order of magnitude as kT for elevated temperatures (500–1,000 K). The existence of such an exceptionally flat potential surface provides a qualitative explanation of the superionic nature of NaβAl$_2$O$_3$. Little resistance to Na$^+$ motion can be provided by the alumina framework, and the conduction mechanism and activation energy will be largely controlled by the interactions between the Na$^+$ ions. Second, the flatness of the potential surface will result in very large and anharmonic thermal parameters in any refinement of diffraction data on the material—a conclusion of obvious importance in structural studies of NaβAl$_2$O$_3$. Third, our present theoretical methods contain limitations. If the potential energy of the Na$^+$ ion between different sites in the conduction plane varies only by $\sim kT$, then transport properties of the solid cannot be adequately modelled by 'static' calculations of the type discussed here because the correlation between the motions of several species cannot be modelled by our technique which concentrates on isolated defect species. Dynamical simulations as reported by

0028–0836/80/310473—02$01.00

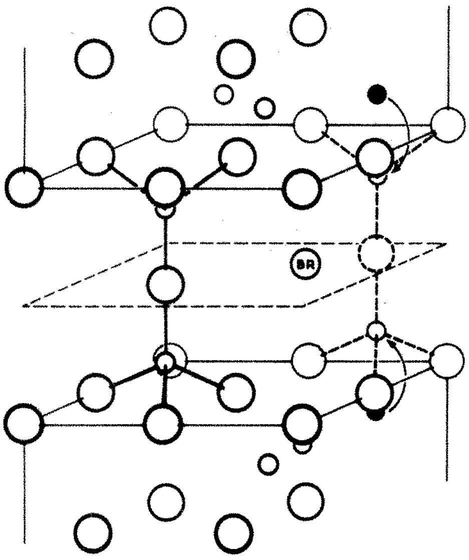

Fig. 2 Oxygen interstitial in conduction plane. The interstitial (◌) is stabilized by the movement of the Al^{3+} ions (●) as shown. A bridging oxygen ion is also shown.

Dixon and Gillan[10] for the superionic fluorite materials will be required.

Excess oxide ions in non-stoichiometric β-Al_2O_3 are incorporated in the conduction plane. Recent diffraction studies have suggested that these O^{2-} ions are stabilized by the displacement of two neighbouring aluminium ions from their lattice positions into 'interstitial' sites above and below the conduction plane; Fig. 2 illustrates the resulting complex. To test the feasibility of these proposals, we performed calculations using the HADES III program first on the conduction-plane O^{2-} interstitial, and second on the interstitial with both neighbouring displaced Al^{3+} ions. We found that displacement of both ions resulted in a stabilization energy of 1.0 eV. Our results confirm the Roth model. They also indicate a tendency for exceptionally large displacement of lattice ions around 'defects' in β-Al_2O_3.

We have performed calculations using the HADES III program of vacancy and interstitial energetics in β-Al_2O_3, and found, remarkably, that the formation of all defect species is energetically favourable. The result is not attributable to inadequacies in our lattice model, as the calculations converged successfully, without excessive ion dipoles developing. Rather, the favourable defect energies are due to the ability of the conduction plane and neighbouring spinel block ions to relax extensively around charged defects—a feature of the defect chemistry of β-Al_2O_3 already shown by the structure of the oxide interstitial, but which our work suggests is general to this material.

It is also clear that if defect formation is a favourable process in $Na\beta Al_2O_3$, then the stoichiometric compound would not be expected to be stable; the compound will disproportionate into a defective non-stoichiometric compound and Al_2O_3. Although our discussion cannot yet be more quantitative, we believe that we have identified the essential feature of $Na\beta Al_2O_3$ responsible for its unusual stoichiometry, namely the exceptional stability of defects which in turn arises from the very large ion relaxations possible around conduction plane species.

Our results suggest that the unique features of β-Al_2O_3 can be attributed to two related factors: the flatness of the sodium ion potential surface in the conduction plane; and the tendency for large ion relaxations around defect species in the plane. This 'fluidity' of the conduction plane is obviously the basic cause of the superionic properties of β-Al_2O_3. However, it raises serious problems for the detailed modelling of the material. Static simulations cannot yield information beyond the general guidance which the present results have provided. Molecular dynamic simulations are necessary. Preliminary results have been reported by de Leeuw[11], but detailed simulations would be of great interest.

Conversion of carbohydrate into hydrogen fuel by a photocatalytic process

Tomoji Kawai & Tadayoshi Sakata

Institute for Molecular Science, Myodaiji, Okazaki 444, Japan

Attempts have been made to find green plants which produce low-molecular weight hydrocarbons[1,2] and to find seaweeds which produce hydrogen from water utilizing solar energy[3,4]. These attempts are aimed at finding methods of making use of the photosynthetic process in plants for direct production. Most green plants, however, synthesize carbohydrates, such as sugar, starch and/or cellulose, from water and carbon dioxide. The C_4 plants[5], such as corns and sugar cane, grow rapidly, utilizing solar energy with ~1% efficiency for the fixation of CO_2. This value is 10 times larger than that of the average efficiency of photosynthesis of plants, 0.1%. However, the carbohydrates produced by these plants cannot be used directly as fuel. Here we show a new route for the conversion of carbohydrates into hydrogen (a clean fuel in the hydrogen energy system), taking advantage of the photocatalytic process. We found that the irradiation of the carbohydrates, not only sugar or starch but also cellulose, in the presence of water and a $RuO_2/TiO_2/Pt$ photocatalyst powder leads to the efficient production of hydrogen gas.

This new process is expressed as equation (1) together with the photosynthesis of carbohydrates by green plants (equation (2)), as follows:

$$(C_6H_{12}O_6)_n + 6n\ H_2O \xrightarrow{h\nu,\ RuO_2/TiO_2/Pt} 6n\ CO_2 + 12n\ H_2 \qquad (1)$$

$$6n\ H_2O + 6n\ CO_2 \xrightarrow{h\nu,\ \text{green plant}} (C_6H_{12}O_6)_n + 6n\ O_2 \qquad (2)$$

$$12n\ H_2O \longrightarrow 6n\ O_2 + 12n\ H_2 \qquad (3)$$

Here, $(C_6H_{12}O_6)_n$ represents sugar (saccharose) ($n = 2$), starch ($n \simeq 100$) or cellulose ($n \simeq 1{,}000$–$5{,}000$) after hydrolysis.

Accordingly, the overall reaction results in the decomposition of water to produce hydrogen (equation (3)), the CO_2 being recycled. The reaction (1) proceeds almost without loss of energy (heat of combustion: 688 kcal mol^{-1} for $(C_6H_{12}O_6)_{n=1}$ and 680 kcal mol^{-1} for 12 H_2).

The typical experimental conditions are as follows: the powders of RuO_2 (Rare Metallic), TiO_2 (Katayama Kagaku) and Pt (Engelhardt) (weight ratio = 10:100:5) were mixed and ground in an agate mortar, and this powder was suspended in

0028-0836/80/310474—03$01.00

neutral water (40 ml) in a Pyrex glass bulb (280 ml). Then a sugar (600 mg, Nissin Seito pure white sugar) or a soluble starch (120 mg, Katayama Kagaku) was dissolved in the solution and the bulb was deaerated and illuminated by a 500 W Xe lamp. For the reaction of cellulose, a filter paper (Toyo Filter) was cut into pieces and put into neutral water or a 6 M NaOH water solution with the photocatalyst forming alkali-cellulose. The gases evolved were collected and analysed by a mass spectrometer, and the amounts of the gases were determined with a manometer with traps at −197, −78 and −10 °C, as described previously[6].

When the photocatalyst suspension in water with the substrate was illuminated, gas bubbles were vigorously generated out of the depth of the solution near the illuminated area. The bubbling stopped when the light was turned off. The evolved gases were mainly H_2 and CO_2, with very small amounts of CH_3OH and C_2H_5OH (less than 0.2% of the total amount). Table 1 summarizes the amounts of hydrogen evolved from sugar, starch or cellulose with water, and Fig. 1*a* shows the evolution of H_2 and CO_2 from sugar plotted against irradiation time. The ratio of the formation rate of H_2 to CO_2 was 3 : 1 to 4 : 1 at the initial stage, becoming about 2 : 1 in the stationary state. No CO, CH_4 and O_2 were evolved. When NaOH was put into the solution to form 6M NaOH solution during the reaction, only H_2 was evolved (Fig. 1*a*), and the CO_2 produced was absorbed in the solution presumably as Na_2CO_3 or $NaHCO_3$. Also with the cellulose in 6M NaOH aqueous solution, pure hydrogen was evolved (Table 1). The quantum yields of the H_2 production determined by monochromatic irradiation at λ = 380 nm for sugar, starch and cellulose were 1.2, 0.8 and 0.3% respectively in neutral water and 1.5, 1.3 and 1.0% respectively in 6M NaOH. These quantum yields, using the $RuO_2/TiO_2/Pt$ photocatalyst, were 100 times larger than those obtained with TiO_2 alone (Table 1). To confirm that no detectable amounts of other products were formed in the solution at the end of the reaction, an experiment was carried out with a small amount of sugar (13 mg, corresponding to 1 mmol of H_2 gas), using a Hg-ultra-high pressure lamp (500 W, Philips) which emits intense UV light ($\lambda < 320$ nm was cut by a Pyrex glass filter), instead of the Xe lamp. The sugar was then completely decomposed within 18 h producing only the corresponding H_2 and CO_2 gases (Fig. 1*b*). These results show that the reaction (1) occurs successfully in this experimental condition at room temperature, simply producing gaseous H_2 and CO_2. Surprisingly, the hydrogen was evolved not only from water and sugar, a relatively large molecule, but also from water and starch or cellulose, the stable macromolecule which consists of about a hundred to thousands of molecules of glucose.

Table 1 H_2 and CO_2 evolution from water and sugar, starch or cellulose on the $RuO_2/TiO_2/Pt$ photocatalyst suspended in neutral water and 6M NaOH solution, irradiated by 500 W Xe lamp

Reactant	H_2 (μmol/20 h)	CO_2 (μmol/20 h)	Quantum yield at λ = 380 nm (%)
Sugar + H_2O	280	133	1.2
Starch + H_2O	204	96	0.8
Cellulose + H_2O	70	42	0.3
H_2O	4	*	0.02
Sugar + 6M NaOH	341	—	1.5
Starch + 6M NaOH	320	—	1.3
Cellulose + 6M NaOH	244	—	1.0
Sugar + H_2O with TiO_2 catalyst	2	1.2	—

Experimental conditions: sugar (600 mg), starch (120 mg), cellulose (120 mg), $RuO_2/TiO_2/Pt$ photocatalyst (300 mg), H_2O (40 ml), 6M NaOH aqueous solution (40 ml). All the values fluctuated within at most ±10%. The rates of gas evolution represent the values at 50 h after the beginning of the irradiation. The quantum yield means the number of electrons used for the H_2 evolution divided by the number of incident photons, taking into consideration that two electrons produce one H_2 molecule.

* Oxygen (1.6 μmol per 20 h) was simultaneously evolved.

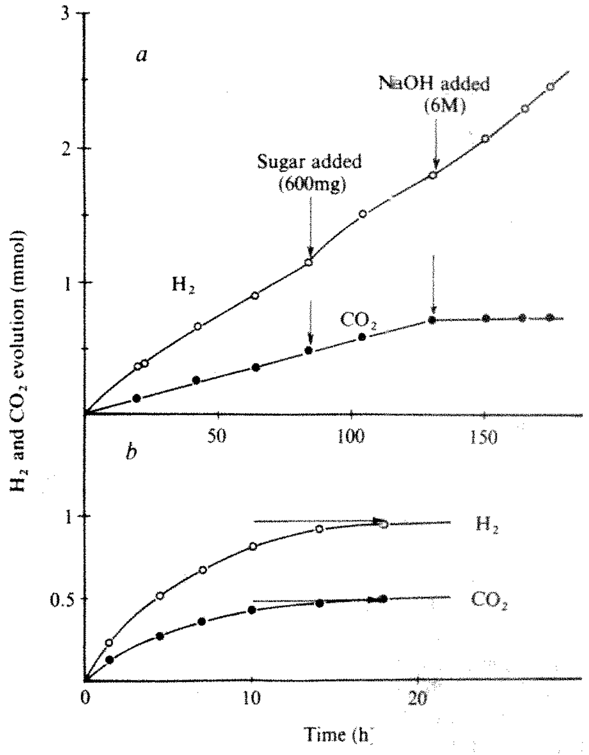

Fig. 1 *a*, H_2 and CO_2 evolution from sugar in water versus the irradiation time. Experimental conditions: sugar (600 mg), H_2O (40 ml), $RuO_2/TiO_2/Pt$ (300 mg), 500 W Xe irradiation. Additional sugar (600 mg) and NaOH (9.6 g) were put into the solution at 85 and 130 h after the start of the reaction, respectively. *b*, H_2 and CO_2 production with the irradiation time from a small amount of sugar. Experimental conditions: 500 W Hg-ultrahigh-pressure lamp, sugar (13 mg), H_2O (40 ml), $RuO_2/TiO_2/Pt$ (150 mg). Arrows (→) indicate the estimated amounts of H_2 and CO_2 which are produced from 13 mg of sugar according to equation (1).

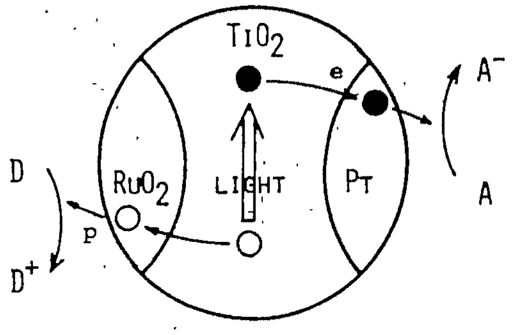
The mechanism of the reaction could be explained by regarding the $RuO_2/TiO_2/Pt$ powder as an electrochemical microcell, as follows: the light of energy larger than the band gap of TiO_2 (3 eV) produces electron–hole pairs; then the separated electron and holes can make redox reactions at the surface of the particle with the molecules in the solution (Fig. 2). This particular $RuO_2/TiO_2/Pt$ photocatalyst is very active in reaction (1) (100 times more active than TiO_2 alone), presumably because RuO_2 is one of the best electrode materials for the oxidation of water[7] and Pt for hydrogen evolution[8]. As carbohydrate is expressed as $(CH_2O)_n$ and is an assembly of $(\mathrm{H{-}\overset{|}{\underset{|}{C}}{-}OH})_n$ which has alcoholic —OH groups, we chose CH_3OH and HCHO as the model C_1 compounds, and examined their photocatalytic reactions with water on the $RuO_2/TiO_2/Pt$ photocatalyst. It is already known that CH_3OH is photooxidized to form HCHO on a single crystal TiO_2 photoanode[9] ($CH_3OH + 2p \rightarrow HCHO + 2H^+$). In our experiment using $RuO_2/TiO_2/Pt$ powder, the CH_3OH was oxidized into HCHO, and simultaneously, H^+ was reduced to form H_2 (Quantum yield ≃44%). It was also observed that HCHO with water was finally converted into H_2 and CO_2 ($H_2 : CO_2 = 2 : 1$) on this photocatalyst ($HCHO + H_2O \rightarrow 2H_2 + CO_2$). Consequently, the carbon chains of carbohydrates in water would be successively oxidized by the hole at the oxidizing site of the catalyst to form H^+ and CO_2, while the electrons would reduce H^+ at the reducing site to form H_2, similar to the case of CH_3OH and HCHO. The larger amount of H_2 production at the beginning of the reaction would be due to the dehydrogenation of the carbohydrate to form >C=O, —CH=O or —COOH functional groups at the initial stage.



Semiconductor particle

Fig. 2 A schematic figure of the $RuO_2/TiO_2/Pt$ particle. O, Hole (p) in the valence band of TiO_2; ●, electron (e) in the conduction band. A and D represent acceptor and donor, respectively, of electrons in the solution. In reaction (1), carbohydrate and proton in the solution play the roles of D and A, respectively.

Note also that this $RuO_2/TiO_2/Pt$ photocatalyst can decompose water directly into H_2 and O_2 with a quantum yield of 0.02% at $\lambda = 380$ nm (Table 1).

As solar energy conversion into chemical energy by a man-made device with efficiency of >1% is not cheap or easy at this stage, the use of the photosynthetic power of green plants for making fuels is still effective[1]. In Brazil, a project is under way in which sugar taken from rapidly growing sugar cane is fermented into ethanol for use as a fuel, using bacteria[1,10]. The fermentation, however, is a delicate procedure, and occasionally an acid is formed instead of alcohol. In our method, the capture and the fixation of dilute CO_2 is left to the plants, and the produced carbohydrates are artificially converted into H_2 and CO_2 using the photocatalytic reactions on the stable inorganic semiconductor powder. This process may be called 'photoinduced fermentation'. The CO_2 evolved can be collected and may be fed back to the plants as concentrated CO_2 gas. In the concentrated NaOH solution, we can get pure hydrogen gas (Fig. 1*a*) and simultaneously Na_2CO_3 or $NaHCO_3$, important substances for the chemical industry. Furthermore, the rates of H_2 production from carbohydrates were greatly enhanced in 6M NaOH solution compared with that in neutral aqueous solution (Table 1). Another method for the production of pure hydrogen, utilizing reaction (1) in a photoelectrochemical cell is now under investigation: the carbohydrate with water is oxidized at a semiconductor photoanode to form CO_2 in one cell, with H_2 production from water at the cathode in the other cell.

Using the strong oxidizing power of the RuO_2/TiO_2 photocatalyst powder, we have demonstrated the photoinduced water–gas reaction with formation of H_2 from water and solid carbon[6], the direct decomposition of water into H_2 and O_2 (refs 11, 12) and, in this study, the decomposition of carbohydrate by $RuO_2/TiO_2/Pt$ to produce H_2. This method may also be applied to the decomposition of excrements containing cellulose, protein and fat, accompanied by the production of H_2 as a fuel. We are also interested in the possibility of the decomposition and scavenging of abandoned carbon compounds in nature (such as corpses of animals) using a semiconductor photocatalyst (Fe_2O_3, WO_3 and so on) instead of bacteria.

Leg 61 of the Deep Sea Drilling Project (DSDP) was concerned with drilling a single continuously cored multiple re-entry hole at site 462 in the Central Nauru Basin (Fig. 1). Preliminary results of this drilling, which penetrated more than 1 km beneath the sea floor, were presented earlier[1,2]. One major result was the discovery of a late Cretaceous off-ridge volcanic/intrusive complex of basaltic composition and great thickness (>500 m). We now present trace element abundance data for these basalts. Results of the drilling provide further support for a relatively long-lived thermal and magmatic event in the late Cretaceous resulting in voluminous and widespread magmatism in the central and western Pacific consistent with earlier suggestions[3–5]. The trace element data show that most of the rocks produced during this event have trace element characteristics intermediate between those of normal and transitional mid-ocean ridge basalts (N- and T-type MORB)[6] and different from Hawaiian basalts[7]. These results indicate that basalts which are depleted in light rare earth elements (LREE) relative to the heavy REE may, in certain conditions, be erupted as voluminous intra-plate eruptions far from active ridge crests.

DSDP site 462 is located in the Central Nauru Basin in a region of low topographic relief and bottom depths of ~5,100 m (ref. 1) and lies on magnetic anomaly M-26 (~155 Myr BP)[8–10]. The Nauru Basin is bounded on the west and south by the Ontong–Java plateau[11–13], on the east and north by the Gilbert and Marshall ridges[3,5,10,14,15] and on the north-west by the Caroline Ridge[15–18] (Fig. 1). It is a region of well developed Mesozoic magnetic anomalies and since the mid-Cretaceous has been the site of turbidite deposition from the surrounding elevated regions[1]. Palaeomagnetic data show that the Nauru Basin basalts are all normally magnetized, indicating that they were largely emplaced during the Cretaceous long normal event which lasted from 109 to 80 Myr BP. As the age of the Pacific crust at this site is about 155 Myr BP, this magmatic event occurred off-ridge on oceanic crust at least 46 Myr old[1,8,19].

Based on on-board petrographic and X-ray fluorescence analyses for several major elements[1] and later shore-based chemical analyses of several hundred samples, it is clear that the basalts produced during the off-ridge magmatic episode in the Nauru Basin are mineralogically and chemically similar to MORB[1,6]. They are quartz and olivine-hypersthene normative and have mineralogy and major trace element characteristics which are very similar to many types of oceanic ridge basalt (see Table 1). However, they differ significantly and systematically in the following respects: (1) Nauru Basin basalts have higher FeO^*/MgO ratios for a given TiO_2 content than N-type MORB. For example, at TiO_2 contents of 1.0 wt %, FeO^*/MgO is 1.3–1.5 compared with 0.8–1.0 for N-type MORB[6,20]. Trends of FeO^*/MgO and TiO_2 wt % for Nauru Basin basalts are parallel to trends for N-type MORB but displaced to higher FeO^*/MgO ratios. (2) Spinels in Nauru Basin basalts have lower Mg/Mg +

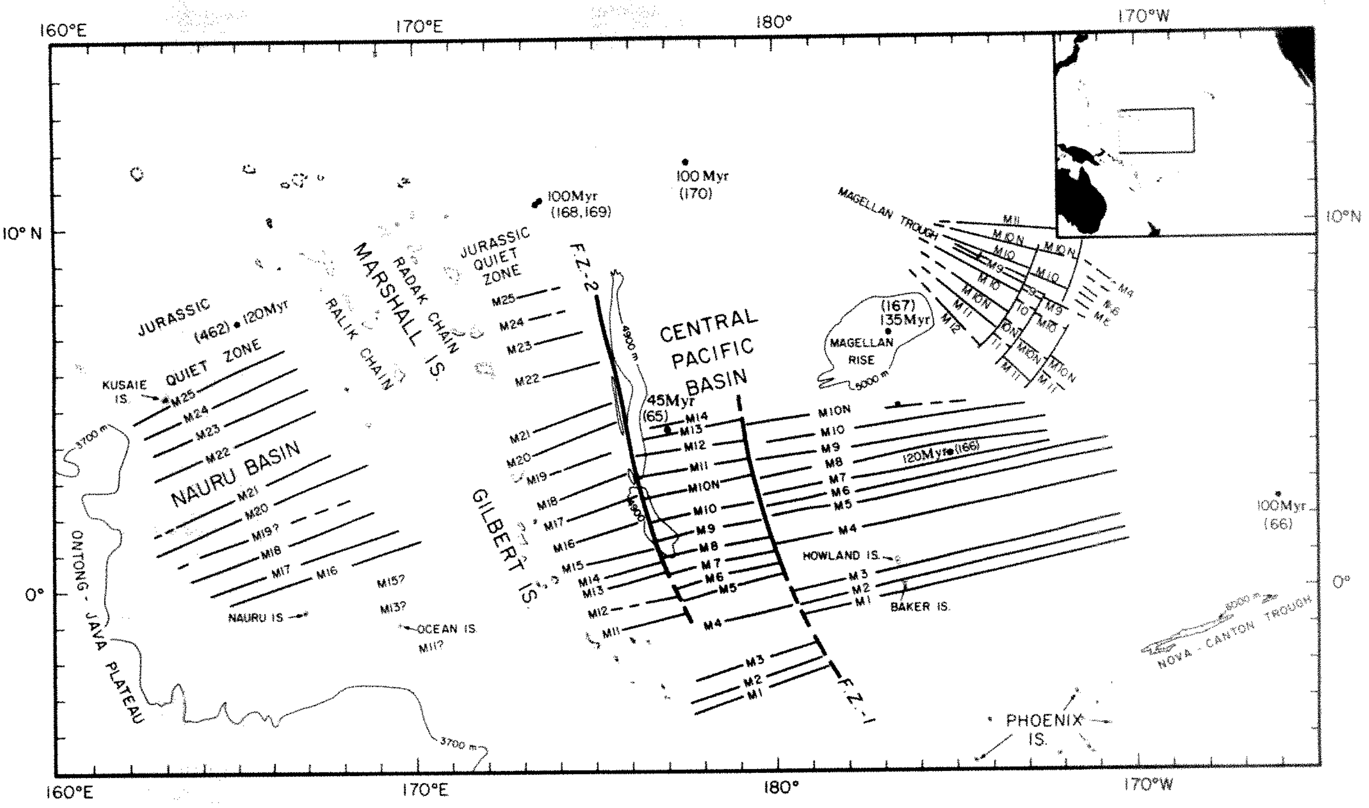

Fig. 1 Bathymetry of the western and central Pacific[23] showing the location of DSDP sites 462 and 169.

Fe^{2+} ratios (0.49–0.54) and higher Cr/Cr + Al ratios (0.54–0.73) than N-type MORB (0.6–0.8 and 0.4–0.6, respectively)[21] and these co-exist with olivine of generally lower Mg number (100 Mg/(Mg + Fe^{2+}) of olivines is 0.83–0.84) than found in N-type MORB. (3) Nauru Basin basalts have higher La/Sm ratios at given Sm contents than N-type MORB, but lower La/Sm ratios than transitional MORB[6] and Hawaiian tholeiitic basalts[7] (see Figs 2, 3). Abundances of Sc, Cr, Co, Ni, Sr, Hf and Zr fall within the range of abundances for MORB (Table 1). Thus, Nauru Basin basalts are depleted in LREE as are N-type MORB, but the level of depletion of LREE is significantly and systematically less than that of N-type MORB.

The geological evolution of the central and western Pacific during the Mesozoic is apparently quite complicated and may involve very rapid spreading rates from several relatively short-lived ridge crest segments, numerous ridge jumps and creation of thick volcanic piles[3,5,22,23]. The formation of abundant seamount and island chains[15,24], guyots[25] and high standing plateaus[5,13] is thought to have occurred in late Mesozoic time but the relationship between this widespread volcanism, vertical movements and plate geometrics and evolution remains problematic[3–5,10,26].

A possible clue to the nature of volcanic/tectonic evolution of the western and central Pacific is provided by the widespread occurrence of off-ridge basalts with trace-element abundances like those of the Nauru Basin elsewhere in the region. Basalts which are depleted in LREE but which have unusually high La/Sm ratios (relative to the N-type MORB) have been encountered in DSDP holes 169 (ref. 27), 289 (ref. 28) and 317 (ref. 29) drilled during Legs 17, 30 and 33. These basalts occur either as sills or as lava flows on plateau regions and contrast chemically with volcanic rocks of broadly similar age which form the seamounts and seamount chains of the western and central Pacific[24,29], all of which are alkalic and more enriched in LREE. It is possible that much of the crust in the area of the Darwin Rise[3], within which the Nauru Basin and other DSDP sites that encountered off-ridge basalt with MORB trace element abundances all lie, is pervasively intruded.

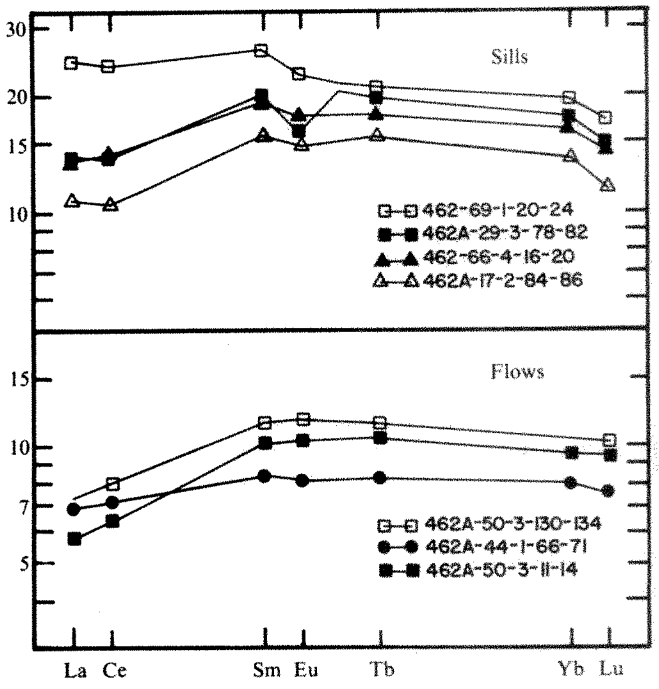

Fig. 2 Representative chondrite-normalized REE abundance patterns for several samples drilled during DSDP Leg 61. The sills (with interlayered sediment) comprise the upper portions of the Nauru Basin igneous complex and the flows occupy the lower portions of the section. Analyses were carried out by instrumental neutron activation analyses[32]. Rare earth and other trace element data will be reported elsewhere[33] but are available before then from R.B.

Table 1 Representative chemical analyses

Oxide (wt %) or element (p.p.m.)	Nauru Basin			Ontong–Java Plateau
	462-64-1-8-11	462A-20-1-115-121	462A-72-3-21-23	289-132-4-6-10

Analyses of two sills from hole 462, core 64 and hole 462A, core 20 and 1 flow from hole 462A, core 72. Analysis of a basalt from DSDP Leg 30 is given for comparison with the DSDS Leg 61 sills. Major element chemistry of the Leg 30 sample is from Stoeser[26] (sample 289-132-4-27). Major element analyses of Leg 61 samples were done by wet chemical techniques and trace elements by instrumental neutron activation analysis[32].

If this speculation is correct, very large portions of the Pacific may have been constructed by a combination of normal oceanic crustal creation processes (at ridges) together with voluminous off-ridge additions of basaltic material of broadly similar chemical composition. Perhaps coincidentally, the Caribbean flood basalts encountered during Leg 15 of DSDP have nearly identical trace element chemistry to the Nauru Basin and other basalts described previously[30] and the crustal ages and structures inferred from geophysical studies are also similar[9,31]. This may indicate that conditions leading to the generation of large volumes of intra-plate basalt chemically similar to MORB were not unique to the Pacific.

The major conclusions from the trace element data of Nauru Basin basalts and interpretation of these data in the light of volcanic and tectonic evolution of the central and western Pacific are as follows: (1) The Nauru Basin volcanic complex is composed of basalt which has trace element characteristics that are intermediate between N- and T-types of MORB. (2) Basalt of this compositon is widely distributed throughout the western and central Pacific in sills and aseismic plateaus, but it is not known if this distribution is continuous. Basalt of similar chemistry is also present in the Caribbean crust. (3) More tentatively, it may be concluded that the wide distribution of off-ridge basalt chemically similar to MORB in the crust of the western and central Pacific is an indication of unusual processes of crustal origin and evolution in this region. Clearly, though, much more information is required before the nature of such processes is determined.

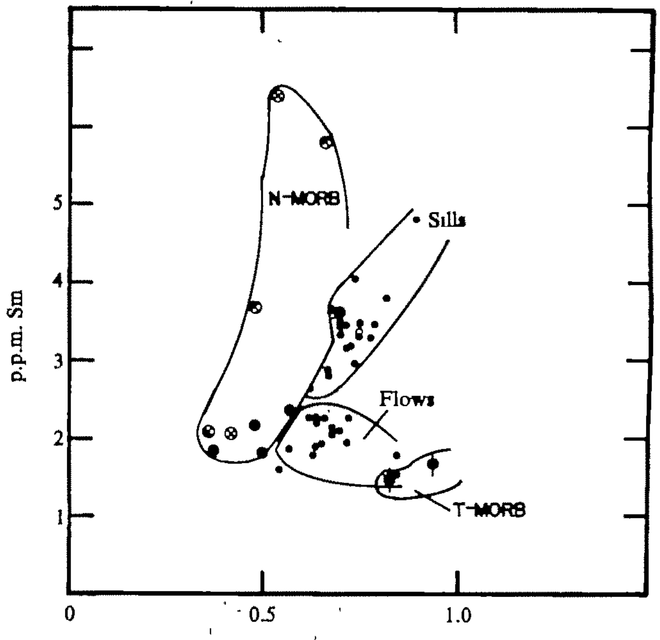

Fig. 3 (La/Sm) chondrite normalized enrichment factor as a function of Sm abundance for Leg 61 lavas (small dots). Also shown, for comparison, are normal mid-ocean ridge basalts (MORB) from the Siqueiros Fracture Zone[34] (circled crosses), analyses from Sun *et al.*[6] (large dots) and analyses from the Ontong–Java plateau (small circles). Note the clear separation of Leg 61 sills from flows and the intermediate La/Sm ratios of Leg 61 basalts. They occupy a field between normal and transitional types of MORB.

We thank Larry Haskin for allowing use of facilities for trace element determinations. This work was partly supported by NSF grant OCE7727001 and the Deep Sea Drilling Project.

Oxygen-18 records of benthic foraminifera from northeastern Atlantic and Southern Ocean cores are significantly different. This difference indicates that the deep water in the northeastern Atlantic Ocean during the last Ice Age was at least 1.3 °C cooler than in modern times. We show here that the occurrence of such a cold deep water mass implies that the North Atlantic was a sink for dense surface waters, replacing the Norwegian Sea where ice cover and stratification prevented the formation of deep water.

Over the last few million years, the Earth's climate has alternated between ice ages and warmer intervals. Although there have been many quantitative studies of the response of the ocean–atmosphere–ice system to climatic changes, most of these have been concerned with the history of ocean surface waters, based on faunal analysis of fossil plankton from deep sea sediments[1]. However, the formation and circulation of deep water are also affected by climatic changes. The present major source of North Atlantic Deep Water (NADW) is the Norwegian Sea, in which an inflow of warm saline surface water is progressively cooled during its transfer towards high latitudes. This loss of heat to the atmosphere within the Norwegian basin increases the density of the surface water so that it sinks to the bottom, where it overflows the sills in the Denmark strait and the Faeroe channel and moves southward into the Atlantic Ocean[2]. During the last ice age, however, the Norwegian Sea bottom water has been shown to be warmer than at present[3], so that the Norwegian Sea was not a sink for surface water, which followed from the disappearance of the Norwegian current[4] and stratification due to a permanent ice cover[5]. This implies a major change in the origin and circulation of the deep water of the Atlantic Ocean. Additional evidence for these changes is found in the benthic foraminiferal fauna changes of the North Atlantic Ocean during the last climatic cycle[6–8]; however, it has not been possible to interpret these faunal changes in terms of temperature variations of the NADW.

During the cruise FAEGAS 1 of the French RV Jean Charcot in the northeastern Atlantic, piston core CH 73139C was collected at 54°38′ N, 16°21′ W from a water depth of 2,209 m (Fig. 1). A sedimentological description of this core has been given elsewhere[9]. Radiocarbon dates have been obtained on the coarse fraction (>44 μm) which consists of a foraminiferal ooze with non-calcareous detrital material below 1 m. The mean sedimentation rate during the past 17,000 yr was calculated to be ~11.9 cm kyr^{-1} (Table 1).

Table 1 ^{14}C dates of cores CH 73139C and MD 73025

Core CH 73139C		Core MD 73025	
Depth (cm)	Age (yr)	Depth (cm)	Age (yr)
7–13	2,020 ± 200	35–39	6,880 ± 330
46–50	5,300 ± 260	76–80	8,230 ± 370
77–83	8,520 ± 350	152–159	8,950 ± 400
112–120	12,020 ± 480	182–186	9,930 ± 440
140–144	11,800 ± 480	226–230	10,400 ± 460
157–165	15,230 ± 770	276–280	12,620 ± 550
180–184	16,900 ± 900	324–329	17,700 ± 1,000
220–224	23,300 ± 2,100	355–359	19,000 ± 1,200
		416–420	24,700 ± 2,400

A ^{14}C half life of 5,730 yr has been used. No correction has been made to take into account isotopic fractionation in samples or apparent age of seawater carbon

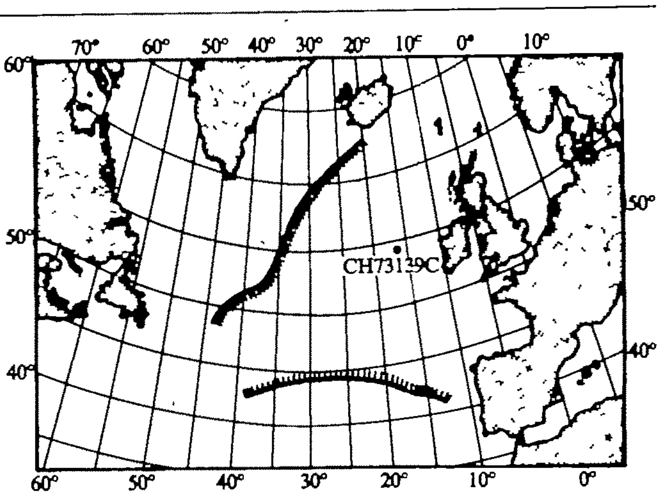

Fig. 1 Location of core CH 73139C. Lines with hachures indicate the extreme poleward and equatorward position of the polar front during isotopic stages 2, 3, 4. Core CH 73139C was north of the polar front during about half of this period[18].

We have measured the $^{18}O/^{16}O$ ratio of the benthic foraminiferal species *Cibicides wuellestorfi* and a mixture of *C. kullenbergi*, *C. gr.lo* and *C.*sp. (ref. 10). Analyses were performed using a Micromass 602 C mass spectrometer with experimental procedures described elsewhere[11]. Replicate analyses of the same carbonate gave a standard deviation of 0.07 ‰ for a single measurement. Results are expressed as $\delta^{18}O$ defined by the relationship:

$$\delta^{18}O = \left[\frac{(^{18}O/^{16}O)\ \text{sample}}{(^{18}O/^{16}O)\text{PDB}} - 1\right] \times 10^3$$

where PDB (Pee Dee Belemnite) is the Chicago PDB 1 standard.

Although most benthic foraminifera yield different oxygen isotopic values[12], all the *Cibicides* species from the same level in the sediment have identical oxygen isotopic ratios within experimental errors. Mean values for each level are reported in Table 2.

The isotopic record of benthic foraminifera in core CH 73139C is reported in Fig. 2*a* with a constant correction factor of 0.64 ‰ to take account of *Cibicides* departure from isotopic equilibrium[8,13]. This record is readily correlated with the standard sequence of stages to stage 6 as defined by Emiliani[14]. The absolute $\delta^{18}O$ values obtained and their variations with core depth closely match those from other cores from the North Atlantic Ocean[8,15], in agreement with the hypothesis that the major signal in these records reflects isotopic changes in the world's ocean water resulting from the variation of continental ice sheets.

The isotopic record shows that the sedimentation rate has varied during the last climatic cycle: assuming an age of 127,000 yr for the boundary between isotopic stage 5 and stage 6 (ref. 13), a mean sedimentation rate of 5 cm kyr^{-1} is obtained below 1.8 m, which is about half of that determined for the upper part of the core. However, the sedimentation rate did not remain constant during that time. From the late glacial maximum to the boundary between isotopic stage 4 and stage 5, a mean sedimentation rate of 5.9 cm kyr^{-1} can be calculated according to the time scale developed by Broecker and Van Donk[16]. Within stage 5, the fine structure of the isotopic record

0028–0836/80/310479—04$01.00

recognized first by Emiliani[17] is not in evidence in core CH 73139C. However, the $\delta^{18}O$ peak between 720 and 620 cm can be unambiguously correlated with isotopic substage 5e on the basis of $\delta^{18}O$ values similar to the modern ones and of the occurrence in the planktonic foraminiferal fauna of warm species like *G. crassaformis* which has been reported only during that substage in the north-east Atlantic ocean[18]. Assuming an age of 115,000 yr for the boundary between isotopic substage 5e and substage 5d, a mean sedimentation rate of 8.3 cm kyr^{-1} is calculated during substage 5e. In contrast, the sedimentation rate has dropped sharply between 115,000 and 75,000 yr BP (isotopic substages 5a to 5d) because only 1 m of sediment was deposited during that time. This low sedimentation rate (2.5 cm kyr^{-1}) is probably responsible for the blurring of the fine structure of the isotopic record[14]. Therefore, this part of the record will not be discussed in terms of palaeooceanographic change and we shall limit our discussion to the last 75,000 yr.

The present bottom water at the location of core CH 73139C is the North Atlantic Deep Water ($T = 3.3°$ C; $S = 34.96$); its $\delta^{18}O$ is +0.12 versus SMOW[19]. The measured $\delta^{18}O$ value for *Cibicides* in the upper 10 cm of core CH 73139C is +2.58 versus PDB. Using a correction factor of 0.64 to take account of *Cibicides* departure from isotopic equilibrium[8,13], we calculated an isotopic temperature of $+3.5 \pm 0.4°$ C, again in good agreement with the modern conditions. The upper part of the benthic record contains $\delta^{18}O$ variations of high amplitude, up to 1.9 ‰ between the Holocene and the last glacial maximum. Such large $\delta^{18}O$ changes have also been reported for two other deep sea cores from the North Atlantic Ocean[8,15]. These large variations reflect the fact that deep water in this area experienced large changes in physical parameters during the last climatic cycle.

In contrast, benthic records from the Pacific and Indian Oceans contain $\delta^{18}O$ variations of much smaller amplitude. One of the most detailed benthic records from this area is that of core MD 73025, collected in the diatom ooze belt at 43°49′ S, 51°19′ E in a water depth of 3,284 m during the cruise OSIRIS I of the French MS Marion Dufresne in the Indian Ocean. Radiocarbon dates (Table 1) have been obtained on the total carbon content of the sediment and indicate that the most recent sediment has been lost during the coring process. However, the first 2.5 m of the core are Holocene in age and the sedimentation rate is as high as 54.5 cm kyr^{-1}. Between 11,000 and 24,000 yr BP, the sedimentation rate was only 11.7 cm kyr^{-1} indicating a sharp decrease of the diatom production during the last Ice Age.

Digital $\delta^{18}O$ values for *Nonion* were reported by Duplessy[11]. The isotopic record of core MD 73025 extends to Emiliani's isotopic stage 6, and, due to the high sedimentation rate, provides one of the most detailed isotopic sequence covering the last climatic cycle. The present bottom water at the coring site is the circumpolar water ($T = +0.6$ °C; $S = 34.69$). Using the measured $\delta^{18}O$ values for *Nonion* in the upper 10 cm of core MD 73025, using a constant correction factor of +0.4 ‰ to compensate for *Nonion* departure from isotopic equilibrium[15], and using Shackleton's palaeotemperature scale which is valid for low temperature[20] when a $\delta^{18}O$ value of −0.3 versus SMOW is assumed for the Circumpolar Water[19], we calculated an

* Mean values are reported for each level.

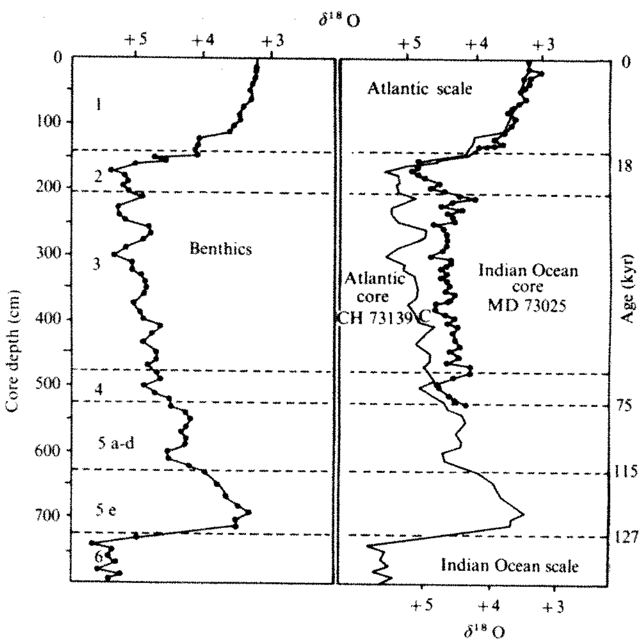

Fig. 2 *a*, Variations of $\delta^{18}O$ of *Cibicides wuellestorfi* and of a mixture of *C. kullenbergi*, *C.gr.io*, and *C.*sp. *b*, Variations of $\delta^{18}O$ of benthic foraminifera in North Atlantic core CH 73139C and southern Indian core MD 73025 with time during the past 75,000 yr. A constant correction factor of 0.64 ‰ for *Cibicides* in core CH 73139C and of 0.40 ‰ for *Nonion* in core MD 73025 have been applied to take account of departure from isotopic equilibrium[11,13,15]. Major isotopic stage boundaries[14] are correlated with dashed lines.

isotopic temperature of 0.8 ± 0.4 °C, in good agreement with the modern temperature at the site. In this record in which both modern and last glacial maximum conditions are well documented, the amplitude of the isotopic shift between isotopic stages 2 and 1 is only 1.6 ‰.

The isotopic record of core MD 73025 is readily correlated with that of the high sedimentation rate core V19 29 from the equatorial Pacific Ocean, analysed by Shackleton[21]. We therefore conclude that the benthic records from the Pacific and Indian Oceans show highly correlated variations with an amplitude of 1.6 ‰ which is 0.3 ‰ smaller than that of the northeastern Atlantic cores.

Figure 2*b* compares the $\delta^{18}O$ records of the southern Indian Ocean core MD 73025 (ref. 11) and the northeastern Atlantic core CH 73139C during the past 75,000 yr. Both cores are plotted with the same time scale, but the $\delta^{18}O$ of the Indian Ocean record has been shifted by 0.25 ‰ to compensate for the present-day difference between the two sites. As the same species has been continuously analysed along each core, this shift, which brings into coincidence the two Holocene mean $\delta^{18}O$ values, allows us to compare the isotopic records at the two sites independently of the correction factors introduced to take into account the departure from isotopic equilibrium in benthic foraminiferal species. The two records are clearly significantly different and cannot both simultaneously reflect only continental ice volume variations. This amplitude difference cannot be explained through a smoothing of the Indian Ocean record due to benthic mixing as this core has a very high sedimentation rate: using the mixing model of Peng *et al.*[22], ^{14}C data from core CH 73139C indicate an upper limit for the mixing layer thickness of 15 cm. This thickness, which is similar to that measured in most cores, is equivalent to a time interval of 1.400–3.000 yr, which is smaller than the duration of the full glacial conditions or any other climatic extreme. In fact, for both cores, the $\delta^{18}O$ values of glacial and interglacial extremes are well defined and practically unbiased by bioturbation. As North Atlantic Deep Water originates in the high latitudes of the North Atlantic Ocean whereas the circumpolar water originates mainly in the Weddel Sea[25] the differences between these two kinds of isotopic records indicate that the northern and southern sources of oceanic deep water have had different histories during global climatic variations.

The only explanation for such a difference between the isotopic records is a cooling of the northeastern Atlantic deep water: at present, Antarctic Bottom Water is formed during the winter when sea water freezes. As the ice forms, it rejects most of the salt from the water, so that the salinity and density of the water increase. As a result, this denser water sinks[23]. As increasing bottom water formation during glacial periods has been inferred from particle size analysis of sediments of the Vema Channel[24], this enhanced formation process which occurs at the freezing point cannot produce bottom water warmer than that produced at present. Thus, as a conservative estimate, we shall assume that the deep water from the southern Indian Ocean experienced no temperature change in the past and that the $\delta^{18}O$ record of core MD 73025 reflects the normal glacial effect, which is continental ice volume variations. Many hypotheses can be advanced to explain the higher amplitude of the benthic record of core CH 73139C. For instance, one might argue that benthic foraminifera were heavy because the glacial NADW became isotopically heavier than expected from the normal glacial effect, without any temperature change. This hypothesis, however, is in conflict with all the reconstructions of the glacial North Atlantic[1,25,26]. The surface salinity map for 18,000 yr BP clearly shows the occurrence of a well defined polar front at 42°N latitude, north of which the salinity decreased[26]. The $\delta^{18}O$ of the surface water should also decrease in the same way. Palaeooceanographic reconstructions clearly demonstrate that there are ways (Labrador current, glacial flow) to get high latitude melt water to intermediate latitudes, north of the polar front. Thus there would be no way that deep water forming in this area could become enriched in ^{18}O, and the 0.3 ‰ amplitude difference between the Atlantic and south Indian benthic records indicates that the glacial NADW was at least 1.3 °C cooler than at present.

A second hypothesis, agreeing with the occurrence of cold deep water, is that there was a complete absence of deep water formation in the North Atlantic during most of the last Ice Age, as suggested by the abundance of *U. peregrina*, a species living today in water with an oxygen content falling to below 5 ml per l (ref. 8). In such a case, the Southern Ocean would be the only source of the world ocean deep water. However, we can rule out this possibility as the benthic foraminifera from the North Atlantic Ocean were isotopically heavier than those of the southern Indian Ocean and Pacific Ocean[21] during isotopic stages 2 to 4. If the only deep water source were located in the southern Indian Ocean, all the deep waters should have the same oxygen isotopic composition and our data would indicate that the glacial NADW was cooler than the deep water source itself, which is impossible.

We thus conclude that the North Atlantic Ocean has been a source of deep water during the past 75,000 yr, even during the coolest periods. The benthic foraminiferal data of Streeter and Shackleton[8] clearly indicate that the dissolved oxygen content of this glacial NADW was sometimes low, reflecting large changes in the production rate of the NADW. During the period 15,000–75,000 yr BP, the glacial NADW was cooler than today. Our evidence is in direct conflict with the theories of Weyl[27] and Newell[28], who in their models of glacial ocean hypothesize warmer deep waters. In contrast, our results suggest that winter freezing in near shore areas, producing cold waters, is the most likely explanation of the isotopic composition of the benthic foraminifera in the North Atlantic Ocean during the last Ice Age. More cores will be necessary to determine the coolest deep water areas in the North Atlantic Ocean during the last climatic cycle, and thus the sources of the Glacial NADW.

As far as isotope stratigraphy is concerned, our data show that the major signal in the isotopic curves is an ice volume record but that minor fluctuations reflecting deep water temperature changes are superimposed on it. Until these temperature changes are more accurately known, worldwide correlations between isotopic records must be restricted only to the major trends which define Emiliani's stages.

We thank M. Kritz, H. M. Sachs, N. J. Shackleton and S. Streeter for reviews, J. Labeyrie for useful discussions B. Le Coat and J. Antignac for help in the isotopic analyses and A. Pujos-Lamy for the determination of the benthic foraminifera. The computer treatment of the data was made by D. Nordemann. Carbon-14 measurements were made by G. Delibrias. We acknowledge the support of our study by CEA, CNRS and DGRST, the support of cruise FAEGAS of the French RV Jean Charcot by CNEXO and the support of cruise OSIRIS I by TAAF.

Enrichment of dissolved phenolic material in the surface microlayer of coastal waters

David J. Carlson & Lawrence M. Mayer

Department of Oceanography, University of Maine at Orono, Walpole, Maine 04573

The sea surface microlayer often has greater concentrations of dissolved organic material (DOM) than subsurface water[1–5], but the chemical nature of this material remains unresolved. Most studies of microlayer organic chemistry have focused on lipid[6–9] and hydrocarbon components[10,11]. Carbohydrate material can account for a significant fraction of the microlayer DOM[4] supporting IR spectroscopic evidence which suggests that the microlayer material is predominantly carbohydrate-proteinaceous complexes[12]. Some similarity of the microlayer DOM to marine humic material has been noted[12–14]. We report here preferential enrichment of dissolved phenolic material in the surface microlayer of coastal waters.

Two major sources of phenolic substances in coastal marine waters are known. Terrestrial drainage delivers dissolved fulvic and humic material containing aromatic structures, partially phenolic, as important components[15,16]. Marine macroalgae, especially the Phaeophyta, have been shown to exude significant quantities of dissolved polyphenols[17].

The UV absorbance of seawater has been used to examine the distribution of DOM in marine waters[18]. Coastal waters exhibit UV absorbance in an inverse relationship to salinity, indicating a terrestrial origin for the substances causing absorption[18–21]. Brown[22] and Mrkva[23] have suggested that this riverine UV absorbance is due to aromatic compounds. The UV absorbance of macroalgal exudates has been ascribed to their polyphenol content[17]. Although UV absorbance has been shown to be inappropriate as an estimate of total DOM in coastal waters[24,25], it may be a useful parameter by which to monitor phenolic substances.

We have examined UV absorbance, dissolved organic carbon (DOC), and phenolic material in the bulk and surface microlayer waters of the Damariscotta and Saco River estuaries. The Damariscotta River estuary is a 30-km long, narrow embayment in central Maine with limited freshwater input, predominantly overflow from Damariscotta Lake. The Saco River is a major drainage in southern Maine with an 8-km long estuary. Microlayer samples were collected by immersing a 30 × 30 cm glass plate and withdrawing it vertically through the water surface[25]. The glass plate collects a surface layer of water 51 ± 2 μm ($\bar{x} \pm 95\%$ C.I.) thick. All samples were filtered through precombusted, rinsed glass fibre filters, and the absorbance at 280 nm measured in 10 cm quartz cells. DOC was measured by persulphate oxidation and FR detection[27] using an Oceanography International carbon analyser. Dissolved phenolic material was analysed by a modification of the Folin–Ciocalteu (F–C) test[28].

The UV absorption of the estuarine waters varies almost linearly with their phenolic reactivity (Fig. 1), supporting earlier suggestions that the UV absorbance of seawater reflects aromatic components. It is not possible definitively to identify the source of the phenolic material. Experiments with natural exudates from *in situ* macroalgae (*Ascophyllum nodosum* and *Fucus vesiculosis*) show that exudates have higher ratios of F–C reactivity to UV absorbance than do the lake, riverine and estuarine samples. However, the F–C reactivity, the UV absorbance, and the resultant reactivity to absorbance ratios of the exudates change with time (range indicated in Fig. 1), as does the UV absorbance of ethanol extracts of the same species[25], and this variation therefore causes some uncertainty as to the source of the estuarine phenolic materials. Bulk water and microlayer samples collected within the Damariscotta estuary show the same ratio of phenolic reactivity to ultraviolet absorbance as samples from Damariscotta Lake. Data from the Saco estuary, which has very little macroalgal input, show exactly the same trend as the Damariscotta estuary, demonstrating similarity between estaurine and lake- or river-derived phenolic material. Based on these data it seems that the surface microlayers of this estuary contain terrestrially derived phenolic material.

Data from the Damariscotta and Saco estuaries (Fig. 2) demonstrate consistent microlayer enrichment of UV absorbance, and hence phenolic material. The DOC levels, however, do not exhibit consistent enrichment. In addition, most samples plot above the line of equal microlayer partitioning of UV absorbance and DOC. Preferential enrichment of phenolic material relative to other DOC is therefore indicated.

Enrichment factors for UV absorbing material are plotted against salinity in Fig. 3. Enrichments of phenolic material occur at all salinities, but are demonstrably greater at higher salinities.

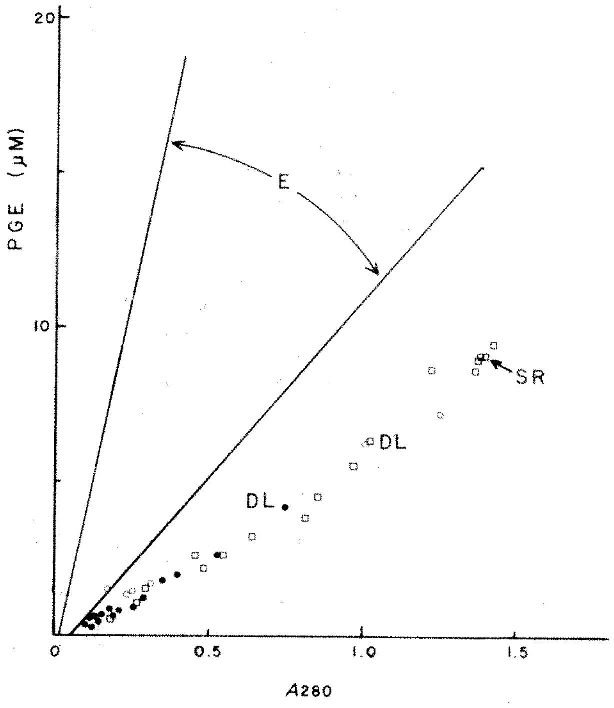

Fig. 1 Absorbance at 280 nm plotted against phenolic reactivity expressed as micromoles of phloroglucinol equivalent (PGE). Lower trend contains samples from Damariscotta transect of October 23, 24 and bulk water samples from the Saco R. estuary on 22 August, 1979. Macroalgal exudates (upper range) obtained by placing emersed fronds of *Fucus vesiculosis* and *Ascophyllum nodosum* in flasks of seawater before immersion by a rising tide. Data represent the difference between pre- and post-exudation values of PGE and A_{280} of the seawater in the flasks. Aliquots of the exudates were analysed after various time intervals. ●, Damariscotta bulk water; □, Saco bulk water; ○, Damariscotta surface microlayer; DL, Damariscotta Lake; SR, Saco River; E, algal exudates.

0028–0836/80/310482—02$01.00

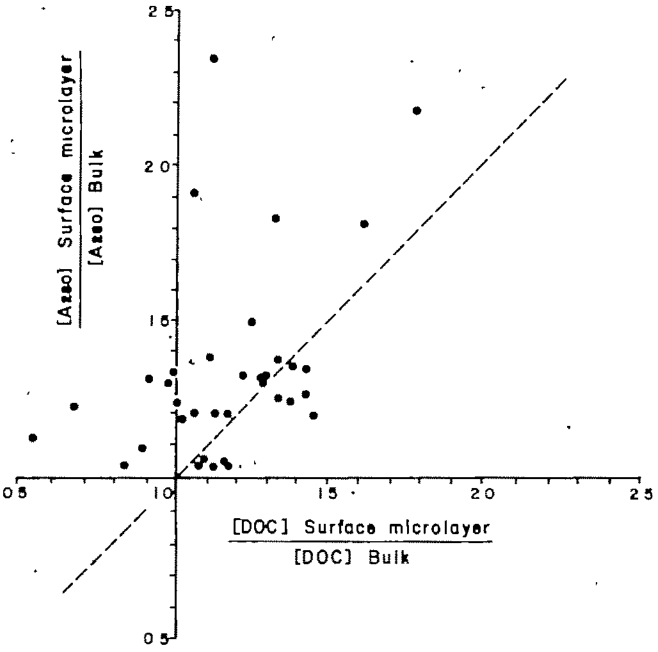

Fig. 2 Surface microlayer to bulk water ratios of DOC and UV absorbing material (A_{280}) in summer and fall 1979 samples from the Damariscotta River estuary and spring 1980 samples from the Saco River estuary. Only data without significant salinity differences between bulk and microlayer water are included. Dashed line indicates equal microlayer partitioning of DOC and UV absorbance. DOC values were 2.5–9.8 mg l^{-1} in bulk water and 2.6–11.9 mg l^{-1} in the surface microlayer.

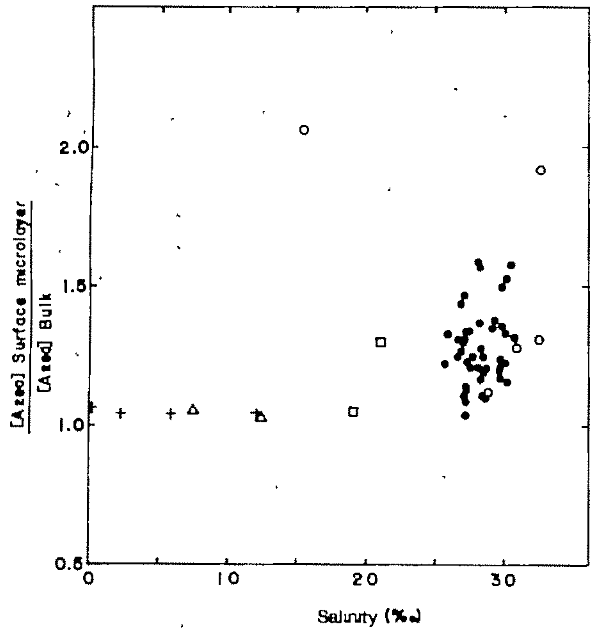

Fig. 3 Microlayer enrichments of UV-absorbance plotted against salinity in samples from the Damariscotta and Saco estuarine systems. Data in which salinity differences between microlayer and bulk water exist have been included by correcting the bulk water absorbance to the absorbance appropriate at the microlayer salinity. ●, Damariscotta summer, 1979; △, ○, Damariscotta autumn, 1979; □, Damariscotta spring 1980; +, Saco spring 1980.

We suggest three alternative explanations for this trend. First, Sholkovitz[29] has shown that terrigenous humic DOC becomes less soluble at high salinities. Higher partition coefficients at higher salinities can be explained if the dissolved phenolic material has similar chemical properties or if the enriched phenolic compounds are humates. Second, the rate of partitioning into the microlayer is unknown at this time; if these enrichments form slowly relative to the flushing time of terrigenous phenols through an estuary, then the higher enrichments at high salinities may simply reflect an ageing phenomenon. Third, if the UV absorbance at high salinities represents macroalgal rather than terrigenous phenolic material, we may be observing different partition coefficients for the two sources of phenols.

These strongly UV-absorbing molecules will be very susceptible to photo-oxidative transformations in the surface microlayer. This zone may therefore be a temporary sink and a reaction site leading to their resolubilization in bulk water as small degradation products[30] or to oxidation[31] and removal to the atmosphere. These aromatic compounds will also serve as important sources of hydrated electrons[32] or free radicals[31] in the microlayer.

Sea surface microlayers often contain greater numbers of bacteria than subsurface water[4,33–35], and have been suggested to be heterotrophically active environments[4,36]. However, apparent inhibition of bacterial activity in the microlayer has been reported[4,37], most notably in coastal waters[35,38]. The presence of phenolic material, potentially inhibitory to bacteria[36,39] and phytoplankton[40], in the surface microlayers of coastal waters may account for this reduction in microbial activity.

Funding for this study was provided by a National Wildlife Federation fellowship to D.J.C., the Faculty Research Fund of the University of Maine at Orono, and NSF grant OCE 79 20244. We thank the graduate students in the Department of Oceanography who assisted in the field work, and P. Rossi for her assistance with the graphics. The comments of W.B. Lyons and B. J. McAlice are gratefully acknowledged.

Late Jurassic lizards from Como Bluff, Wyoming and their palaeobiogeographic significance

Donald R. Prothero

Department of Vertebrate Paleontology, American Museum of Natural History, New York, New York 10024

Richard Estes

Department of Zoology, San Diego State University, San Diego, California 92182

Fossils from the late Jurassic Morrison Formation, Como Bluff, Wyoming (Tithonian, ~140 Myr ago) show that three genera of European lizards from the later Jurassic of England and Portugal (*Cteniogenys, Paramacellodus, Dorsetisaurus*) also inhabited North America. These specimens corroborate evidence from mammal and other terrestrial vertebrate faunal similarities that western Europe and western North America had a continuous land connection in the late Jurassic. Some of this similarity, however, is pre-Tithonian, indicating that widespread mid-Jurassic transgressive seas in Europe were no barrier to vertebrate dispersal.

Between 1968 and 1970, a joint American Museum of Natural History–Yale University expedition made new collections at Quarry Nine, the famous 'mammal quarry', in the Upper Jurassic Morrison Formation at Como Bluff, Wyoming. The expedition collected many mammalian specimens described elsewhere[1], as well as dinosaur material, glyptopsid turtles[2], crocodiles, sphenodontids, frogs, lungfish, amioid fish and lizards. A review of this and previously known lizard material from the Morrison Formation has resulted in the identification of at least three genera of lizards. Only one, *Cteniogenys antiquus* Gilmore 1928, was known previously from North America; it has been shown to be an eolacertilian[3].

Hecht and Estes[4] reported an ilium of what they believed to be a true lacertilian from previous Quarry Nine collections, but did not name it. Lacertilian ('true') lizards are known from the late Jurassic of Europe and China[3,5]. A presumed lacertilian was described from the late Triassic of China[6], but one of us (R.E.) believes it to be an eolacertilian. The new material from the Morrison Formation not only verifies the occurrence of both eolacertilians and lacertilians in the late Jurassic of North America, but also shows for the latter group a well-established, derived, 'autarchoglossan' organization at this early time, which is in agreement with previous identifications of some Jurassic European forms as scincomorphs. The three lizard species identified in the Morrison Formation are classified as follows:

Order Squamata
Suborder Lacertilia
Infraorder Eolacertilia
Cteniogenys antiquus Gilmore 1928

The new collection includes two jaws referable to this species. (Other jaws, including the type specimen, were found in the original Marsh collections made at Como Bluff in 1879 and 1880.) *Cteniogenys* was later identified by Seiffert[3] from the late Jurassic (Kimmeridgian) fauna from Guimarota, Portugal. We agree with Seiffert's identification of *Cteniogenys* as an eolacertilian, closely related to the 'flying lizards', or kuehneosaurs, known from the late Triassic of Europe[7] and North America[8]. *Cteniogenys* is known from jaws, maxillae and parietals. The other species are true lacertilians, of which the first is:

Infraorder Lacertilia
Paramacellodus sp.

Paramacellodus oweni was first described from the late Jurassic Purbeck Formation of England, and allied with the cordyloid scincomorphs[5]. Several jaws referable to *Paramacellodus* (including two from the new collection) occur at Quarry Nine (Fig. 1*a,b*); they may represent the same species but the material is insufficient to determine this. Some postcranial material possibly referable to *Paramacellodus* also occurs in the new collection. The specimen (AMNH 11523) consists of a left prefrontal, a left scapulocoracoid, one trunk vertebra, a partial pelvis, seven caudal vertebrae, and a nearly complete left hind limb. The hind limb, pelvis and sacral vertebrae are articulated. All other elements are disarticulated, but closely associated on the block of matrix.

A detailed description of this material is in preparation, but the important features of AMNH 11523 can be summarized as follows. The prefrontal has a sculpture pattern like that of an unidentified Jurassic specimen from Portugal (Fig. 1*c,d*)[3] and may possibly represent the prefrontal of *Paramacellodus*. The scapulocoracoid (Fig. 1*e,f*) is fully lacertilian, with expanded coracoid region that resembles the derived condition in cordyloid lizards. In the pubis, the iliac blade differs in shape from the ilium described by Hecht and Estes[4], but both are generally similar in morphology to the ilia of some cordyloid lizards (Fig. 1*g–j*). In the tail (Fig. 1*k*), the transverse process of the sixth vertebra may show an autotomic septum, implying fragility of the tail. If so, the septum would split the vertebra into two parts as in many lizards. Comparison of AMNH 11523 with recent lizard skeletons showed that this autotomic configuration is very similar to that of comparably sized lizards belonging to several families, particularly some scincids; cordyloids have the autotomic plane anterior to the transverse process. The third species is:

Family Dorsetisauridae
Dorsetisaurus sp.

There are two dentaries of *Dorsetisaurus* sp.[5]. Neither specimen is well preserved (Fig. 1*l–n*), and both are visible only in lateral view. The elongated, flattened, blade-like teeth, some of which are antero-posteriorly expanded, make this identification clear. Hoffstetter, who originally described *Dorsetisaurus*, placed it in its own family Dorsetisauridae, with which we agree. He also included the family in the Anguimorpha; if so, dorsetisaurs would be very primitive members of that group.

The presence of three genera of small lizards in both North America and Europe in the late Jurassic is an indication of the close faunal affinities of the two regions at that time. Continental reconstructions show that the North American plate was still in contact with Europe at the end of the late Jurassic[11,12]. Como Bluff, Wyoming, and southern England were approximately 2,500 km apart, equivalent to the present distance between San Francisco, California and St Louis, Missouri. Some recent lizards have ranges larger than this. In addition, several other small animals apparently ranged from England to the present western United States. These include four genera of shrew-sized mammals[1,13,14] (*Docodon, Amblotherium, Ctenacodon, Trioracodon*), the crocodile *Goniopholis*[15], the dinosaur *Camptosaurus*[16], and the amioid fish *Ophiopsis*[17]. Also, most of the Morrison mammal taxa have their closest sister-groups in Europe, and a cladogram of therian mammals shows no separation of the taxa into European and American clusters, as might be expected if long-term endemism had taken place[1].

Direct comparisons have not been made in other groups, but most other elements in the Morrison fauna have their closest relatives in the European later Jurassic. Turtles from the early Cretaceous of England[18] and sphenodontids from the Kimmeridgian of Portugal[19] have been examined recently, and are most closely related to Morrison taxa. Complete faunal lists of the Kimmeridgian Guimarota fauna of Portugal have not yet been published, but the partial one given by Kühne[13] is very similar to that from the Purbeck and Morrison Formations. To date, the mammals[13,14], dinosaurs[20], crocodilians[21], turtles[22] and lizards[3] have been described, and most forms show their closest

affinities with forms from the Morrison and Purbeck Formations. Kimmeridgian sauropods from Portugal (*Apatosaurus*, *Brachiosaurus*) are congeneric with Morrison taxa[23]. Pre-Kimmeridgian Jurassic dinosaur faunas in both North America and Europe are highly similar[24–26]. Bathonian (middle Jurassic) mammals from England[27] and Scotland[28] show close affinities with Morrison mammals[1].

These strong faunal resemblances between western Europe and western North America seem to indicate a continuous land connection between these regions throughout the Jurassic. Yet reconstructions by Ager[29], Hallam[30], and Hallam and Sellwood[31] show both southern England and Portugal submerged or surrounded by seaways during most of the Jurassic. The maximum extent of Jurassic epicontinental seas was during the Oxfordian and Kimmeridgian (early late Jurassic)[30]. During the Tithonian, widespread tectonism uplifted large areas of land, reconnecting Europe and North America[30,31]. The amount of exposed land in the late Tithonian reached a maximum level matched only by the earliest Jurassic (Sinemurian–Pliensbachian) regression[30].

If the similarity of land faunas were restricted to the late Tithonian, then rapid migration during the maximum phase of regression would be sufficient to explain the lack of endemism. But the similarity persists throughout the Jurassic, indicating that the submergence was not continuous or effective enough to be a barrier to vertebrate migration. Hallam (personal communication) has suggested that the epicontinental seas were so shallow that the numerous short-term regressions occurring throughout the Jurassic[30] would create transient land corridors. Migration then reached a peak during the Tithonian when dry land connection extended across Europe and North America.

We thank M. C. McKenna, E. S. Gaffney, R. J. Emry and J. H. Ostrom for permission to study specimens in their care. The new Como Bluff specimens were collected by T. H. Rich, prepared by C. S. Schaff and curated by E. Manning. We thank H. Green, A. Hallam, J. Gauthier and E. Manning for helpful comments. D.R.P. was supported by a Columbia Faculty Fellowship and an NSF graduate fellowship and R.E. was supported by NSF grant DEB-77-14995.

Green anole in Dominican amber

Olivier Rieppel*

Department of Zoology, Natural History Museum, Basel, Switzerland

A lizard of the iguanid genus *Anolis* enclosed in amber of Oligocene or Miocene age from the Dominican Republic represents the first complete vertebrate fossil in amber as well as the oldest and only complete fossil of its genus. The fossil *Anolis* is very closely related to a recent form and will shed some light on the evolution of its genus which otherwise has a poor fossil record.

The evolution of the iguanid genus *Anolis* on the Caribbean islands serves as a model for the ecology of colonization and speciation on small islands[1,2]. The evolution of the Caribbean *Anolis* has been reconstructed by Etheridge on the basis of osteology and by Gorman *et al.* on the basis of cytology. Their findings have been summarized by Williams[1]. Etheridge was able to divide the genus into an α and a β section. α *Anolis* lacks transverse processes on the caudal vertebrae whereas they are present on β *Anolis*. A striking result of Etheridge's analysis is that the α *Anolis carolinensis* from the south-eastern United States is not related to the β anoles from Mexico, but it has Caribbean affinities, being related to the species of the *carolinensis* complex of the western Caribbean. *Anolis carolinensis* invaded the continent from a tropical island. The geographic centre of the *carolinensis* complex today is Cuba. Some slightly more primitive α anoles occur on Hispaniola. Of these, members of the 'green anole species group' as defined by Williams[3], such as *A. chlorocyanus* or *A. coelestinus*, were found by Etheridge to be most closely related to and possibly ancestral to the *carolinensis* complex.

This phylogenetic scenario is usually assumed to have taken place during the Pleistocene. The genus *Anolis* is thought to have colonized the Caribbean islands after the Early Miocene inundation[1], but no fossil remains of these lizards older than the latest Pleistocene age have been reported, either from the Caribbean islands or from the southeastern United States. The oldest fossil *Anolis* remains are skin fragments enclosed in amber of Oligocene or Miocene age from Mexico[4].

In 1979, Dr C. Baroni-Urbani from the Natural History Museum in Basel obtained a more or less completely preserved specimen of *Anolis* in amber from the Mina 'La Toca', Cordillera Septentrional, Dominican Republic (Fig. 1). Dominican amber is thought to be of middle Oligocene or early Miocene age[5]. The generic affinities of the fossil lizard are indicated by the structure of the toes, which bear scansorial pads on the lower surface of their expanded distal parts (Fig. 1). X-ray analysis revealed an incompletely preserved skeleton. Important characters such as the structure of the pectoral girdle or the number of presacral vertebrae cannot be determined. However, caudal vertebrae can be shown to lack transverse processes, a feature characteristic of α anoles (Fig. 2).

In view of its uniqueness I propose to name the fossil anole:

Anolis dominicanus n. sp.

Holotype: Natural History Museum Basel, Department of Entomology collection no. P 52. Mina 'La Toca', Cordillera Septentrional, Dominican Republic.

Diagnosis: A member of the α section of the genus *Anolis*: ventral scales hexagonal, subimbricate, smooth; scales on tail imbricate, keeled, arranged in verticils comprising 4–5 middorsal scales; 22–24 lamellae under fourth toe.

Description: The fossil *Anolis* has a total length of approximately 71 mm; the head is 9.2 mm long; snout–vent length is 26.5 mm; the tail is complete and not regenerated. The left front limb is difficult to measure because of three-dimensional

---

*Present address: Paläontologisches Institut und Museum der Universität, Künstlergasse 16, 8006 Zürich, Switzerland

0028-0836/80/310486—02$01.00

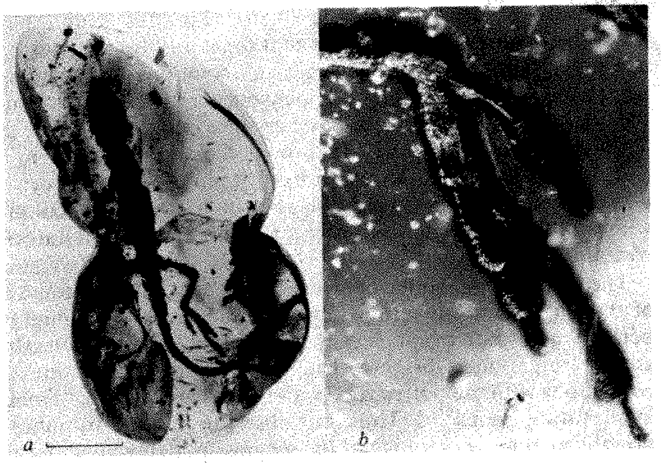

Fig. 1 *a*, *Anolis dominicanus* n. sp., holotype, as preserved in dorsal view. Scale bar, 10 mm. *b*, Lower surface of enlarged right pes, showing the lamellae on fourth digit.

distortion; it is approximately 12 mm long. The right hind limb can be measured accurately: its length up to the tip of the fourth toe is 17.3 mm. The total length of the specimen indicates either a juvenile or a small species.

The colour of the lizard has not been preserved. The squamation of the dorsum lies immediately below the surface of the amber and cannot be made out in detail. The scales on the ventrum are partially preserved. They are hexagonal, sometimes with a rounded posterior edge, subimbricate and smooth. The scales covering the gular region are only partially preserved. They are smaller than the ventral scales, granular, juxtaposed and smooth. Gular scales smaller than ventrals probably imply that the specimen is a female. A weakly expressed longitudinal gular fold is observed. The dewlap appears to have been small or vestigial, which might be correlated with the juvenility or with the sex of the specimen, or it might represent a primitive characteristic.

The tail is trigonal in cross-section. The scales of the tail are imbricate, keeled and arranged in verticils. The verticils are sometimes not distinctly set off from one another. They can well be made out in a middle section of the tail where I counted 5-4-5-4-4-4 middorsal scales in 6 verticils.

The lower surface of the expanded distal part of the fourth toe certainly bears more than 20 lamellae: the exact number is difficult to establish because of a break in the amber obscuring the view (Fig. 1). There could be 22–24 lamellae, 23 being a probable number.

As described above, all the visible characteristics of *A. dominicanus* match Williams's[3] definition of the Hispaniolan 'green anole species group', a group of four rather generalized species of moderate to small size and green colour, which live in the crowns of trees. Within the 'green anole species group', the first subgroup (*A. chlorocyanus*–*A. coelestinus*) is characterized by somewhat longer hind limbs (190% of head length) than the second subgroup (*A. aliniger*–*A. singularis*, hind limbs 162–172% of head length). *A. dominicanus* shows a relative length of the hind limb as it is observed in the *A. chlorocyanus*–*A. coelestinus* subgroup (Table 1). Among the green anoles of Hispaniola, *A. coelestinus* is the species with the relatively longest head. The proportions of the head are the same in *A. dominicanus* (Table 1).

Fig. 2 X-ray picture of a well preserved vertebra from the posterior part of the tail, showing the absence of transverse processes. The length of the vertebra equals ~1 mm.

Table 1 Body measurements of Hispaniolan green anole species

Species	*n*	SVL (mm)	HDL = % SVL	HLB = % HDL
A. chlorocyanus	9	34.5–70	31 (32.7) 34.8	178.4 (190.6) 206.6
A. coelestinus	11	26–77	29.8 (34) 38.4	180 (190.9) 200
A. aliniger	10	41.8–60.5	29.5 (31.7) 35	151.6 (162.3) 186.2
A. singularis	17	37–73	29.8 (32.5) 35.4	157.1 (172.3) 187
A. dominicanus	1	26.5	34.7	188

n, Number of specimens examined; SVL, snout–vent length, the maxima and minima values of all specimens examined are indicated; HDL, head length, expressed as % of snout–vent length; HLB, hind limb, expressed as % of head length. The figures indicate maxima and minima, and the arithmetic mean of all specimens examined is given in parentheses. Measurements are based on the following specimens: *A. chlorocyanus cyagnosticus*, MBS 19778, 20100, 20268, 20344–45; *A. c. chlorocyanus*, MBS 19834, 19975, 20302–03; *A. coelestinus*, MBS 3056–58, 19841–43, 19853–54, 20402–03, 20405; *A. aliniger*, MCZ 143367–76; *A. singularis*, MCZ 124629–45. MBS, Natural History Museum Basel; MCZ, Museum of Comparative Zoology, Harvard University.

In conclusion, the fossil *A. dominicanus* from Dominican amber is evidence of the presence of *α* anoles closely related to recent forms (especially *A. coelestinus*) since the Oligocene or early Miocene. This is a much earlier date than that which has usually been assumed to account for the evolution and dispersal of *α* anoles on the Greater Antilles.

I thank Drs E. E. Williams and R. Etheridge for loaning specimens, critically examining X-ray pictures and reading a draft of this report. X-ray analysis was done by Professor W. Stürmer.

Note added in proof: New dating of amber matrix from the Dominican Republic by Dr J. B. Saunders, Basel, indicates an age range of between 20 and 23 million years BP (lower part of early Miocene).

Unique adaptations for submarine pollination in seagrasses

J. M. Pettitt*, C. A. McConchie†, S. C. Ducker† & R. B. Knox†

Australia 3052

Seagrasses are flowering plants that are adapted for pollination submerged in the sea. Many species, including the Australian sea nymph, *Amphibolis antarctica*, have filiform pollen grains. These grains have no exine[1–4]—the resistant pollen wall layer characteristic of terrestrial plants—and each may be up to 5 mm in length. The pollen has a similar density to seawater so that it remains suspended or floats after release from the anther. The stigma of the sea nymph and related seagrasses is a simple branched structure which protrudes between the leaves when receptive and has a surface secretion with cytochemically detectable enzymatic activity[1–3,5]. This stigma coating is not

0028-0836/80/310487—03$01.00

dispersed in seawater. However, submarine pollen–stigma interactions have never been observed in any species of seagrass. We demonstrate here that pollination in the sea nymph has several unusual features when compared with the events in terrestrial flowering plants. These features include the waterproof nature of the adhesive binding the pollen to the stigma surface, the unique mechanism for pollen germination in the inaperturate filiform grains, and the mode of pollen germination in the inaperturate filiform grains, and the mode of pollen tube penetration into the stigma. Taken together these characteristics suggest a considerably more refined level of adaptation to the marine environment than hitherto supposed.

Mature flowering plants of *Amphibolis antarctica* were collected from natural populations growing on the coast of Victoria, Australia, and held in aerated seawater aquaria at 14 or 22 °C. Ripe pollen from dehiscing anthers was taken up in a Pasteur pipette and applied to the stigmas in a stream of seawater. Grains adhered immediately on contact, and were allowed to remain for up to 48 h before fixation in buffered 2.5% glutaraldehyde and processing for light and electron microscopy[5].

The pollen grains are held tenaciously on the stigma by a meniscus of adhesive material which is formed on contact from the surface coating of both interacting surfaces (Fig. 1*a*). This adhesive is waterproof, a quality which contrasts with the adhesive of terrestrial plants. In *Gladiolus*, for example, water-soluble arabinoglactan proteins have been implicated in pollen–stigma adhesion[6,7]. Germinated pollen produced numerous tubes in the vicinity of the contact zone with the stigma (Fig. 1*b*). We have observed that the grains failed to germinate until they came into contact with the submerged stigma, suggesting that molecular transfer may be important for promoting pollen tube growth, as in the seagrass *Zostera marina*[8].

The filiform grains of seagrasses do not have preformed apertures—special sites for pollen tube emergence. Instead, the position of the aperture is first detectable cytologically by a marked loss of staining affinity in the wholly fibrillar wall[4] after attachment of the grain to the stigma (Fig. 1*c*). Our interpretation of this phenomenon is that focal autolysis forms the aperture. Reorganization of cytoplasmic components, including starch grains, is seen beneath the incipient aperture (Fig. 1*c*), but the first indication of pollen tube emergence is the appearance of a mucilaginous cap protruding through the aperture to form a bubble-like structure. This overlies the emerging tube cytoplasm (Fig. 1*d*) and the cap mucilage stains a light purple colour with toluidine blue, indicative of low molecular weight carbohydrates[9].

The formation of pollen apertures by means of focal autolysis of the wall is not known for any other flowering plant, and is perhaps a further adaptation to the aquatic environment. In germinating pollen of terrestrial angiosperms the intine is contiguous with the pollen tube wall in both aperturate[10,11] and inaperturate grains[12,13]. Thus, our observations call into question the assumed homology of the seagrass pollen wall with the intine of their land-based relatives, notwithstanding the structural and cytochemical similarities[2–5].

Hydration is an essential prelude to germination of the pollen of terrestrial angiosperms[6,11,12,14,15]. In seagrass pollen, however, the hydrodynamic principles must be different, although our observations show that submarine germination is triggered by stigma contact. The differences extend also to subsequent reproductive events. In *Amphibolis*, the germinating tubes grow within a water-resistant mucilaginous sheath towards the stigma surface where they make contact with the cuticle. Using light microscopy, we have observed digestion of the cuticle by the pollen tubes and entry of the tubes into the polysaccharide matrix of the receptive cell wall (Fig. 1*b*) as well as initial growth through the transmitting tissue to the ovary. This sequence first necessitates penetration of the cuticle, a process which accommodates one level of control in those terrestrial angiosperms with dry stigma types, where cutinase activation is implicated[6,12,14,16,17]. Precisely how these cutinases are produced and deployed in the seagrasses remains to be determined.

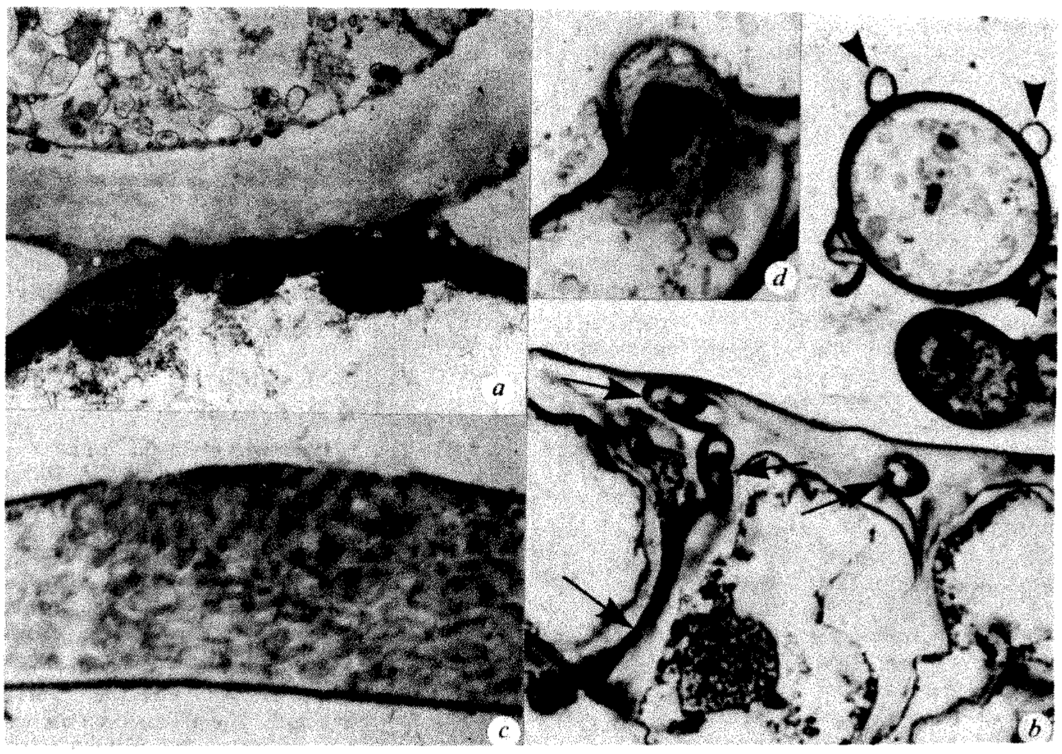

Fig. 1 *a*, A meniscus of insoluble adhesive forms at the point of contact between the pollen grain (upper half) and the stigma in *Amphibolis antarctica* and binds the two together. Electron micrograph of a section stained with silver proteinate after periodate oxidation[21] ×14,400. *b*, Pollen at the surface of the stigma. The filamentous grains have been sectioned transversely and the circular profiles of several pollen tubes passing towards the stigma are indicated by arrow heads. Pollen tubes are also present beneath the stigma cuticle in the walls of the receptive cells (arrows). Thick section of resin-embedded specimen stained with toluidine blue, ×1,200. *c*, The aperture for pollen tube emergence is formed by autolysis of the pollen grain wall. The site of the future aperture is first detectable by the loss of staining affinity in the wall and reorganization of the cytoplasmic components beneath the site. Staining as for *b*, ×800. *d*, After formation of the aperture tube emergence begins. The first structure to appear is a mucilaginous cap and immediately behind this is a zone of densely staining cytoplasm. The pollen grain wall forming the border of the aperture flanks the emerging pollen tube. Staining as for *b*, ×960.

The special adaptations to submarine pollination are important for an understanding of the mechanisms associated with discrimination of self (compatible) from foreign seagrass pollen in interspecific and intergenic matings. Two species of *Amphibolis* are sympatric in southern Australian waters and other seagrass genera occupy adjacent habitats. Although the flowering periods are often coincidental, authenticated hybrids are unknown. In terrestrial pollination systems, barriers to discriminate against foreign pollen operate at initial contact, before adhesion, when many foreign grains simply fail to hydrate, while others are blocked at later steps leading to fertilization[6,11,12,14,15]. Our observations of the seagrasses suggest that barriers to foreign pollination may operate at the moment of adhesion, or even at the time of stigma penetration within the waterproof coating. Experiments are now in progress to test the validity of these predictions.

It is generally believed that seagrasses are angiosperms which have adapted successfully to their marine environment by the loss or modification of terrestrial features[18,19]. In view of both the present discoveries and the distinctive structural and physiological features—such as filiform and flexible pollen grains up to 5 mm in length; precocious microspore mitosis following soon after tetrad period in pollen development[3,20]; the wholly fibrillar nature of the pollen wall in many species[1-5]; water-resistant surface-coating of the receptive stigma[1] which also possesses acid phosphatase activity[5] as well as esterase activity characteristic of terrestrial stigmas; and coincidence of flowering in some species with tide cycles[5]—the explicit phylogenies of the groups need to be determined.

We thank the Australian Research Grants Committee for financial support (to S.C.D. and R.B.K.) and the Royal Society for the award of a Royal Society and Nuffield Foundation Bursary to enable J.M.P. to work at the University of Melbourne.

Relict diapause in an introduced weevil in New Zealand

S. L. Goldson

Ministry of Agriculture and Fisheries, PO Box 24, Lincoln,
New Zealand

R. M. Emberson

Department of Entomology, Lincoln College, Canterbury,
New Zealand

The Argentine stem weevil *Hyperodes bonariensis* Kuschel, a stem boring weevil native to the southern part of South America, was first reported in New Zealand in 1927[1] where it has become a widespread and serious pest of Graminae. Recent investigations[2] have demonstrated the existence of reproductive hibernatory diapause induced by a critical photoperiod in the population in Canterbury, New Zealand (latitude 43°39′ S). Coincidentally, it was noted that similar ovarian diapause occurs in *H. bonariensis* found at a corresponding latitude (41° S) in the Bariloche region of Argentina[3]. Owing to the imminence of the autumnal equinox at diapause induction (early March in both localities), identical daylengths are experienced successively over a wide latitudinal range within a week. In the present report, examination of the New Zealand population at this time, sampled over at 8° range of latitude, revealed a corresponding synchronous induction of diapause without the usual latitudinal and therefore temperature-related shift in critical photoperiod[4]. This lack of temperature-related shift and the relatively mild winters suggest that the diapause behaviour of *H. bonariensis* throughout New Zealand is an adaptively inappropriate relict response resulting from the recently arrived weevils cueing into the same photoperiodic seasonality as their South American counterparts, which in regions such as Bariloche, must have evolved diapause behaviour to survive.

During a 3-day period, samples of weevils were collected from localities near sea level in the North Island of New Zealand between 35°39′ S and 40°23′ S and examined by dissection for diapause status. This allowed comparison with comprehensive data collected from Canterbury on *H. bonariensis* diapause induction during 1977–79.

The results, summarized in Table 1, show the similarity of diapause condition found in the populations sampled from four widely separated locations at the end of the second week of March. Surprisingly, the diapause-related physiological reorganization seemed somewhat further advanced in the populations collected from the warmer northern areas. This is indicated in Table 1 by the percentage of the population with clearly defined oocyte resorption bodies[5]. When a population is fully reproductive, oocyte resorption bodies are very rare and 80–90% of the reproductively competent weevils have eggs. Table 2 shows that during diapause induction (28 February–14 March) daylengths of increasing shortness were experienced in Whangarei (35°39′ S) about a week before identical daylengths were experienced at Lincoln (43°39′ S). This implies that the populations of weevils in the northern areas would have experienced the presumed common critical photoperiod shortly before their Lincoln counterparts and hence accounts for the slightly more advanced diapause condition of these northern populations.

Table 1 indicates that the time of diapause induction of Argentine stem weevil was completely unaffected by variation in mean daily temperature over a considerable latitudinal range. Such a response to photoperiod irrespective of ambient temperature is frequently observed in other species within a local region, as there is a stable correlation between the seasonal course of daylength and temperature. However, this correlation varies sharply with latitude. Daylength provides a reliable means of anticipating winter conditions independent of the vagaries of weather. In general, with an increase in latitude, the cooler conditions necessitate earlier onset of hibernatory diapause which is often regulated by longer critical photoperiods[4]. Thus, intraspecific latitude (and therefore temperature) related variation in critical photoperiod is to be expected in widely dispersed hibernating insect populations. In spite of this

there was no evidence of a temperature-compensated shift in critical photoperiod among any of the *H. bonariensis* populations sampled (Table 2).

The results of this experiment confirm the exotic origin of the *H. bonariensis* population in New Zealand. With an estimated overall threshold temperature of development of ~10°C (ref. 6) there seems to be little adaptive reason for diapause during the comparatively mild New Zealand winters, particularly in the north. The seasonal behaviour of *H. bonariensis* in New Zealand is undoubtedly a relict response resulting from the insect cueing into a photoperiodic seasonality identical to that of its native habitat. In some South American localities the evolution of hibernatory diapause must have been necessary to allow the weevil to survive the relatively severe winter conditions, such as those of Bariloche (a ski resort) in Argentina. Here, at 41° S, *H. bonariensis* has been observed in diapause between March and July, as occurs in New Zealand.

The relict diapause behaviour of *H. bonariensis* in New Zealand therefore elegantly demonstrates the overriding effect of photoperiod on the adult stage resulting in diapause induction irrespective of other abiotic factors and the associated adaptive implications. In effect, the New Zealand weevils demonstrate a local diapause response over a wide geographical area (35°39′ S to 43°39′ S), suggesting their introduction from a localized source in Argentine. Furthermore, the complete absence of any latitudinal effect on the critical photoperiod indicates no evolutionary change in diapause behaviour since their establishment. This lack of adaptive evolution, and perhaps the very existence of diapause itself, confirms that *H. bonariensis* is a recent addition to New Zealand's insect fauna, which has very few native diapausing species[7].

The synchronous induction of reproductive diapause of this pest species has important practical implications. It means that any phenological management approach should be applicable throughout New Zealand without the need to establish and adjust for regional variation in biological responses.

Gametocytogenesis by malaria parasites in continuous culture

D. C. Kaushal*, R. Carter*, L. H. Miller* & G. Krishna†

*Laboratory of Parasitic Diseases, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland 20205

†Laboratory of Chemical Pharmacology, National Heart, Lung and Blood Institute, National Institutes of Health, Bethesda, Maryland 20205

Asexual proliferation of malaria parasites proceeds by multiplication of the parasites within red cells. Following rupture of the host cells the released merozoites re-invade other red cells. On re-invasion, a proportion of merozoites become, not asexual parasites but gametocytes, the sexual stages infective to the mosquito vectors. Conversion of asexual parasites to gametocytes occurs not only during natural infections but also in continuous *in vitro* culture as reported first by Trager and Jensen[1–4] and by others[5,6]. We showed previously that the proportion of early intra-erythrocytic stages (ring stages) of *Plasmodium falciparum* which developed into gametocytes in culture was influenced by culture conditions[7]. Gametocyte formation was rare in conditions supporting rapid proliferation but frequent when parasite densities were static. We now show that nearly 100% of ring stages develop into gametocytes in response to 1 mM cyclic AMP in static cultures whereas in rapidly growing cultures few rings become gametocytes in response to cyclic AMP.

We have used the Z isolate of *P. falciparum* grown in continuous culture in human red cells as previously described[1] (see Table 1 legend). Complete development of *P. falciparum* gametocytes, either in culture or in man, takes approximately 10 days. During this time the gametocytes develop from ring forms into mature crescent-shaped parasites capable of undergoing gamete formation. One of the developmental stages of gametocyte maturation, the stage II gametocyte, is easily identified and occurs 48 h after ring formation. In our previous study[7] we devised a method for the daily measurement of the rate of production of gametocytes based on the percentage of rings that develop into stage II gametocytes 48 h later. Using this method,

Parasites were grown in human red cells in continuous culture using a method we have described previously[1] and based on the methods developed by Trager and Jensen[1] and by Haynes *et al.*[9] Cultures were grown in tissue culture flasks (Corning, 25 cm², polystyrene, 25100) in type A, Rh+ human red cells at a 5% haematocrit in culture medium. The culture medium was made up in double distilled water from RPMI 1640 powdered medium with glutamine and without bicarbonate (Gibco) to which was added HEPES buffer (Sigma) to 25 mM. Immediately before use sodium bicarbonate was added to 24 mM and the medium was supplemented to 10% with inactivated human serum, blood type A, Rh+. The complete medium was filtered through a 0.45 µm Nalgen filter. No antibiotics were used. Culture flasks contained 10 ml of the parasitized blood cell suspension and were laid on their broad sides (25 cm²) to give a medium depth of 4 mm and a cell depth of 0.2 mm. Medium was replaced daily and the flasks gassed with a mixture of 3% CO_2, 6% O_2, 91% N_2, hermetically sealed and maintained at 37°C. Fresh cultures were established by diluting a growing culture with uninfected red cells at a 5% haematocrit in culture medium to give an initial parasitaemia of 0.1–0.5%. The diluted cultures were thereafter dispensed into flasks and maintained as described above. Four days after setting up a *P. falciparum* culture in fresh red cells and medium, each flask was divided and 3 ml of the culture suspension was placed into each of two new flasks. The flasks were placed on their smallest end to give a medium depth of 3.3 mm and a cell depth of 0.17 mm. One flask was cultured as before with normal medium; in the other the medium was supplemented with 1 mM cyclic AMP. Ring stages and gametocyte densities were estimated daily from blood smears stained with Giemsa's stain. Stage II and stage III gametocytes are defined by morphological criteria and are estimated to be 2–3 and 3–5 days old, respectively (see refs 4, 7, 10). Results are given as the mean ± 1 s.e. of 9 separate experiments.

*Parasite counts are expressed as the number of parasites (gametocytes or rings) per 100 red cells

†The per cent of rings developing into stage II gametocytes 2 days later (see ref. 7 for full explanation)

we have studied the effect of cyclic AMP on the production of gametocytes in culture.

The mean densities of ring stages and gametocytes (stages II and III) during culture in the presence or absence of 1 mM cyclic AMP are shown in Table 1. Cyclic AMP was added and measurement of gametocyte production was begun after the parasites had been growing for 4 days in fresh red cells and medium. The percentage of rings which developed into gametocytes was 5–10 times greater in the presence of cyclic AMP. The data show that 24 h after their appearance as stage II gametocytes, they progressed quantitatively into stage III gametocytes. Measurement of the high proportion of rings developing into gametocytes in the presence of cyclic AMP is not, therefore, an artefact due to the accumulation of stage II gametocytes in culture.

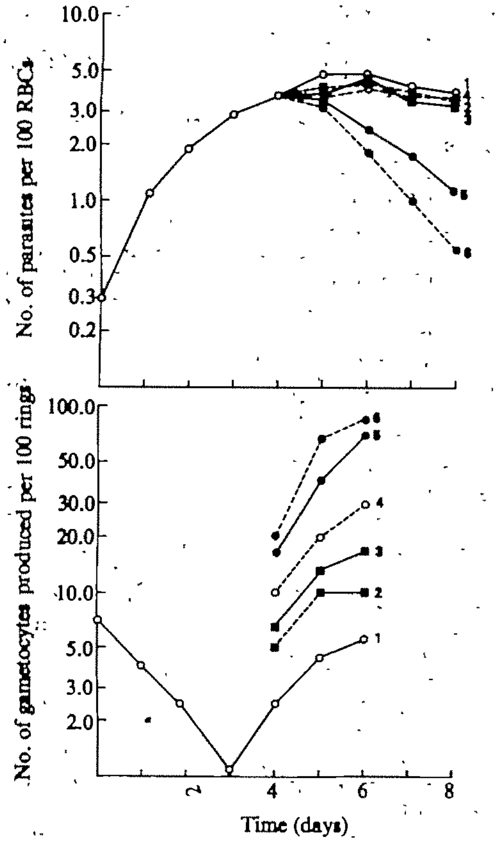

Fig. 1 The effects of different concentrations of cyclic AMP added from the fourth day of culture onward on the asexual parasitaemia and rate of gametocyte formation during *in vitro* culture of *Plasmodium falciparum*. in human red blood cells RBCs. (1) No cyclic AMP added; (2) 0.01 mM cyclic AMP; (3) 0.05 mM cyclic AMP; (4) 0.1 mM cyclic AMP; (5) 0.5 mM cyclic AMP; (6) 1.0 mM cyclic AMP.

When cultures were exposed to various concentrations of cyclic AMP (Fig. 1), 1 mM cyclic AMP mediated the greatest increase in the proportion of rings forming gametocytes. Higher concentrations (above 1 mM, data not shown) were lethal to all stages of the parasite. At concentrations as low as 0.01 mM the proportion of rings forming gametocytes was still more than twice that of cultures without added cyclic AMP.

Dibutyryl cyclic AMP, an analogue of cyclic AMP, was equally effective at equivalent concentrations in inducing gametocyte formation. Administration of 0.1 mM and 1 mM cyclic GMP and dibutyryl cyclic GMP had no effect on gametocyte formation. To test the effects of degradation products of cyclic AMP, we administered 5′-AMP, 3′-AMP, ADP and ATP, adenine and adenosine at concentrations of 0.1 mM and 1 mM. None of these compounds influenced gametocyte formation.

The following experiment was carried out to test the effect of cyclic AMP on the proportion of rings which develop into gametocytes at different times during culture. A parasite culture was diluted with fresh red cells and medium to achieve a parasite density of 0.5% and the culture divided equally into seven flasks. To each flask 1 mM cyclic AMP was added starting on a different day. The proportion of rings which were developing into gametocytes was measured 24 h after the addition of cyclic AMP. During the first 3 days after subculture, when there was rapid growth of the asexual parasites (Fig. 2), the proportion of rings which formed gametocytes following addition of cyclic AMP remained low (<10%) and even fell slightly (Fig. 2). Prolonged exposure of the parasites to 1 mM cyclic AMP during this period of rapid asexual growth was uniformly lethal to the asexual parasites (data not shown). In cultures without added cyclic AMP the proportion of rings forming gametocytes typically fell to very low levels (Fig. 2). From the fourth day onward the rate of asexual proliferation was very low and degenerate asexual parasites began to appear in culture. During this time the proportion of rings which spontaneously developed into gametocytes began to increase again. Moreover, during this phase of the culture, addition of 1 mM cyclic AMP elevated the proportion of rings which developed into gametocytes to about 10 times the spontaneous rate (Fig. 2). By the sixth day in culture, when 10–15% of rings spontaneously developed into gametocytes, almost 100% of rings were stimulated to become gametocytes 24 h after the addition of 1 mM cyclic AMP.

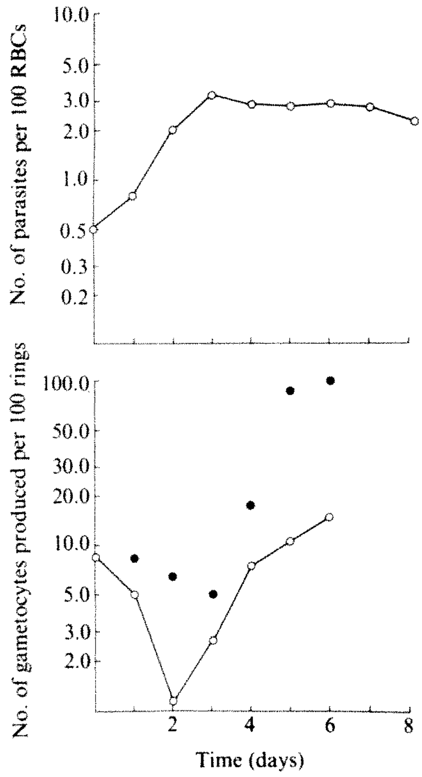

Fig. 2 The changing rate of formation of gametocytes from rings in response to cyclic AMP added on different days during the growth of *P. falciparum* in culture. A subculture of *P. falciparum*, set up by addition of fresh red cells and medium to a growing culture as described in Table 1 legend, was divided into 3-ml aliquots among seven flasks; the starting parasitaemia was 0.5%. One culture flask had no cyclic AMP added and showed the asexual growth and the daily rate of spontaneous formation of gametocytes from rings (○–○). To each of the other six flasks 1 mM cyclic AMP was added beginning on day 0 for flask 2, on day 1 for flask 3 to day 5 for flask 7. For each flask the rate of formation of gametocytes from rings was determined after the parasites had been exposed to cyclic AMP for 24 h (●). The rate of formation of gametocytes for flask 2 is shown on day 1, for flask 3 on day 2 and so on.

Our results demonstrate that the response to cyclic AMP by rings of *P. falciparum* in continuous culture changes according to the state of the culture. During rapid asexual proliferation, few rings develop into gametocytes in response to 1 mM cyclic AMP. Indeed, prolonged exposure to 1 mM cyclic AMP is lethal to the parasites. After rapid proliferation has ceased and the density of asexual parasites is constant, almost 100% of ring forms develop into gametocytes in response to 1 mM cyclic AMP. This change in responsiveness to cyclic AMP parallels the change in the rate of spontaneous gametocyte formation. Thus, during rapid asexual proliferation, spontaneous gametocyte formation falls to low levels or is absent; after asexual densities have become more or less constant, up to 10% of rings develop into gametocytes.

A similar change in responsiveness to a cyclic AMP stimulus was found in the amoeba *Dictyostelium discoideum. In* the presence of an adequate food source the free-living amoebae proliferated exponentially and did not respond to 0.001 mM cyclic AMP[8]. When the food supply became exhausted and exponential growth ceased, the amoebae became highly sensitive to cyclic AMP and formed aggregates in the early stages of spore formation. An analogous situation may apply to *P. falciparum* in culture. Parasites in cultures in which densities are not increasing are also in a state of near starvation; glucose levels become almost totally depleted before each addition of fresh culture medium. The state of starvation may, therefore, be associated with the development in the ring stages of a state of responsiveness to stimuli which induce gametocyte formation.

Determination and cellular commitment in the embryonic amphibian mesoderm

D. Forman & J. M. W. Slack

Imperial Cancer Research Fund, Mill Hill Laboratories,
Burtonhole Lane, London NW7 1AD, UK

In classical embryology, the term 'determination' was used to describe the process by which a region of the embryo became committed to form a particular part of the body and it was understood that there was a particular stage of development at which determination occurred with respect to each decision[1–3]. Some authors[4,5] insisted that only an irreversible commitment should be described as determination, but this leaves undefined the nature of the preceding events involved in its establishment. We show here that there may be several stages of commitment for an organ rudiment that can be distinguished from one another by the use of different methods for altering the pathway of development. We have investigated the region of the amphibian mesoderm that is destined to become somitic muscle in the course of normal development and applied to it a variety of isolation and grafting techniques. The results, which show an extensive period of lability within this region, can be used to explain how pattern formation might occur within the dorsoventral axis of the mesoderm.

In the experiments described here, the prospective somite region of the axolotl (*Ambystoma mexicanum*) was treated in one of four different ways as shown in Fig. 1. (1) The region was dissected out, wrapped in an ectodermal jacket obtained from the anteroventral region of a stage 13 embryo, and cultured in a buffered salt solution for 10 days. (2) After dissection, the explant was dissociated into single cells and allowed to reaggregate into clumps for 48 h. The clumps were then wrapped in ectoderm and cultured as in treatment (1). (3) After dissection, the explant was grafted into another embryo of the same stage to replace a piece of ventral mesoderm and the host embryo was allowed to develop for 12 days. (4) The region was dissected out, dissociated and reassociated, and then grafted ventrally to a host embryo of the same stage as the donor had been at the time of explantation. The host was allowed to develop for 12 days.

The results of treatment (1) show that at both neurula and head process stages the isolated tissue behaves in a similar way to normal development in that it differentiates predominantly into muscle (Table 1*a*, Fig. 2*a*). According to this criterion, one could therefore describe the prospective somite region of the mesoderm as being determined by the neurula stage and, indeed, the result is consistent with classical work using both urodele and anuran embryos, which indicated that the determination of this region had occurred by the time of gastrulation[6,7]. Some of the isolates also formed small amounts of pronephric tubules and/or mesenchyme. The formation of more than one tissue type is common in these experiments and we think that it may be the result of single cells or small groups of cells becoming detached from the main mass of tissue and behaving differently as a result. Because unwrapped controls remained undifferentiated, we believe that the ectodermal

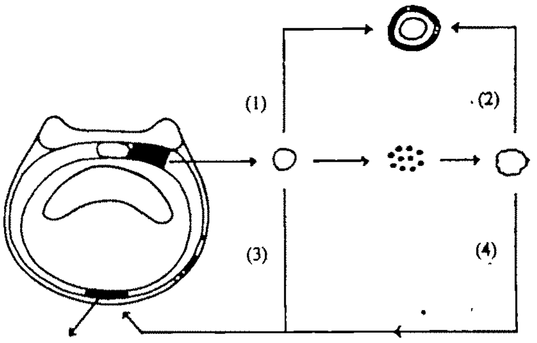

Fig. 1 The four experimental procedures. The diagram represents a transverse section through the trunk region of an axolotl neurula and shows the location of the prospective somite region (dorsal, shaded). This region was dissected out of the embryo on both sides with tungsten needles in ½ strength 'normal amphibian medium' (NAM)[11] containing 0.05% trypsin. The explants were washed, fused and allowed to round up in full-strength NAM for 30 min. Operations were carried out on neurulae (stages 15–18)[14], head process stages (21–24)[14] and tail bud stages (26–28)[14]. By the head process stage the somite region had begun segmentation at the anterior end (1) Explants were wrapped in ectoderm and cultured in NAM for 10 days. (2) Explants were dissociated by washing in Ca^{2+}/Mg^{2+}-free NAM and then treated for 5 min with Ca^{2+}/Mg^{2+}-free NAM containing 1 mM EDTA. The single cells were micropipetted into the centres of agar-coated 0.4-ml multiwell plates containing NAM. After 48 h of reaggregation, the resulting cell clumps were wrapped in ectoderm and cultured in NAM for 10 days (3) A piece of tissue, about one-quarter of the size of the prospective somite file, was grafted into the ventral region of host embryos of the same stage The embryos were allowed to develop in ½ strength and later $\frac{1}{10}$ strength NAM for 12 days. (4) A piece of dissociated–reaggregated tissue was grafted ventrally as in (3) All cultures were kept at 18 °C and after the appropriate period, the isolates or host embryos were fixed and processed for histological examination. Details of the methods used for obtaining embryos, operational procedures and tissue identification have been given previously[11]

jackets are essential for the successful differentiation of these isolates.

Treatment (2) gave significantly different results (Table 1*b*). At both neurula and head process stage there was now a much reduced tendency for the isolates to differentiate into muscle. Instead, the main tissue found was pronephric tubules together with substantial amounts of mesenchyme (Fig. 2*b*). We feel that the most likely interpretation of this result is that undifferentiated cells which would have turned into muscle turn into pronephros instead. The difference cannot be due to the selective overgrowth of one committed cell population by another because the culture medium used in these experiments is not nutritive and although the cells undergo several cleavage divisions there is no net growth of the tissue. Such selection would therefore have to be accompanied by massive cell death, which we do not observe. Because some undifferentiated cells persist in the isolates after the culture period, the only possible explanation based on selection is that the differentiation of committed pre-kidney cells is inhibited in treatment (1) and the differentiation of committed pre-muscle cells is inhibited in treatment (2). We cannot exclude this explanation but we believe it to be unlikely. By the tailbud stage of development the lability of the tissue seems to be lost because muscle is then the dominant cell type formed by the reaggregated isolates (Table 1*b*).

Table 1 Tissue types identified in isolated explants of prospective somite region of axolotl mesoderm

Stage from which tissue isolated	Cases	Muscle	Pronephros	Blood	Mesenchyme
a, Undissociated					
Neurula	8	7 (87%)	2 (25%)	0	6
Head process	13	13 (100%)	7 (54%)	0	9
b, Dissociated-reaggregated					
Neurula	15	6 (40%)	14 (93%)	0	15
Head process	12	2 (17%)	12 (100%)	0	10
Tailbud	8	7 (87%)	6 (75%)	0	7

Prospective somite regions which were grafted to the ventral position while donor and host embryos were at the neurula stage (treatment (3)) differentiated predominantly into erythrocytes (Fig. 2*c*,*d*). Small amounts of muscle and pronephric tubules were also found in some of the grafts (Table 2*a*). At later stages of development the grafts gave rise to more muscle and fewer erythrocytes (stages 19/20 in Table 2*a*) and by the head process stage the grafts differentiated mainly into muscle (Fig. 2*e*) and the few erythrocytes which were formed were dispersed around the outside of the graft tissue. This type of switch from position-dependent to source-dependent development has been reported by Yamada[8], although in his work on the newt *Cynops pyrrhogaster* the switch occurred rather earlier, at about stage 15.

If the prospective somite region is dissociated and reaggregated before being grafted to a ventral position (treatment (4)), the period of lability is even longer (Table 2*b*). As with the reaggregated isolates there was a much reduced differentiation into muscle and a much increased formation of pronephric tubules. There was also a significant formation of erythrocytes which was more extensive at the neurula than at the head process stage. Results with the undissociated controls confirm that these effects were not due to the fact that the reaggregated isolates were cultured for 48 h before grafting. Indeed, the 48-h culture period for the controls actually reduced the lability of the neurula stage ventral grafts; cultured grafts always maintained their capacity for muscle differentiation whereas non-cultured grafts did not (compare Table 2*a* neurula with Table 2*b* neurula control).

For all the operations reported in Table 2*a*, *b* we are confident that the tissues we identify are genuinely derived from the graft and not from the host. This is because grafts to the ventral position persist as readily visible clumps of tissue for many days, as shown in Fig. 2*c*. Also, 21 of these grafts, including cases from each experimental class, were carried out using triploid donor embryos and these triploid cells were later identified in the graft (Fig. 2*f*). In axolotls the number of nucleoli per nucleus corresponds to the ploidy[9] and so the identification of trinucleolar cells is proof of their donor origin. Nucleoli are readily visible in muscle and kidney cells and although they cannot be seen in mature erythrocytes they can be prominent in the erythrocyte precursor cells which are an intimate part of the graft tissue.

The results are summarized in Table 3.

It seems, therefore, that the prospective somite region is determined with respect to self-differentiation in isolation throughout the developmental period considered. However, the determination of the tissue can be modified by grafting to a ventral position up to the head process stage and can be modified by dissociation and reaggregation up to the early tailbud stage. This latter stage is the time at which muscle specific differentiation products can first be detected in the region (T. J. Mohun,

Table 2 Tissue types identified in grafted material following a graft of prospective somite region axolotl mesoderm to replace ventral mesoderm in a donor of equivalent stage

Stage at which graft performed	Cases	Muscle	Pronephros	Blood	Mesenchyme
a, Undissociated					
Neurula	16	4 (25%)	5 (31%)	15 (93)%	6
19/20	11	6 (55%)	1 (9%)	7 (63%)	3
Head process	10	9 (90%)	2 (20%)	7 (70%)	5
b, Dissociated–reaggregated

Neurula control*	10	10 (100%)	1 (10%)	10 (100%)	2
Head process	10	2 (20%)	10 (100%)	4 (40%)	8
Head process control*	8	8 (100%)	3 (37%)	5 (62%)	1

* Controls were undissociated isolates cultured in salt solution for the time period during which dissociated cases were allowed to reaggregate.

R. Tilly, R. Mohun and J.M.W.S., unpublished data) and which we therefore consider to be the onset of cytodifferentiation. Thus, in this case there is no state of truly irreversible determination before cytodifferentiation.

Yamada[10] suggested that the dorsoventral pattern of structures in the mesoderm was specified by a graded signal emanating from the dorsal end of the tissue, which is the prospective notochord. Mesoderm closest to the notochord would be programmed to form the somites, the next layer would be programmed to form the kidney and the most ventral layer to form the blood islands. Our own previous work[11] supports the idea of a dorsal signal for the specification of the somite region and the experiments reported here suggest that the maintenance of this determined state may require the preservation of intercellular contacts. The fact that erythrocytes can be formed by grafts to the ventral position but not in isolates suggests the existence of a second 'blood inducing' signal which is present in the ventral region of the neurula. This would imply that in the absence of all signals the mesoderm would develop into kidney which is what we find in the isolated tissue after disaggregation and reaggregation.

Although this scheme of pattern formation is largely speculative, it is consistent with all our results and does bear some formal similarity to 'double gradient' models which have been advanced to explain other embryonic phenomena[12,13]. Further experiments to test its validity are in progress.

Table 3 Summary of results

a, Neurula	*Isolate*	*Ventral graft*
No dissociation	Muscle	Erythrocytes
Dissoc./reagg.	Pronephros	Erythrocytes (pronephros)
b, Head process		
No dissociation	Muscle (pronephros)	Muscle (erythrocytes)
Dissoc./reagg.	Pronephros	Pronephros

The predominant tissue was found in >85% of cases and the minor tissue in >50% of cases.

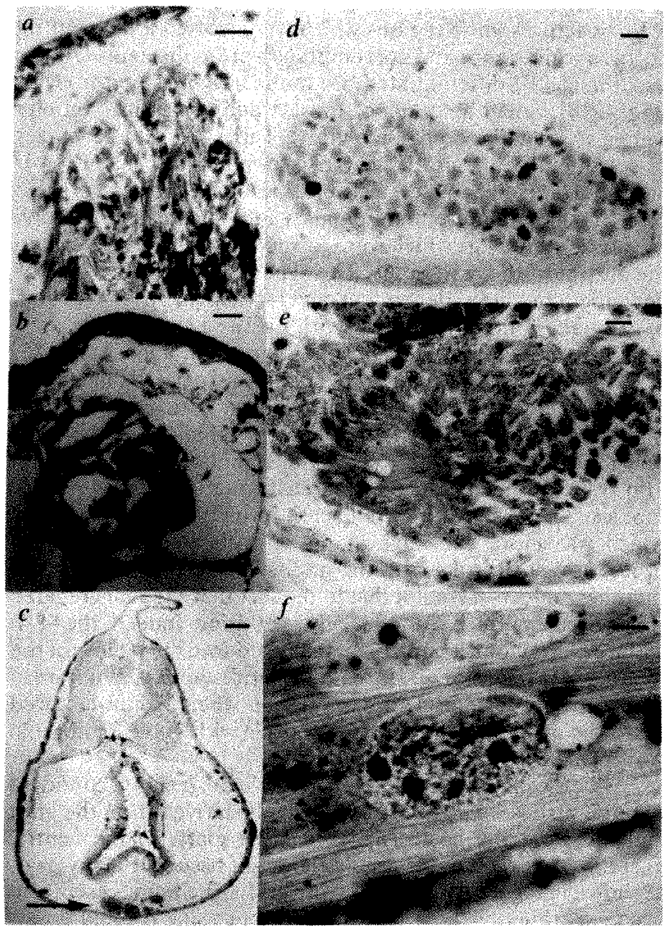

Fig. 2 *a*, Section through prospective somite region which was isolated from a neurula, wrapped in ectoderm and cultured for 10 days (treatment (1)). The tissue, although still containing yolk granules, has largely differentiated into muscle (scale bar, 50 µm). *b*, Section through prospective somite region which was isolated from a head process stage embryo, dissociated and reaggregated, wrapped in ectoderm and cultured (treatment (2)). The tissue has formed pronephric tubules (scale bar, 50 µm). *c*, Transverse section through the trunk region of an early larval stage axolotl which received a graft of prospective somite region into the ventral position (treatment (3)). The graft was carried out at the neurula stage, 12 days previously. The graft tissue is shown by an arrow (scale bar, 200 µm). *d*, High power view of the graft indicated in *c*, showing erythrocytes (scale bar, 20 µm). *e*, High power view of ventral graft of prospective somite region carried out at head process stage, showing muscle (scale bar, 20 µm). *f*, Donor muscle cell in graft region autonomously marked by possession of three nucleoli in the nucleus. Triploid donor embryos were obtained by a 10-min heat shock of 36 °C given 30–45 min after fertilization. The nucleoli are differentially stained by the Unna-Pappenheim stain (scale bar, 5 µm).

A hypolipaemic factor from the corpus cardiacum of locusts

I. Orchard & B. G. Loughton

Department of Biology, York University, Downsview,
Ontario M3J IP3, Canada

The glandular cells in the glandular lobe of the corpus cardiacum (CC) of locusts are the source of adipokinetic hormone (AKH), a hyperlipaemic hormone which has been characterized, sequenced and synthesized[1–4]. The release of AKH is under the synaptic control of axons within the nervi corporis cardiaca II (NCC II)[5]. We show here that a second factor with hypolipaemic activity is also under the control of axons within the NCCII. However, its release sites lie within the storage lobe. Insulin, at physiological doses equivalent to those found in vertebrates, mimics the action of the hypolipaemic factor, and axons which show immunoreactive staining with anti-insulin have been located within the storage lobe. The locust hypolipaemic factor and insulin seem to have some common molecular features.

The CC of locusts has proved an attractive resource for insect endocrinologists because of its anatomical division into storage (which is composed largely of the axon terminals of the median neurosecretory cells) and glandular (composed almost entirely of intrinsic neurosecretory cells) lobes. This has allowed the localization of the source of locust AKH[1–4] in the glandular lobe. The CC is supplied by two nerves, the paired nervi corporis cardiaca I (NCC I) which enter the anterior aspect of the storage lobe and expand to constitute the bulk of the storage lobe, and

0028-0836/80/310494—03$01.00

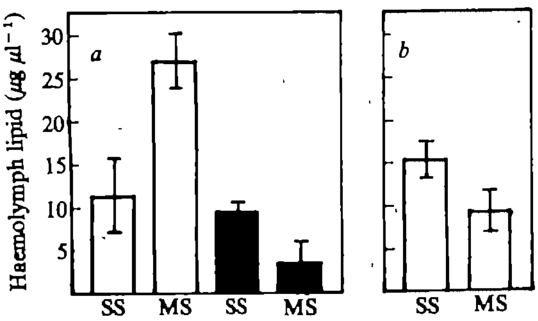

Fig. 1 *a*, Haemolymph lipid levels after injection of perfusate of the glandular lobe of the CC following its stimulation through the NCC II in the presence (solid bars) and absence (clear bars) of phenoxybenzamine. Note that the perfusate following maximal stimulation (MS, open bars) caused elevation of haemolymph lipid (hyperlipaemia) but that the perfusate following maximal stimulation in the presence of 10^{-6} M phenoxybenzamine caused a reduction in haemolymph lipid compared with controls (SS, open and closed bars). Release of hyperlipaemic hormone is obviously blocked in the presence of phenoxybenzamine but the release of hypolipaemic hormone is not. Mean ± s.e. of four assayed locusts. *b*, Haemolymph lipid levels after injection of perfusate of isolated storage lobe following stimulation of the NCC II. Note that the perfusate following maximal stimulation (MS) caused a reduction in haemolymph lipid (hypolipaemia). Mean ± s.e. of 12 assayed locusts. SS, Sub-threshold stimulation; MS, maximal stimulation.

the two nervi corporis cardiaca II(NCC II) which enter the storage lobe dorsally, close to the junction of storage and glandular lobes. We have recently demonstrated[5] that stimulation of the NCC II causes the release of hyperlipaemic factors from the glandular lobe (see Fig. 1*a*, MS open bars).

During experiments on the pharmacology of the neurotransmitters mediating the release of hyperlipaemic factors, we observed preparations which, when stimulated through the NCC II in the presence of the α-adrenergic blocking agent phenoxybenzamine, caused a reduction in the haemolymph lipid of the insects studied (Fig. 1*a*, MS, closed bars). We interpreted this finding as indicating the continued release of a hypolipaemic factor, evident only when the release of the hyperlipaemic hormone(s)[1–4] was inhibited by blocking the synapse between NCC II axons and the intrinsic cells of the glandular lobe to the CC. To substantiate this hypothesis we examined the hypolipaemic activity in greater detail.

AKH activity has been associated primarily with the glandular lobe[6]; therefore, it was expected that the source of the hypolipaemic factor should lie elsewhere. Because incubation of the CC in phenoxybenzamine without nervous stimulation did not bring about release of hypolipaemic activity, it was assumed that its release was controlled by axons of the NCC II. Mason[7] has shown that NCC II sends axons into both the storage and glandular lobes of the CC of *Schistocerca*. This was confirmed for *Locusta* by recording a propagated response from both storage and glandular lobes following stimulation of NCC II. Two approaches were adopted to confirm the presence of a hypolipaemic factor in the storage lobe of the CC. CCs were carefully dissected from mature adult female locusts so as to retain as much of the NCC I and NCC II as possible. Next, the glandular lobe was dissected away leaving the NCC II attached to the storage lobe. As several workers have pointed out[8] that the boundary between storage and glandular regions is not discrete, we could not always be certain that all the glandular lobe had been removed. The storage lobe was placed in 100 μl of physiological saline[9]. The cut end of the NCC II was then drawn into a suction electrode and stimulated with impulses of subthreshold current intensities at 5 Hz for 10 min. The bathing solution was collected and the preparation replaced with 100 μl of fresh saline. The procedure was repeated but the level of stimulation was increased to bring about a maximally propagated response in the form of a compound action potential recorded from the internal face of the ventral lobe of the storage lobe of the CC. The control saline (collected after sub-threshold stimulation) and the experimental saline (following recording of compound action potentials) were assayed for hypolipaemic activity. Groups of four adult male locusts (10–14 days old) were each injected with 20 μl of the test saline. After 45 min the insects were bled through the cervical membrane. The lipid in the haemolymph was estimated gravimetrically[5]. In two out of three storage lobes stimulated in this way, the 'experimental saline' caused a 38% diminution of haemolymph lipid when compared with controls (Fig. 1*b*). Stimulation of NCC I failed to cause release of a hypolipaemic factor. We believe that in the third experiment the storage lobe might have retained some glandular lobe contaminants as lipid levels increased on injection of this preparation.

In a second series of experiments the ventral lobe of the storage lobe was dissected out of mature female locusts and homogenized in 100 μl of saline. Aliquots of the saline extract were injected into adult male locusts. Control insects received injections of saline or extracts of fat body. The lipid levels in the haemolymph of the test insects were determined 45 min later. Figure 2 shows the effects of injections of storage lobe extracts on the lipid levels in the haemolymph of test insects. It can be seen that as little as 0.0025 equivalents of the storage lobe

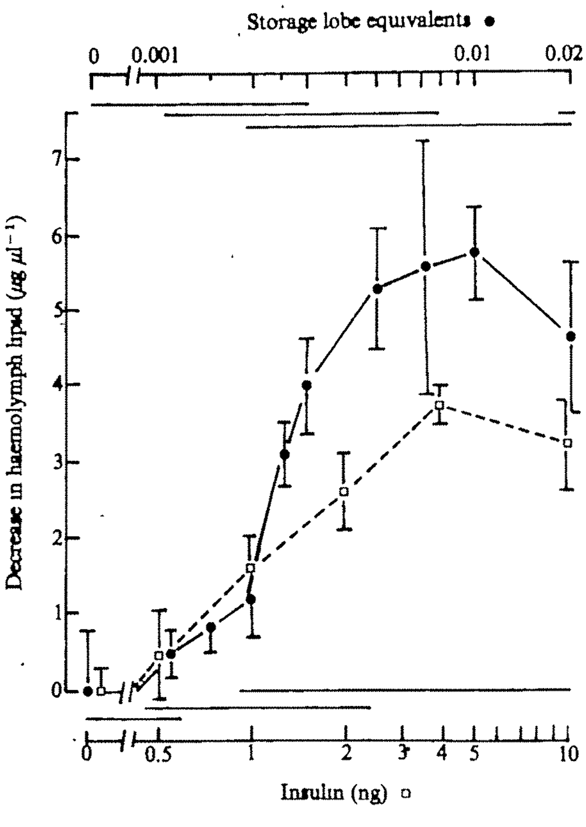

Fig. 2 Decrease in haemolymph lipid following injection of extracts of ventral lobe of the storage lobe of the CC or solutions of insulin (porcine). The resting level of lipid in the control insects for the storage lobe experiment was $10.1 \pm 0.8\ \mathrm{g\,l^{-1}}$, giving a maximum hypolipaemic effect of 57% reduction in haemolymph lipid. Resting level in the insulin experiment was $6.6 \pm 0.3\ \mathrm{g\,l^{-1}}$, giving a maximum hypolipaemic effect of 56% reduction in haemolymph lipid. The resting levels of lipid in the two sets of experiments reflect differences in the age and diet of the 'assay locusts'. The horizontal lines at the top and bottom of the figure denote homogeneous subsets formed by Student–Newman–Keul multiple range test ($\alpha = 0.05$) for storage lobe and insulin, respectively (results of one-way analyses of variance: for storage lobe, $F = 6.23$; d.f. = 9, 127; $P < 0.001$; for insulin: $F = 8.35$; d.f. = 5, 79; $P < 0.001$). The points are mean ± s.e.

caused a significant diminution of haemolymph lipid and that the hypolipaemic effect increased as higher concentrations of storage lobe were used.

In vertebrates, insulin decreases glucose levels in the blood and promotes lipid synthesis in the tissues. Several authors[10-12] have reported the presence of insulin-like molecules in insects. Furthermore, insulin has been shown to decrease the release of lipid from *Hyalophora* fat body *in vitro*[13]. Antibodies against porcine insulin (Sigma) were generated in rabbits and used to localize insulin immunoreactive substances in sections of brains and CC of locusts using the peroxidase–anti-peroxidase method[14]. Positive staining was detected in the ventral lobe region of the storage lobe and in median neurosecretory cells of the brain. The presence of insulin-like molecules in the CC prompted us to investigate the effect of insulin on the lipid levels in locust haemolymph. It can be seen from Fig. 2 that injection of insulin caused a marked decrease in haemolymph lipid. The similarity in the effect of extracts of storage lobe of the CC and insulin together with the presence of anti-insulin immunoreactive molecules in this part of the CC suggest the locust hypolipaemic factor and insulin have some common molecular features.

Although the hypolipaemic factor has not been demonstrated in the haemolymph, the manner of its release from the CC suggests that the hypolipaemic factor in the storage lobe of the locust CC is indeed a newly discovered hormone. A slight hypolipaemia has been reported in cockroaches following injection of extracts of whole CC or corpora allata[15] and Goldsworthy and Cheeseman[16] suggested the possibility of such a hormone following the observation of slight hyperlipaemia in starved locusts in the absence of changes in AKH titre in the haemolymph. The physiological significance of the hypolipaemic factor could be to overcome the inhibition of glycolysis in flight muscle brought about by increased levels of diglyceride in the haemolymph[16] or to restore haemolymph lipid levels to 'normal' following its dramatic increase during flight.

Influence of voluntary intent on the human long-latency stretch reflex

J. C. Rothwell, M. M. Traub & C. D. Marsden

University Department of Neurology, Institute of Psychiatry and King's College Hospital Medical School, De Crespigny Park, Denmark Hill, London SE5 8AF, UK

In man, sudden stretch of an actively contracting muscle evokes a classical monosynaptic spinal reflex followed by an automatic 'long-latency' response, both evident as bursts of activity in the electromyogram (EMG)[1]. This long-latency response, extensively investigated in the human long thumb flexor, but present in many other muscles[2], occurs too early to be voluntary and much indirect evidence suggests it represents the operation of a 'long-loop', perhaps transcortical, stretch reflex mechanism[3,4]. Some investigators have found that the long-latency responses may be modified substantially by the subject's intent, possibly by pre-setting of excitability levels within the central nervous system thereby influencing the 'long-loop' mechanism[5-9]. However, others have observed little effect of voluntary set on the automatic long-latency stretch response[10,11]. It is notable that these studies, which have yielded conflicting results, have involved different muscles in a variety of experimental conditions. In some studies a warning signal preceded muscular stretch, while in others control trials were interspersed with stretches. To resolve the dilemma we have examined the influence of these variables, and found that the automatic long-latency response can be modified most strongly in conditions when the voluntary reaction time is shortest, for example, when the timing of the stimulus can be predicted accurately. We suggest that modification of a long-loop stretch response is not due to some central pre-setting process, but merely represents interaction between a reflex of long latency and a subsequent very rapid voluntary event, occurring early because of predictability of the stimulus.

We have investigated the effect of voluntary intent on the long-latency stretch response in flexor pollicis longus (FPL) and biceps brachii of 10 normal volunteers. The experimental apparatus has been described previously[1,2]. In the experiments on FPL, the thumb was clamped at the proximal phalanx and the subject maintained a constant position of the distal phalanx of the thumb against a background force (2.5 N) offered by a low inertia motor. For biceps, the subject rested his upper arm on a table top at chest height and maintained his semi-pronated forearm vertical against a constant force (8 N) exerted by means of a light chain attached to the motor and pulling on the wrist to extend the elbow. Surface EMGs were recorded by a PDP 12 computer after being rectified and integrated. In each subject muscle stretch was produced every 10–20 s by sudden increases in motor force lasting 1s (to 5 N for FPL; 24 N for biceps). These disturbances were administered in three separate ways (*a*, *b* and *c* given in random order); (*a*) 500–650 ms after a warning bleep, the time being set by a pseudo-random generator; (*b*) a constant 8 s after the bleep; and (*c*) as in condition *a* but with 50% of randomly selected controls (unrecorded) in which the bleep was not followed by a change in motor force. Before each warning signal the subject was instructed in random sequence either to 'let go' by relaxing completely, or to 'resist' by flexing as hard as possible on perceiving the disturbance. It was stressed that he was to react to the stretch and not to the earlier bleep signal. The computer recorded each trial over a period of 250 ms before the disturbance. Sixteen 'let go' and sixteen 'resist' trials were averaged separately in each group. The duration of the long-latency response was measured from the rectified EMG records of the 'let go' trials in condition *c*. The size of the response was measured from the integrated EMG records as the percentage increase in activity over control levels extrapolated from the first 50 ms of the sweep.

It has been shown previously that when a stimulus is preceded by a warning signal, the simple reaction time increases with the length and variability of the fore-period[12]. Thus we expected the reaction time to be shortest in condition *a* in which the subject could predict the timing of the stretch stimulus most accurately. It was in this condition that the subject could voluntarily influence the size of the long-latency stretch response most effectively (Figs 1, 2). The addition of control trials (condition *c*)

0028–0836/80/310496—03$01.00

or increasing the length of the fore-period to 8 s (condition *b*), both of which made the exact timing of the disturbance less certain, reduced the influence of voluntary intent on the stretch response by a similar amount.

Interestingly, there was a considerably greater effect of voluntary set on the stretch response in biceps than in FPL. This was unlikely to be due to a difference in voluntary reaction time because the latency of the EMG response to an auditory stimulus was longer in biceps than in FPL (biceps 151 ms ±7.3 s.e.m. ($n = 8$); FPL 133±7.7 ($n = 8$); paired Student's t-test, $P < 0.005$). It is possible that because of the low inertia of the distal phalanx of the thumb, the stretch stimulus caused a relatively large and rapid change in length in FPL thus saturating the reflex output (see Fig. 1). However, when a smaller thumb disturbance was given (increase in force from 2.5 to 3.0 N) in condition *a*, the influence of voluntary set was reduced, presumably because of the increase in voluntary reaction time to the smaller stimulus.

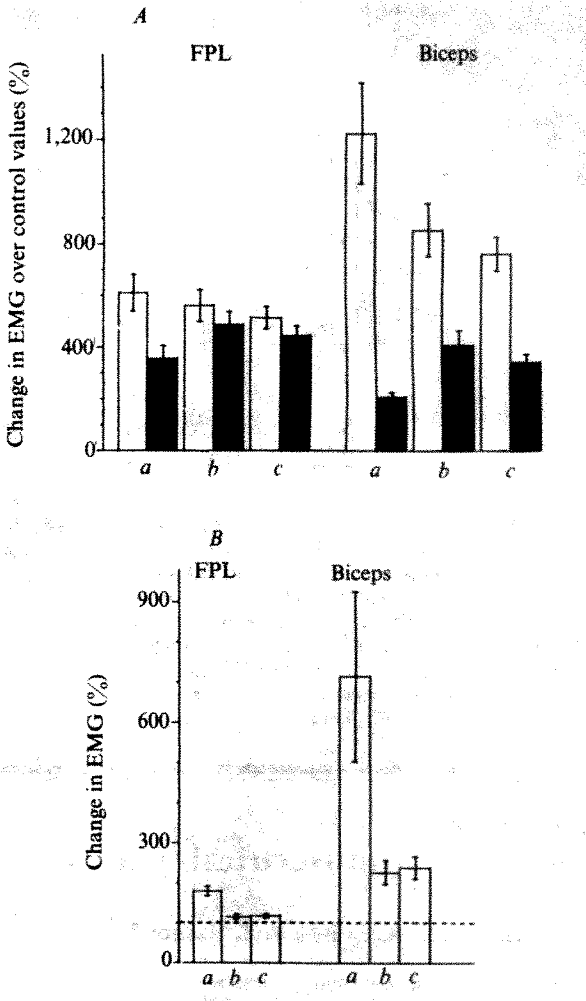

Fig. 2 *A*, Average size of the long latency stretch reflex (±1 s.e.m.) in FPL and in biceps of 10 subjects in the three different experimental conditions *a*, *b* and *c* (see text). Open bars indicate the size in the 'resist' (p) trials; hatched bars the 'let go' (l) trials. Size of reflex EMG was measured from integrated records and is expressed as a percentage of basal levels of activity calculated for the same duration as the reflex, but extrapolated from the control period immediately before the stretch stimulus. *B*, Mean percentage change (±1 s.e.m.) in the size of the stretch reflex during the 'resist' trials compared with the size in the 'let go' trials for each experimental condition (see text). The horizontal dotted line at 100% indicates that the reflex size was the same in both conditions.

Fig. 1 The effect of prior instruction on the automatic long-latency response to muscle stretch in flexor pollicis longus (left-hand traces) and in biceps (right-hand traces) in a single subject. The top records illustrate the angular position of interphalangeal joint of the thumb and the elbow, the initial positions of the joints being 10° and 90° flexion respectively. The lower three traces show rectified EMG. The motor torque was increased 50 ms after the start of each sweep and the subject was instructed before each trial to 'resist' (p) or 'let go' (l) on perceiving the disturbance. Each trace shows the average of 16 p trials superimposed on the average of 16 l trials. The three experimental designs, *a*, *b* and *c*, performed as described in the text, in the sequence *b*, *c*, *a*. Position traces (top) are from trial *a*. The duration of the long-latency stretch response (vertical dotted lines) was estimated from the 'let go' (l) trials in trace *c*. A vertical arrow marks the onset of a small spinal latency component of the response with a latency of about 25 ms in FPL and about 15 ms in biceps.

In a subsidiary experiment the smaller stretch was administered together with a simultaneous electric shock (60 V; 50 μs) to the contralateral median nerve at the wrist (voluntary reaction to the electrical stimulus alone was 100 ms ±2.8 s.e.m.) so as to shorten the reaction time to a small non-saturating stretch stimulus. Now the influence of voluntary intent was enhanced to levels greater than observed in the conditions described previously for larger stretches (Figs 2, 3). In contrast, a simultaneous electric shock had no apparent effect on reflex size when given with a larger stretch when reaction time was already short (Fig. 3).

In conclusion, the degree of voluntary modification of the size of the long-latency automatic stretch response depends on factors which affect reaction time. The relatively small effects of

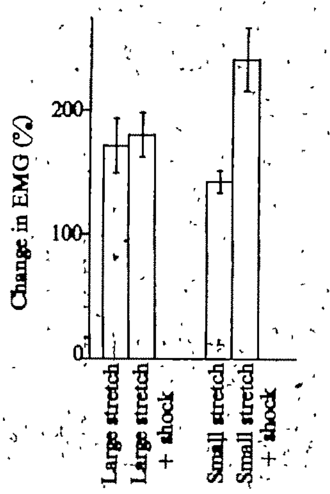

Fig. 3 Average percentage change (±1 s.e.m.) in the size of the long-latency stretch reflex in FPL of ten subjects during the 'resist' and 'let go' conditions when the stretch stimulus was given alone or paired with a simultaneous electric shock to the contralateral median nerve at the wrist. All trials performed under condition *a*, with a warning signal given 500–650 ms prior to the muscle stretch. Left bars, large stretch (from 2.5 to 5 N); right bars, small stretch (from 2.5 to 3 N). The electric shock was arranged to be above threshold for thenar muscle contraction.

voluntary intervention seen in FPL may be because it is impossible to administer a stretch stimulus which is both easily and therefore rapidly perceived, and yet which does not saturate the stretch reflex mechanism. In contrast, the stretch response in biceps does not saturate so easily (because the inertia of the arm precludes very rapid stretches with the apparatus used), so that the influence of rapid voluntary intervention is seen more easily than in FPL. Prior instruction, rather than pre-setting excitability levels in the long-loop pathways, seems to influence the automatic long-latency response to stretch by superimposing fast descending voluntary activity on the earlier automatic event.

Interaction of anaesthetics with electrical synapses

M. F. Johnston, S. A. Simon & F. Ramón*

Departments of Physiology and Anaesthesiology, Duke University Medical Center, Durham, North Carolina 27710

Studies of the interaction of anaesthetics with various preparations, from whole animals to organic solvents, have been continuing since Overton and Meyer found a correlation between anaesthetic potency and solubility in olive oil[1]. Although the physiological basis of anaesthesia is far from clear, one popular hypothesis is that anaesthetics act primarily by interfering with the normal functioning of chemical synapses[2–4]. This hypothesis is supported by experiments showing that these synapses are more sensitive to both local and general anaesthetics than are axons. The effects of anaesthetics on electrical synapses (gap-junctions or nexus) have not previously been studied. These ubiquitous structures, presumably responsible for cell-to-cell communication[5], are found in most vertebrate and invertebrate tissues. We report here the effects of several anaesthetics on electronic coupling between nerve cells, and show that electrical synapses are less sensitive to most anaesthetics than are chemical synapses and axonal membranes.

Experiments were performed on segmented giant axons of the nerve cord of crayfish (*Procambarus clarkii*). Each axonal segment is coupled to its neighbours by bidirectional electrical synapses near each segmental ganglion[6,7]. Measurements were made at the second or third abdominal ganglion. Intercellular coupling was determined by injecting hyperpolarizing square pulses of current and measuring the voltage responses at both sides of the intersegmental septum with intracellular microelectrodes. Septal resistance (R_s) and axon membrane resistance (R_m) were calculated from these measurements[7–9]. Propagated action potentials (p.a.ps) were also recorded as they travelled through the septal region. Control values for resting membrane potential and action potential amplitude are 88.9±2.0 mV and 123.8±3.8 mV (mean±s.d.), respectively. Septal resistance and membrane resistance averaged 40±17 KΩ and 188±18 KΩ, respectively.

Axons were bathed in a modified van Harreveld solution containing 205 mM NaCl, 13.5 mM $CaCl_2$, 5.4 mM KCl, 2.6 mM $MgCl_2$, and 5 mM HEPES, adjusted to *p*H 7.5. Anaesthetics, with the exception of ketamine which was obtained from Parke–Davis, were purchased from Sigma. All drugs were added extracellularly unless otherwise stated. The standard internal solution (SIS) contained 15 mM NaCl, 109 mM KF, 37 mM K citrate, 96 mM mannitol and 1 mM HEPES, adjusted to *p*H 7.5. The more water-soluble anaesthetics were added directly to the external solution. Octanol and nonanol were added to the external solution from 1M stock solutions in dimethylsulphoxide (DMSO). The final concentration of DMSO was always less than 0.5% (v/v), which by itself had no effect on electrical behaviour. Drug concentrations were increased until the axon would no longer maintain a propagated action potential. Experiments were performed at 15 °C.

Figure 1 summarizes data obtained when heptanol (3 mM) was applied externally. This figure shows propagated action potentials and the voltage–current relationships of the septal region during control (*a*, *d*), heptanol (*b*, *e*) and recovery (*c*, *f*). Data for other anaesthetics at various concentrations were obtained similarly.

Figure 1*b* shows that 3 mM heptanol blocks propagation of action potentials across the septum. These effects of heptanol are reversible (Fig. 1*c*). Blockade of action potentials can be explained, from septal *V–I* relationships, by an increase in resistance from 50 KΩ (Fig. 1*d*) to 600 KΩ (Fig. 1*e*). In these data only the *V–I* curves in the third quadrant (hyperpolarization) are relevant. The nonlinearity of the *V–I* relationships seen in the first quadrant is due to changes in membrane resistance during axon depolarization. Under voltage-clamp conditions the *V–I* relationships are linear over a voltage range of ±100 mV[8,9]. In Fig. 1*g*, the septal resistance obtained from the slope of the *V–I* relationships is plotted against time. Arrows at 30 and 80 minutes indicate the beginning and end of heptanol perfusion, respectively.

Table 1 summarizes the results obtained with local and general anaesthetics with regard to their effect on p.a.ps (column

Table 1 Effect of anaesthetics at the crayfish septal synapse

Anaesthetic	Concentration (mM)	Effect on p.a.ps	Coupling at synapse	Reversibility
Local				
Procaine	5.0	blocked	normal	++++
Benzocaine	3.0	blocked	normal	++++
Propranolol	1.0	blocked	normal	++
General				
Ketamine	2.0	delayed	normal	++++
n-Hexan-1-ol	10.0	blocked	slightly decreased	++++
n-Heptan-1-ol	3.0	blocked	uncoupled	++++
n-Octan-1-ol	1.0	blocked	uncoupled	+++
n-Nonan-1-ol	0.3	blocked	slightly decreased	+++

Scale: ++++, completely reversible; +, irreversible.

3), ability to electrically uncouple the axons (column 4), and reversibility (column 5). Table 1 shows that ketamine, procaine, propranolol (all of which exist in both the charged and neutral form at *p*H 7.5), and benzocaine (which is uncharged at *p*H 7.5), produced no significant changes in septal resistance despite their profound effects on p.a.ps. For the homologous series of *n*-alcohols, from hexanol to nonanol (C6–C9), the bulk concentrations correspond to approximately equal membrane concentrations[1]. Alcohols from C6 to C9, all of which block action potentials at the concentrations used, affect septal resistance with a marked dependence on alcohol chain length. Specifically, heptanol and octanol dramatically increased septal resistance whereas hexanol and nonanol produced only minimal changes (Fig. 2). For example, octanol applied externally increased junctional resistance from 40 KΩ to 1.3 MΩ. All the anaesthetics reduced the resting membrane potential by 2–10 mV.

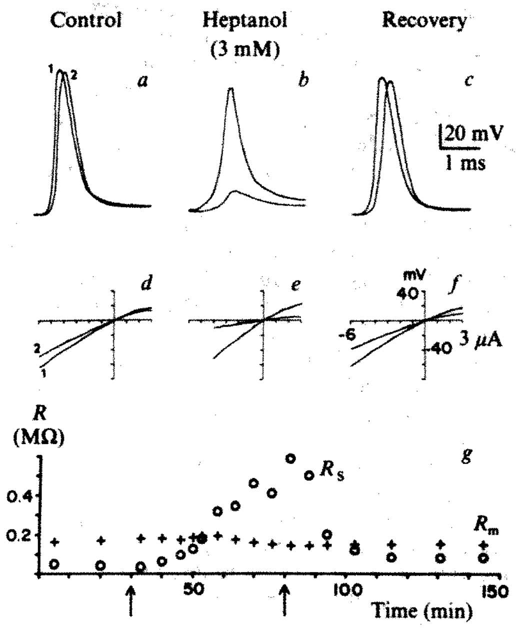

Fig. 1 Propagated action potentials (*a–c*) and voltage–current relationships (*d–f*) in the septal regions of an axon externally perfused with heptanol (3 mM). Data were obtained using three microelectrodes, one for current injection and the others for voltage measurements across the septum. Calibrations at *c* apply also to *a* and *b*, and those on *f* also to *d* and *e*. The small numbers beside the action potentials in *a* and the *V–I* relationships in *d* indicate (1) pre- and (2) postsynaptic recordings respectively. *g* shows septal (R_s, circles) and membrane (R_m, crosses) resistances calculated from the *V–I* relationships in the hyperpolarizing direction. Arrows at 30 and 80 min indicate the beginning and end of heptanol perfusion.

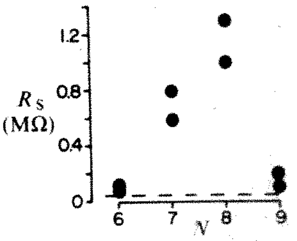

Fig. 2 Maximum septal resistance reached during external perfusion with hexanol (10 mM), heptanol (3 mM), octanol (1 mM) and nonanol (0.3 mM). Abscissa is alkyl chain length (*N*) of the alcohol. Results from two separate experiments are shown for each alcohol. The horizontal dashed line depicts the control value for septal resistance.

As octanol produced the greatest increase in R_s, additional experiments were performed to determine its 'site' of action. These experiments were performed using a technique previously developed to perfuse the interior of segmented axons[8,9]. When one of the axons was perfused with SIS and 1 mM octanol was added to the external solution, uncoupling was similar to that described above. When 10 mM octanol was perfused internally the action potential was blocked as expected[10]; however, the septal resistance remained unchanged.

The above results have implications for mechanisms of anaesthesia. In addition they provide information regarding modulation at electrical synapses: (1) from Table 1 it is clear that electrical synapses are less sensitive to representative anaesthetics than either chemical synapses or axonal membranes, virtually eliminating them from the scope of structures that might be involved in anaesthesia. (2) The lack of effect of certain anaesthetics on electrical synapses and the chain length effect exhibited by alcohols serve to exclude several possibilities regarding mechanisms responsible for uncoupling. Positively charged molecules propranolol, ketamine and procaine (at *p*H 7.5) and the neutral molecule benzocaine had no effect on septal resistance. Thus, generalized membrane changes due to surface charges[11,12], dipole potentials[13,14], thickness[14], tension[28] and membrane fluidity[15,16] produced by these molecules apparently do not affect the operation of electrical synapses. For many preparations the homologous series of alcohols behave in a manner consistent with their solubility in membranes. This is the case for axons[10,17], phospholipid bilayers[18–21], monolayers[22], red blood cells[1] and synapses in the abdominal ganglia of *Aplysia*[23]. Such is not the case for the electrical synapse we investigated. A different alcohol chain length behaviour was described by Gage *et al.*[25,26] on chemical synapses. These authors measured the time constants of decay of miniature end plate currents and found that the normal alcohols from C1 to C6 increased the time constant to decay, whereas octanol decreased it. Similarly, Richards *et al.*[18] showed that no simple correlation exists between an alcohol's ability to block nerve conduction and to perturb bilayer structure.

The striking differences in potency of these alcohols in uncoupling the crayfish synapse implies an interaction which is strongly dependent on the alkyl chain length. Furthermore, the persistence of coupling when octanol is applied internally suggests that this 'site' is accessible only from the external medium. This chain length effect does not exclude a possible role for the hydroxyl group (or other polar groups) in the uncoupling mechanism. It would be of general interest to know, in light of current models of electrical synapses[27], how heptanol and octanol act to uncouple these synapses.

We thank Professors P. B. Bennett, M. Harmel and J. W. Moore for their support. This project was supported by grants HL-22767 and HL-12157.

Diffusion of acetylcholine in the synaptic cleft of normal and myasthenia gravis human endplates

S. G. Cull-Candy, R. Miledi & O. D. Uchitel

Department of Biophysics, University College London,
Gower Street, London WC1E 6BT, UK

When acetylcholinesterase (AChE) is inactivated the time constant of decay of the miniature endplate current ($\tau_{m.e.p.c.}$) depends on the lifetime of the endplate channel and on the speed of clearance of acetylcholine (ACh) from the synaptic cleft[1–3]. The latter will be influenced by the binding of ACh to receptors, hence by their density and by the proportion of the ACh packet which attaches to them. By comparing $\tau_{m.e.p.c.}$ at various levels of receptor density, for example, following curare treatment, it is possible to estimate the proportion, *p*, of the ACh packet which normally attaches to the receptors[1]. We have estimated *p* at the normal human endplate and compared this with myasthenia gravis (MG) affected human endplates where, as a result of reduced receptor density, there is a reduction in miniature endplate potential (m.e.p.p.)[4] and m.e.p.c. amplitudes[5,6], α-bungarotoxin (α-Btx) binding[7,8] and ACh-sensitivity[9]. The properties of the ACh-induced channels are similar at normal and MG endplates[4,10] and it is unlikely that normal or MG channel properties are markedly altered by the various drug treatments used here[11,12]. Therefore, at treated normal and at MG endplates any reduction in the time constant of decay of m.e.p.cs indicates that the speed of clearance of the ACh from the cleft is increased. In the experiments reported here the proportion of the ACh packet which binds is estimated to be about 0.5 at normal human endplates. At MG endplates in the absence of cholinesterase activity m.e.p.cs decay more rapidly than normal and the proportion of the ACh packet attaching is reduced.

Human intercostal nerve muscle was obtained from myasthenia gravis and control patients. The preparation of muscle bundles and electrophysiological techniques for intracellular recording and voltage clamping were as previously described[5,6].

Application of neostigmine to human endplates increases the amplitude of the spontaneously occurring m.e.p.ps by inhibiting cholinesterase activity. The amplitude of m.e.p.ps and the time constant of decay of the miniature currents have been studied over a range of neostigmine concentrations to determine the optimum level required to inhibit cholinesterase. This was found to be 10^{-7} to 5×10^{-7} g ml^{-1} neostigmine; higher concentrations reduce the m.e.p.p. and m.e.p.c. amplitude. The amplitude and time course of m.e.p.cs were obtained at normal human endplates equilibrated in neostigmine (5×10^{-7} g ml^{-1}). Tubocurarine (TC) was then applied either iontophoretically or in the bathing medium (10^{-6} g ml^{-1}). At this concentration TC has no appreciable effect on endplate channel properties in frog muscle[11]. In addition, in some experiments α-Btx (5×10^{-7} g ml^{-1}) was used to block receptors partially, because even at doses higher than those used here it does not appreciably alter the characteristics of the remaining endplate channels[1]. M.e.p.cs were sampled during progressive block or during the recovery stage.

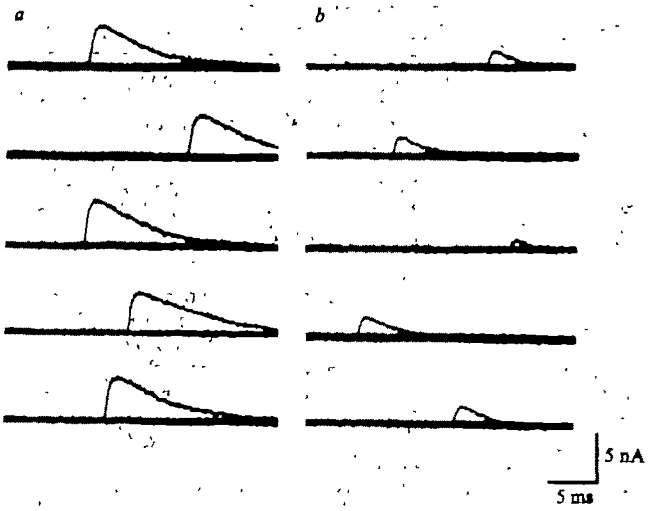

Fig. 1 M.e.p.cs recorded from a single normal human endplate in normal medium in the presence of neostigmine (5×10^{-7} g ml^{-1}) (*a*) and after application of tubocurarine and neostigmine (5×10^{-7} g ml^{-1}) (*b*). In the presence of TC the m.e.p.c. amplitude is reduced and the time constant of decay of the m.e.p.cs becomes briefer. M.e.p.cs are recorded under voltage clamp ($V_m = -80$ mV, $T = 22$°C) through a 500-Hz low pass filter which prolongs the rising phase and slightly attenuates the amplitude. The rising phase of m.e.p.cs is also prolonged by the presence of neostigmine. Tubocurarine is applied iontophoretically. Tetrodotoxin (5×10^{-7} g ml^{-1}) was present throughout.

Figure 1 shows examples of normal m.e.p.cs in neostigmine and m.e.p.cs at the same endplate following iontophoretic application of TC ($V_m = -80$ mV). The reduction in m.e.p.c. amplitude, to less than one-third the normal size in this example, is accompanied by a decrease in $\tau_{m.e.p.c.}$ as previously reported for partially blocked endplates in other species[1,13,14].

The ratio of control to curarized $\tau_{m.e.p.c.}$, which in anti-esterase-treated endplates reflects the relative rates of clearance of ACh from the synaptic cleft, was obtained either from a semilogarithmic plot of the m.e.p.c. decay phase or from power density spectra of m.e.p.cs. Figure 2 illustrates power spectra of m.e.p.cs obtained from a single voltage-clamped human endplate in normal medium (neostigmine 5×10^{-7} g ml^{-1}) and after bath application of TC. $\tau_{m.e.p.c.}$ is obtained from the half-power frequency, f_c, at which the spectral density is reduced to one-half of the zero-frequency asymptote, according to $\tau_{m.e.p.c.} = 1/(2\pi f_c)$. In the examples in Fig. 2 the frequency shift from 27 Hz in normal medium to 35 Hz in TC indicates a decrease in $\tau_{m.e.p.c.}$ from 5.89 ms to 4.54 ms on partial curarization.

It has been suggested[1] that if a fraction, *p*, of the ACh molecules in the cleft binds to receptors, diffusion will be slowed down by the factor $1/(1-p)$. Then from the ratio of the time constants of the control and curarized m.e.p.cs, τ/τ_{TC}, and the ratio of their amplitudes, α, it is possible to obtain an estimate of p: $\tau/\tau_{TC} = (1-\alpha p)/(1-p)$.

$$p = (\tau - \tau_{TC})/(\tau - \alpha\tau_{TC})$$

0028-0836/80/310500—03$01.00

Several kinetic assumptions involved in this relationship have previously been considered[1,14]. The fraction of the packet which attaches is reduced to αp by reducing the number of available receptors, for example, during curarization or at the human MG endplate, where the density of receptors is reduced by an anti-receptor antibody (reviewed in refs 15, 16). Thus, when p is known at untreated endplates it should vary as αp for different levels of receptor block. In the experiment in Fig. 2 the fraction, p, of the ACh packet attaching to receptors is 0.41. The range of values for p, obtained by treating with TC or α-Btx, was 0.4–0.6 at normal human endplates; the mean value for p was 0.56 ± 0.05 (±s.e., five endplates from three muscles).

We have found no significant difference between $\tau_{\text{m.e.p.c.}}$ at normal and MG endplates in normal bathing medium (that is, in the absence of esterase inhibitors) examined in four normal and four MG muscles (Table 1, see also ref. 10). On addition of neostigmine the decay time of both normal and MG m.e.p.cs increased markedly. For normal endplates $\tau_{\text{m.e.p.c.}}$ increased about three times whereas for MG endplates it was approximately doubled. Therefore, in the presence of neostigmine MG m.e.p.cs decay more rapidly than normal m.e.p.cs: $\tau_{\text{m.e.p.c.}}$ (normal) = 5.56 ms and $\tau_{\text{m.e.p.c.}}$ (MG) = 3.65 ms ($V_m = -80$ mV, $T = 22$°C). These values are significantly different, $P < 0.001$ (see Table 1). The simplest explanation for such a difference between normal and MG m.e.p.cs is that the rate of diffusion from the cleft is faster at MG endplates as a result of the reduced ACh-receptor density.

If we compare the mean value of $\tau_{\text{m.e.p.c.}}$ for myasthenia gravis and normal m.e.p.cs in neostigmine (Table 1), where the ratio of the mean m.e.p.c. amplitudes, $\alpha = 0.35$ (range of values for α at 20 endplates, 0.17–0.46), the fraction of the packet attaching at the normal endplate is estimated to be $p = 0.45$ (range of values at 20 endplates, 0.38–0.60). This is assuming that the reduced amplitude and rapid time course of MG m.e.p.cs results mainly from a decreased receptor density at MG endplates. Furthermore, the fraction of the packet, αp, expected to attach at MG endplates is about 0.16 (range of values, 0.08–0.20). We have recorded MG m.e.p.cs before and after treatment with TC or α-Btx. In these conditions m.e.p.cs become so small that accurate estimates of $\tau_{\text{m.e.p.c.}}$ are difficult to obtain. However, it was possible to obtain values at five MG endplates at a clamp potential of −120 mV. This increased the amplitude of the m.e.p.cs and because of the voltage sensitivity of the channel lifetime[10] caused a slight prolongation of $\tau_{\text{m.e.p.c.}}$. Although there has been no detailed study on the dependence of p on membrane potential, from the information available no marked change is expected. Table 1 shows typical values from a myasthenic endplate treated with α-Btx in which $p = 0.17$. The range of values of p obtained was 0.1–0.2; the mean value for p was 0.16 ± 0.03 (±s.e., five endplates in two muscles).

Table 1 Proportion of the ACh packet (p) attaching to receptors: *a*, for normal endplates by comparison of normal with myasthenic m.e.p.cs; *b*, for a normal endplate by curarizing normal m.e.p.cs; *c*, for a myasthenia gravis endplate by α-bungarotoxin treating MG m.e.p.cs

		$\tau_{\text{m.e.p.c.}}$ (ms)	$\tau_{\text{m.e.p.c.}}$ (ms) (neostigmine)	V_m (mV)	α*	p
a	Normal	1.77 ± 0.07 ($n = 15$)	5.56 ± 0.25 ($n = 16$)	−80	0.35	0.45
	Myasthenia gravis	1.80 ± 0.05 ($n = 18$)	3.65 ± 0.12 ($n = 20$)	−80		
		$\tau_{\text{m.e.p.c.}}$ (ms) (neostigmine)	$\tau_{\text{m.e.p.c.}}$ (ms) (neostigmine + TC or α-Btx)	V_m (mV)	α†	p
b	Normal	5.3	4.0 (TC)	−80	0.78	0.59
c	Myasthenia gravis	6.12	5.40 (α-Btx)	−120	0.36	0.17

Values in *a* are mean ±s.e., where n = no. of endplates examined. All measurements were made at 22°C.

* α = MG m.e.p.c. amplitude/normal m.e.p.c. amplitude.

† α = treated m.e.p.c. amplitude/untreated m.e.p.c. amplitude.

Therefore, the similarity in estimates of p (in the absence of esterase activity) obtained by curarizing normal endplates or by comparing normal with MG miniature currents, indicates that the curarized normal endplate resembles the MG endplate in certain respects. The fact that MG miniature currents decay faster than normal miniature currents may be explained by a loss of 'ACh binding sites' which results in a more rapid escape of ACh from the synaptic cleft. This renders unattractive the possibility that at MG endplates there is a decrease in the number of functional channels without a concomitant decrease in ACh binding sites. The reduced fraction of the ACh packet attaching at MG endplates falls within the range expected from the reduction in receptor density estimated from measurements of m.e.p.c. amplitudes. This suggests that the affinity of the receptors for ACh is similar at normal and MG endplates. It therefore seems that the presence of anti-receptor antibody on the postsynaptic membrane[17,18] or changes in the endplate geometry associated with myasthenia[9,19] do not have a predominant role in determining the time course of ACh diffusion out of the synaptic cleft.

We conclude that the fraction of the ACh packet attaching at anti-esterase-treated human endplates is similar to that previously reported for frog[1,20] and rat[12] endplates. In addition, the fraction of the ACh packet attaching at MG endplates seems to be about one-third of that at the normal human endplate, due to a reduction in available ACh receptors. This results in a faster than normal clearance of ACh at the MG endplate.

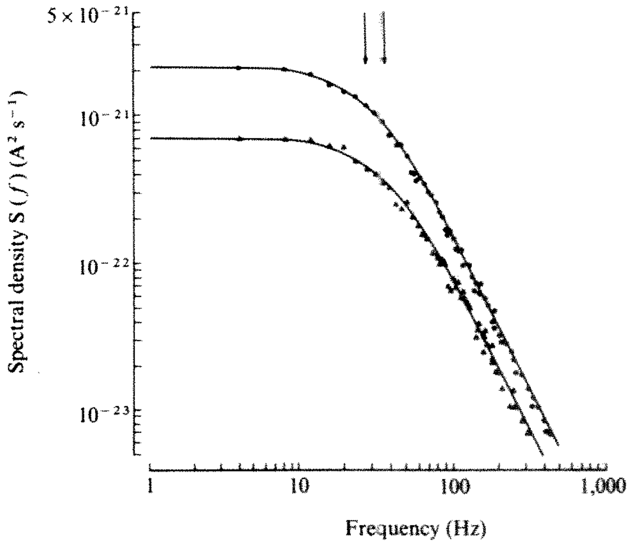

Fig. 2 Effect of tubocurarine on power density spectra of normal human m.e.p.cs from a single voltage-clamped endplate. ●, m.e.p.cs in normal medium, in the presence of neostigmine (2×10^{-7} g ml^{-1}) at a clamp potential $V_m = -80$ mV, $T = 22$°C. Averaged spectrum of 12 individual m.e.p.c. spectra. Cut-off frequency indicated by arrow is $f_c = 27$ Hz, hence $\tau_{\text{m.e.p.c.}} = 5.89$ ms. ▲, m.e.p.cs treated with tubocurarine (10^{-6} g ml^{-1} applied in the bathing medium) in the presence of neostigmine (2×10^{-7} g ml^{-1}), $V_m = -80$ mV, $T = 22$°C. Averaged spectrum of 13 m.e.p.c. spectra. Cut-off frequency indicated by arrow is $f_c = 35$ Hz, hence $\tau_{\text{m.e.p.c.}} = 4.54$ ms. The zero frequency asymptote is three times smaller for the spectrum of m.e.p.cs treated with TC indicating that the ratio: curarized m.e.p.c. amplitude/normal m.e.p.c. amplitude, $\alpha = 0.58$, where the ratio of the amplitudes, α, before and after TC is obtained from the ratio of the square roots of the respective spectral densities. Hence, from the relationship, $p = (\tau - \tau_{TC})/(\tau - \alpha\tau_{TC})$, $p = 0.41$ for this particular case.

We thank Professor B. Katz for helpful discussions, Mr J. R. Belcher and Dr J. Newsom Davis for help in obtaining biopsies, the patients for their collaboration and the MRC and the Muscular Dystrophy Association of the UK for support.

Erythroid developmental agglutinin is a protein lectin mediating specific cell–cell adhesion between differentiating rabbit erythroblasts

F. Lynne Harrison & C. James Chesterton

Department of Biochemistry, King's College London, Strand,
London WC2R 2LS, UK

In many developmental systems β-galactoside-specific protein lectins have been identified as components which appear at the cell surface in concert with an initial requirement for cell–cell adhesion during tissue formation[1–8]. Although some of these lectins have been purified, there has been little direct evidence concerning their role in establishing specific cell–cell contact. A mammalian system where selective cell–cell adhesion is evident and which is amenable to study is that of erythroid differentiation in the adult bone marrow[9]. Here, the differentiation of erythroblasts takes place with the participants clustered together in the vicinity of a macrophage 'nurse' cell until the enucleation stage, when the immature reticulocyte is released and passes through the sinusoidal wall into the circulation. We show here that a small, β-galactoside-specific, protein lectin can be extracted from erythroblast-enriched marrow and purified to homogeneity. This factor, termed erythroid developmental agglutinin (EDA), exhibits properties which strongly suggest that it is responsible for inter-erythroblast recognition and adhesion *in vivo*.

EDA, purified from lactose washes of erythroblast-enriched rabbit bone marrow (see Fig. 1 legend), shows 95–100% Coomassie blue staining in a single component after electrophoresis on native, urea or SDS-containing polyacrylamide gels, where it exhibits a molecular weight of 13,000. No staining is observed with Schiff-periodic acid reagent, and GLC analysis for sugars in EDA hydrolysates detected less than 1 molar equivalent carbohydrate. Completely pure EDA can be obtained by repeating the affinity chromatography step once or twice more. The lectin electrofocuses as a single component at pH 5–6.

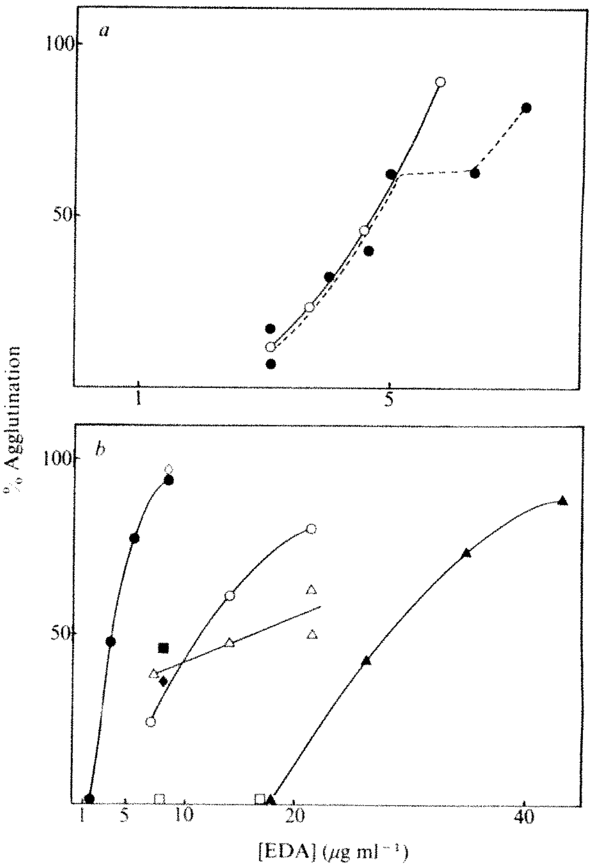

Fig. 1 *In vitro* agglutination studies. The ability of EDA to mediate intercellular cross-linking was tested using cells which were washed twice in MESL and resuspended in buffered medium. In addition, fractions enriched for erythroblasts, immature myeloid cells and marrow reticulocytes were prepared by sedimentation through a Percoll gradient (experimental details will be published elsewhere). The cellular composition of the fractions used was determined by cytocentrifugation and histological staining to be: 90% erythroblast, 5% myeloid, 5% reticulocyte; 69% myeloid, 26% reticulocyte, 5% erythroblast; and 87% reticulocyte, 4% erythroblast, 9% myeloid, respectively. Cell suspensions (0.25 ml, 10^7 cells per ml buffered medium) were mixed at room temperature by end-over-end rotation (4 r.p.m.) in small plastic vials at various EDA concentrations. Aliquots were taken throughout the incubation, diluted fivefold with 0.2% trypan blue in buffered medium (to check viability) and aggregation was assessed by counting the number of single cells present in a haemocytometer. The points plotted represent single cells lost after 10 min incubation with EDA. In the absence of EDA no agglutination was seen. *a*, Agglutination of a mixed cell population: ●, anaemic rabbit bone marrow; ○, erythroblasts for comparison. *b*, Agglutination of cell fractions: ●, erythroblasts; ○, myeloid cells; △, marrow reticulocytes; □, erythrocytes; ▲, Chinese hamster ovary cells. Erythroblasts in the presence of : ◇, 24 mM sucrose; ■, 0.66 mM lactose; ◆, 0.32 mM thiodigalactoside. EDA was purified from the bone marrow of 20 rabbits made anaemic by phenylhydrazine injection[11]. The tissue was gently disaggregated and the cells washed 3 × in a total of 30 ml MESL. After centrifugation at 27,000g for 15 min followed by 120,000g for 2 h, the washes were treated with 100% saturated $(NH_4)_2SO_4$ and centrifuged at 30,000g for 20 min. Pelleted protein was dissolved in MES (14 mM 2-mercaptoethanol, 2 mM EDTA, pH 8, 150 mM NaCl) and fractionated by gel filtration through Sephadex G-100. Fractions with haemagglutination activity[10] were concentrated by ultrafiltration, applied to a column of Sepharose 4B (4.4 × 28 cm) and eluted with MES. EDA was eluted after the main protein peak. Active fractions were concentrated by ultrafiltration.

The specific location of EDA *in vivo* was demonstrated by immunolabelling. The IgG fraction from anti-EDA antiserum raised in a sheep was absorbed out with that protein from an EDA preparation which did not bind to the affinity column and yielded a single precipitin line in a double-diffusion test against EDA or crude lactose extract. This was used to locate the agglutinin by standard indirect immunofluorescence techniques in whole marrow freshly obtained from healthy or anaemic rabbits. Fluorescence was detected only on the surface of erythroblasts and reticulocytes and this could be completely eliminated by preincubation of the cells and antibody with purified EDA (Fig. 2). Washing the marrow with 0.3 M lactose removes all the cell-surface agglutinin detectable in the same batch of unwashed marrow. Developing myeloid cells and the macrophage 'nurse' cell were not labelled unless in contact with an erythroblast (Fig. 2).

The agglutinin is capable of linking inert cells together by a mechanism blocked by β-galactosides. The assay used to monitor the lectin during preparation is a simple haemagglutination test with trypsinized rabbit erythrocytes[10]. EDA also gives a positive haemagglutination reaction when such cells are fixed in glutaraldehyde, a procedure which chemically cross-links and inactivates surface protein. This activity was inhibited by 0.6 mM lactose and 0.5 mM thiodigalactoside but was not affected by 230 mM sucrose, confirming previous observations on the behaviour of unfixed cells.

The *in vitro* specificity of EDA was first tested on lactose-washed cells from anaemic marrow, a mixed cell population. With increasing concentrations of the lectin, two phases of aggregation were seen. Approximately 60% of the cells agglutinated at 5 μg ml^{-1} EDA, and the remainder required a higher concentration (Fig. 1*a*). Phase contrast microscopy showed that the initial aggregates contained almost exclusively erythroblasts which stained preparations revealed constituted 67% of the marrow. The erythroid specificity suggested by these results and previously shown by immunofluorescent labelling was confirmed by the behaviour of different cell fractions in this assay. Lactose-washed erythroblasts from either healthy or anaemic rabbits were agglutinated by 2–8 μg ml^{-1} EDA, whereas immature myeloid cells required three or four times more lectin to achieve 50% aggregation, and a Chinese hamster ovary cell line needed a level over fivefold higher (Fig. 1*b*). Erythroblast agglutination was inhibited by low concentrations of β-galactosides (Fig. 1*b*). The intra-marrow concentration of EDA is not known, but an estimate can be made from the yield of agglutinin protein after purification. This is approximately 0.2 mg per rabbit or 40 μg ml^{-1} marrow from anaemic animals and 0.05 mg or 10 μg ml^{-1} from healthy rabbits; thus, the affinity of

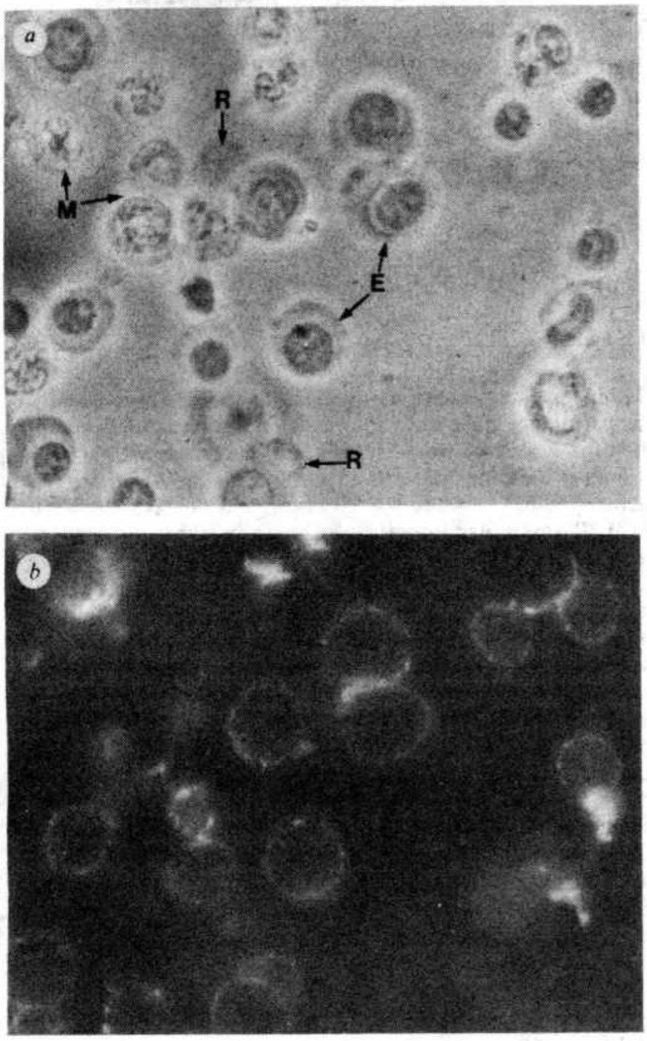

Fig. 2 Detection of EDA in fresh bone marrow by indirect immunofluorescent labelling. The marrow was gently disaggregated in Gibco 109 medium buffered with 25 mM HEPES and the suspension of cells allowed to settle on to microscope slides precoated with polylysine or concanavalin A. The immobilized cells were incubated with preimmune or anti-EDA IgG (3.4 mg ml^{-1}) followed, after washing, by fluorescein-conjugated rabbit anti-sheep IgG. After washing again, the cells were mounted in 80% glycerol in phosphate-buffered saline and viewed with a Vickers M17 microscope using visible light under phase contrast (*a*) or incident fluorescent illumination (*b*). Fluorescent labelling was detected strongly on the surface of erythroblasts (E) and weakly on marrow reticulocytes (R). No labelling was detected on the surface of myeloid cells (M). Furthermore, no labelling was seen in the following conditions: when IgG from a preimmune serum was substituted for anti-EDA IgG; if the cells and IgG were preincubated with 0.5 and 1.7 μg ml^{-1} EDA, respectively; or when the cells were prewashed with MESL (28 mM 2-mercaptoethanol, 2 mM EDTA, *p*H 8, 150 mM NaCl and 0.3 M lactose). ×1,155.

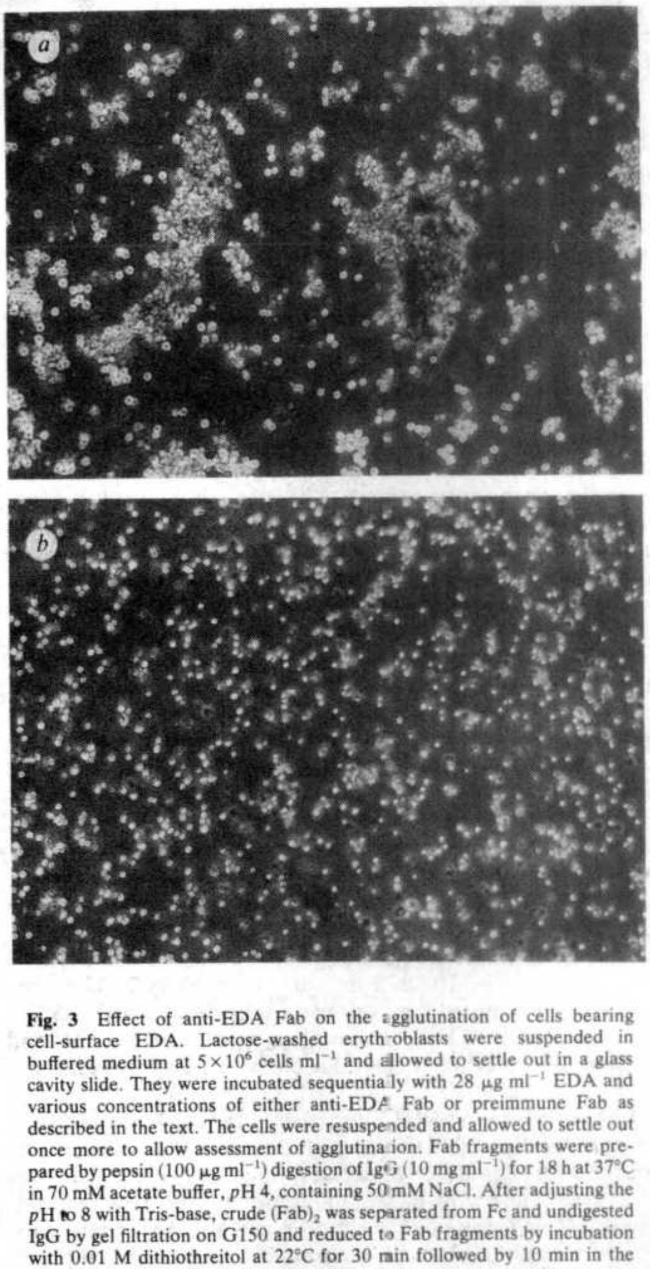

Fig. 3 Effect of anti-EDA Fab on the agglutination of cells bearing cell-surface EDA. Lactose-washed erythroblasts were suspended in buffered medium at 5×10^6 cells ml^{-1} and allowed to settle out in a glass cavity slide. They were incubated sequentially with 28 μg ml^{-1} EDA and various concentrations of either anti-EDA Fab or preimmune Fab as described in the text. The cells were resuspended and allowed to settle out once more to allow assessment of agglutination. Fab fragments were prepared by pepsin (100 μg ml^{-1}) digestion of IgG (10 mg ml^{-1}) for 18 h at 37°C in 70 mM acetate buffer, *p*H 4, containing 50 mM NaCl. After adjusting the *p*H to 8 with Tris-base, crude $(\mathrm{Fab})_2$ was separated from Fc and undigested IgG by gel filtration on G150 and reduced to Fab fragments by incubation with 0.01 M dithiothreitol at 22°C for 30 min followed by 10 min in the presence of 0.022 M iodoacetamide. The product was separated by repeating the gel filtration step and its purity was checked by SDS-polyacrylamide gel electrophoresis. (The method was communicated to us by M. Virji.) The photographs show erythroblasts after incubation with preimmune Fab (*a*) or anti-EDA Fab (*b*), both at 5 mg ml^{-1}. ×115.

EDA for the erythroblast surface which can be demonstrated *in vitro* seems to be adequate to account for the clustering seen *in vivo*.

The presence of EDA is coincident with the requirement for adhesion *in vivo*. Erythroblasts at all stages of differentiation discernible in the marrow were strongly labelled by anti-EDA IgG but marrow reticulocytes showed a weaker surface fluorescence (Fig. 2). Only faint fluorescence was observed on early circulating reticulocytes and none could be detected on late cells or erythrocytes. Erythroblasts, separated into fractions enriched for the various developmental classes by unit gravity sedimentation[11], all showed a similar degree of agglutination by EDA *in vitro*. However, aggregation of bone marrow reticulocytes required higher levels of agglutinin and erythrocytes were not visibly affected apart from a transient clustering at high EDA concentrations (Fig. 1*b*).

The immunofluorescence studies described above demonstrate that anti-EDA antibody binding does not displace EDA from the erythroblast surface. Therefore, it is possible that if EDA mediated cell aggregation by triggering a secondary mechanism at the cell surface, cell–cell adhesion would not be affected by the binding of an antibody molecule. On the other hand, if an EDA bridging mechanism induces agglutination, the presence of bound anti-EDA IgG, rendered monovalent by conversion to Fab fragments, would almost certainly stearically hinder the process. The experiment was carried out using lactose-washed erythroblasts which had been allowed to settle out into a monolayer on the surface of a cavity slide. The cells adhere to the glass strongly enough for the surrounding medium to be changed without significant disturbance. *In situ*, the erythroblasts were loaded with agglutinin and subsequently incubated with either control preimmune Fab or anti-EDA Fab. After subsequent resuspension, the cells were allowed to settle once more to enable assessment of their state of aggregation (Fig. 3). In the presence of up to 14 mg ml^{-1} control Fab protein, normal EDA-induced agglutination was observed whereas anti-EDA Fab at 14, 10 or 5 mg ml^{-1} completely blocked cell clustering; 2.5 mg ml^{-1} produced an inhibition of about 50%. A second batch of both preparations gave similar results and we find the experiment reproducible with cells from different animals.

Using the experimental advantages of the erythroid system, it has thus been possible to demonstrate that many of the criteria required for identifying molecules which link cells together *in vivo* are fulfilled by EDA. In particular, the fact that this agglutinin will cross-link inert cells and that its action when bound to erythroblasts is blocked by monovalent antibody strongly suggests that a bridging mechanism is involved. EDA is a typical small, acidic, β-galactoside-specific, protein lectin. It may be, therefore, that all such animal lectins act as cell–cell bridging molecules.

Perhaps the temporal role of the β-galactoside-specific lectins in development is now clearer. The inter-erythroblast adhesion mediated by EDA occurs at an early stage of tissue formation and is reversible, the erythroblastic island being a transient structure. Examination of the relationship of other such factors extracted from embryonic tissue to the developmental pattern of the embryo reveals that in all cases activity is only observed at an early stage[12-15]. It is possible that these have a similar role to that of the erythroid lectin. However, in most non-haemopoietic tissue, such links would be overridden by more powerful binding mechanisms. In the marrow, the cohesion is reversed and the maturing cell is lost irretrievably from its tissue of origin.

We thank Tessa Beswick for technical assistance, Susan Godsave, David Wraith and Nicholas Parsons for help with the agglutination experiments and EDA preparation, Dr Elizabeth Hounsell for GLC analysis, Neill Spencer and Karen Wells for analysis of EDA by electrofocusing, Dr N. Totty for Chinese hamster ovary cells, and all in the laboratory for aid in preparing the manuscript. L.H. is a Cancer Research Campaign-supported research fellow and the work was additionally funded from the SRC and MRC.

Abelson murine leukaemia virus transformation involves loss of epidermal growth factor-binding sites

Jonas Blomberg*, Fred H. Reynolds Jr†, Wim J. M. Van de Ven† & John R. Stephenson*

* Laboratory of Cellular and Molecular Biology, National Cancer Institute, Frederick, Maryland 21701
† Carcinogenesis Intramural Program, Frederick Cancer Research Center, Frederick, Maryland 21701

Malignant transformation by mammalian RNA sarcoma viruses has previously been shown to involve a reduction in receptor sites for a well characterized 6,000-molecular weight (MW) growth-promoting substance, designated epidermal growth factor (EGF)[1-3]. Although Abelson murine leukaemia virus (AbLV) resembles sarcoma viruses in its ability to transform embryo fibroblasts in cell culture[4], AbLV induces a rapid B-cell lymphoid leukaemia rather than fibrosarcomas *in vivo*[5,6]. The major translational product of AbLV is a highly phosphorylated polyprotein[7,8] of MW 120,000 which exhibits an associated tyrosine-specific protein kinase activity[9,10] and probable transforming function[11-14]. We show here that AbLV transformation resembles transformation by RNA sarcoma viruses with respect to the abolition of EGF-binding sites. EGF binding is restored to control levels following loss of polyprotein expression in morphological revertants of AbLV-transformed clones and remains uninfluenced in cell lines infected with transformation-defective (td) AbLV mutants encoding polyproteins deficient in protein kinase activity. These findings indicate that AbLV transformation involves a polyprotein-associated, tyrosine-specific protein kinase activity which mediates its effect through a mechanism resulting directly or indirectly in the abolition of EGF-binding sites.

The wild-type (wt) and td mutant AbLV FRE Fisher rat and CCL64 mink cell clones analysed in the present study are described in Table 1. In contrast to the wt AbLV-transformed clones, each of the td AbLV mutant clones is highly contact inhibted (data not shown) and lacks the capacity for colony formation in soft agar. Moreover, none of five td AbLV mutant clones were found to be tumorigenic on inoculation into a syngeneic Fisher rat host. Each of the td AbLV non-productively-infected clones express a 120,000-MW polyprotein, P120, at levels comparable with wt AbLV-transformed clones, but in contrast to the latter clones, the polyprotein expressed lacks detectable protein kinase activity. Two morphological revertants of one wt AbLV-transformed mink clone, 64Ab2-2, lack detectable AbLV P120 expression, protein kinase and ability to grow in soft agar. This defect in expression of transformation is cellular rather than viral in nature as demonstrated

0028-0836/80/310504—04$01.00

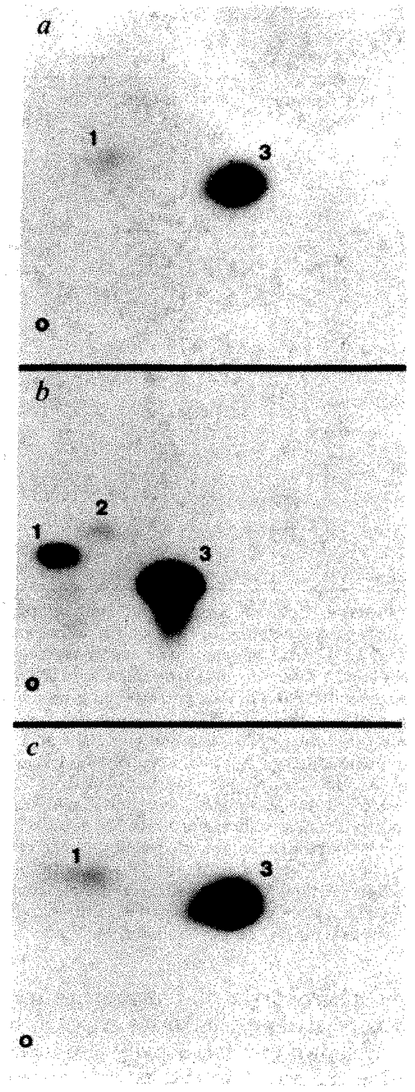

Fig. 1 Identification of amino acid acceptor residues phosphorylated *in vitro* by phosphotransferase activity. *In vitro* ^{32}P-labelled extracts of control FRE cells (*a*) or FRE cells infected with either wt AbLV (Cl 4-4) (*b*) or td AbLV (2-112-F2) (*c*) were hydrolysed in 6 M HCl at 100 °C for 1 h. Two-dimensional separation was carried out by electrophoresis at 500 V for 3 h in acetic acid/formic acid/water (15:5:80; *p*H 1.9) (horizontal dimension) and chromatography in 0.5 M ammonium hydroxide/isobutyric acid (3:5) (vertical dimension). *In vitro* phosphorylated amino acid residues were identified by comparing their position relative to phosphoamino acid standards stained with ninhydrin[19]. These included phosphothreonine, phosphotyrosine and phosphoserine and co-chromatographed with spots 1, 2 and 3, respectively.

by the presence of AbLV genomic sequences measured by molecular hybridization (data not shown) and the rescuability of wt AbLV by appropriate type C helper viruses[15,16].

The above findings do not indicate whether the lack of [γ-^{32}P]ATP-mediated *in vitro* phosphorylation of AbLV P120 is a defect in the AbLV P120-associated protein kinase activity, or whether it reflects an inability of P120 expressed in td AbLV-infected cells to act as substrate. To resolve these possibilities, we examined the levels of phosphotyrosine in representative wt and td AbLV-infected cell clones. As shown in Fig. 1, phosphotyrosine was not observed to a significant extent in control FRE rat cells but was readily detectable in a representative wt AbLV-transformed cell line. In contrast, appreciable levels of phosphotyrosine were not observed in td AbLV-infected cell lines. These findings suggest that the lack of phosphorylation of AbLV P120 in td mutant-infected clones does not simply reflect a lack of substrate activity.

In view of the previously reported loss of EGF-binding sites following transformation by avian and mammalian RNA sarcoma viruses[1-3], we examined the possibility that AbLV transformation might also result in abolition of EGF-binding sites. For this purpose, each of the above-described wt and td AbLV-transformed cell clones was analysed for the ability to bind ^{125}I-labelled EGF. As summarized in Table 1, EGF-binding by AbLV non-productively-transformed rat and mink cells was ~20-fold lower than that by uninfected control cell lines. Scatchard plot analysis shows this difference to be primarily due to a decrease in receptor site number rather than an altered binding affinity (Fig. 2). Although the absolute number of cellular binding sites on CCL64 mink cells was about sevenfold greater than exhibited by the FRE rat cell line, the binding affinities were similar. Mink or rat cells non-productively

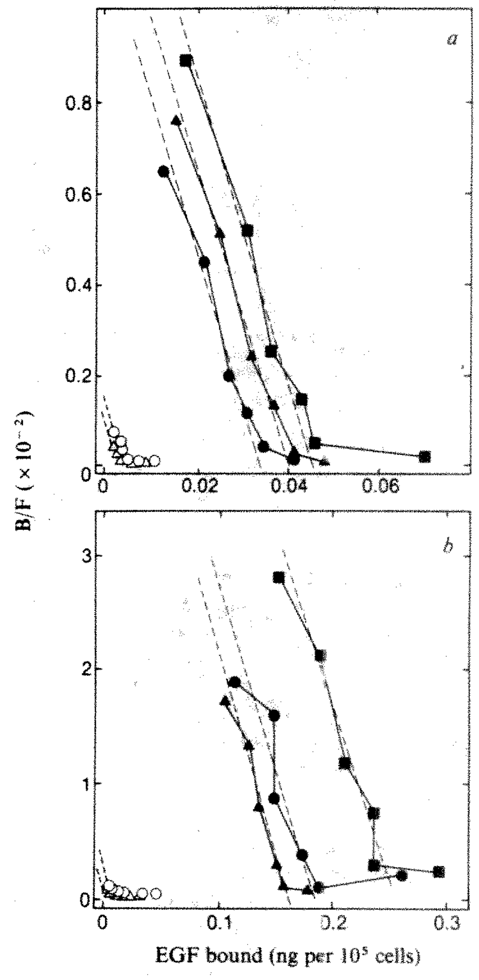

Fig. 2 Analysis of EGF-binding characteristics according to the method of Scatchard[25]. Mouse EGF (Collaborative Research) was labelled with ^{125}I at high specific activity (10–40 μCi per μg) according to previously published methods[17,18]. Cell lines were cultured at around 10^5 cells per well in 24-well cluster plates (Costar). After 48 h, individual wells were washed once with complete DMEM, incubated for 3 h at 37 °C in serum-free DMEM, and for an additional 4 h at 4 °C in 0.2 ml of HEPES buffered (*p*H 7.4) DMEM containing 0.1% ovalbumin and concentrations of ^{125}I-labelled EGF ranging from 5,000 to 500,000 c.p.m. Cells were then washed three times in serum-free medium, dissolved in 1% SDS (1 ml) and their radioactivity measured in a γ-scintillation counter. For cell number determinations, duplicate wells were stained with Sedi-stain (Becton-Dickinson). Results are based on triplicate determinations and are expressed as ng EGF bound per 10^5 cells and as the ratio of bound to unbound EGF (B/F). Cell lines tested are described in detail in Table 1 legend and include *a*, FRE (●), Cl 4-4 (○), 2-112-F2 (▲), 2-109-F5 (■), 2-112-RT2 (△), and *b*, CCL64 (●), 20-1-F6 (○), 64Ab2 (△), 9-104-7 (▲), 64 Ab2-2 (■).

Cells were propagated in Dulbecco's modification of Eagle's medium (DMEM) supplemented with 10% calf serum (Colorado Serum Co.). Details of the isolation and preliminary characterization of each of these cell lines have been previously reported[16,17]. Plating efficiency in soft agar was determined as previously described[16,17]. Results represent mean values from three separate determinations. Levels of AbLV P120 expression were estimated on the basis of competitive immunoassays for their p12 structural components[16,17]. *In vitro* phosphotransferase assays were carried out as described previously[9]. Cells (1×10^7) were disrupted in 5 ml of 10 mM Tris-HCl buffer (*p*H 7.2) containing 100 mM NaCl, 5 mM $MgCl_2$, 0.1% Triton X-100, by repeated aspiration through a 19-gauge needle. Extracts were preabsorbed overnight with normal goat serum (50 μl) and 0.5 ml of a 10% v/v suspension of protein-A–Sepharose (Pharmacia), and clarified by centrifugation of 40,000*g* for 90 min. Immunoprecipitation was by addition of 5 μl goat anti-Moloney-MuLV and 50 μl protein-A–Sepharose (10% v/v suspension) to 1 ml extract, agitation overnight and collection of immunocomplexes by centrifugation at 2,000*g*. Protein kinase reactions were carried out by resuspension of immunoprecipitates or aliquots of total lysates in Tris-HCl buffer (*p*H 7.2) containing 5 mM $MgCl_2$, 1 μCi [γ-^{32}P]ATP 100 Ci mmol^{-1} (NEN) and incubation for 10 min at 30 °C. Samples were washed in ice-cold 10 mM sodium phosphate buffer (*p*H 7.2), 0.9% NaCl, 1% Triton X-100, 0.5% sodium deoxycholate and 0.1% SDS, collected by centrifugation at 2,000*g* for 10 min, transferred and collected on glass fibre filters (GF/C, Whatman) with 10% trichloroacetic acid containing 1 mM AMP. Incorporated radioactivity was quantified by liquid scintillation and results expressed as pmol ^{32}P incorporated into trichloroacetic acid-insoluble precipitates and corrected for nonspecific radioactivity at zero reaction time. Determination of phosphotyrosine as a percentage of total cellular phosphoamino acids was determined by scraping individual ^{32}P labelled phosphoamino acids from TLC plates; radioactivity was quantified by liquid scintillation. Results are expressed as the ratio of ^{32}P-labelled phosphotyrosine to total ^{32}P label in all three phosphoamino acids. NT, Not tested. The number of EGF-binding sites per cell and binding affinities are estimated on the basis of Scatchard binding plots prepared according to the method of Scatchard[25] and illustrated in Fig. 2. Results represent average values of two to four separate determinations±s.e.m. As recently discussed by Norby *et al.*[26], values obtained by this means may represent slight overestimations of the actual binding site numbers.

infected with each of eight td AbLV mutants examined, exhibited similar numbers of EGF-binding sites and binding affinities to the uninfected control cell lines from which they were derived. Moreover, as shown in Table 1, restoration of AbLV P120-associated protein kinase activity following retransformation of a representative td AbLV mutant clone by wt AbLV was associated with a reduction in the number of EGF receptors. Thus, the defect in transforming potential by td AbLV mutants is associated with simultaneous loss of protein kinase activity and an impairment in the process resulting in EGF-receptor site abolition.

As described above, morphological reversion of AbLV transformation is associated with loss of detectable levels of AbLV P120 expression. Thus, if AbLV P120-associated protein kinase activity is necessary for the abolition of EGF-receptor binding sites in AbLV-transformed cells, we would predict that such sites would reappear and that cellular phosphotyrosine levels would be reduced to those characteristic of nontransformed cells in revertant clones. To test this possibility, several morphological revertants of AbLV-transformed mink clones were analysed with respect to EGF-binding properties and levels of cellular phosphotyrosine. These clones are of particular interest because the transformation defect seems to be cellular in nature and to occur at high frequency[15,16]. As shown in Table 1, in both of the revertant cell clones examined, phosphotyrosine levels were reduced to control levels. Moreover, in both cell lines, EGF binding was restored to levels comparable to that exhibited by uninfected control cells.

To test the generality of restoration of EGF binding after morphological reversion of transformation, levels of EGF binding by uninfected control, Gardner feline sarcoma virus (FeSV)-transformed cells and morphological revertants of FeSV-transformed mink cells were examined. The Gardner FeSV transformation system was chosen because of its resemblance to AbLV in that FeSV has also been shown to encode a high molecular weight phosphorylated polyprotein translational product[17,18] with associated protein kinase activity[9]. In fact, we have more recently shown that this activity also has specificity for phosphotyrosine acceptor sites and have demonstrated elevated levels of phosphotyrosine in mink and rat cells following FeSV transformation[19]. As shown in Table 2, EGF binding was over 10-fold lower in FeSV-transformed than uninfected control mink cells. Following reversion of one such clone to a nontransformed phenotype, EGF binding was restored to control levels. Thus, an undefined mechanism resulting in simultaneous loss of expression of viral polyprotein expression and phenotypic transformation also leads to restoration of EGF-binding capacity.

The present findings establish an association between AbLV-induced transformation and reduction of EGF-binding sites and suggest that both depend on the presence of tyrosine-specific protein kinase, either intrinsic to, or associated with, AbLV P120. The fact that EGF binding by td AbLV mutant-infected

Table 2 EGF binding by uninfected control, FeSV-transformed and morphological revertant cell clones

The isolation and preliminary characterization of these cell lines have been previously reported[14,16]. EGF receptor site numbers and binding affinities were determined as described in Table 1 legend.

cell lines is equal to that exhibited by uninfected control cells, despite levels of AbLV P120 expression comparable to those in wt AbLV transformants, suggests that if AbLV does directly interact with EGF-binding sites, its expression in the absence of protein kinase activity is not sufficient for transformation. For instance, phosphorylation of one or more tyrosine acceptor sites within the EGF receptor, AbLV P120 itself, or in some undefined cellular regulatory protein may be involved in the process. Alternatively, reduction of EGF binding associated with AbLV P120 protein kinase activity may be due to activation of one or more cellular growth-promoting factor(s) analogous to sarcoma growth factor (SGF) described by Todaro and colleagues[20].

Our results do not resolve the problem of whether the reduced EGF-binding activity associated with AbLV transformation is directly attributable to AbLV P120 protein kinase activity or whether loss of EGF binding represents a secondary phenomenon resulting from expression of the transformed phenotype. The previous demonstration, however, that EGF binding is reduced only partially in avian sarcoma virus-transformed cells and remains essentially unaltered in cells morphologically transformed by DNA viruses such as SV40 and polyoma, argues against the latter possibility. This difference in effect on EGF receptors by RNA and DNA tumour viruses of mammalian origin is somewhat surprising in view of results indicating that transformation by SV40 and polyoma may also involve protein kinase activities[21–24].

Activation of growth factor regulatory systems may represent one of several mechanisms for spontaneous and chemically and virally induced malignant transformation. In particular, the transforming function associated with acquired cellular sequences represented within recombinant genomes of certain RNA tumour viruses, such as AbLV, may be mediated by this pathway. A major advantage of the AbLV system for studies of the role of the growth-promoting factors in transformation relates to the fact that an AbLV-encoded protein with tyrosine-specific protein kinase activity and probable transforming function has been identified. In addition, many td AbLV mutants and morphological revertants have been isolated and characterized in some detail. AbLV transformation thus provides an excellent model system for further elucidation of the molecular events involved in malignant transformation.

'Activation-labile' glucocorticoid–receptor complexes of a steroid-resistant variant of CEM-C7 human lymphoid cells

Thomas J. Schmidt*, Jeffrey M. Harmon† & E. Brad Thompson

Laboratory of Biochemistry, DCBD National Cancer Institute,
NIH Bethesda, Maryland 20205

For cytoplasmic glucocorticoid–receptor complexes to enter and accumulate in the nucleus a temperature-dependent event, 'activation' is required[1–4]. Activation can be achieved *in vitro* by increased ionic strength[3–6], dilution or gel filtration[7] and is manifested by an increased affinity of steroid–receptor complex for DNA[3,5,7,8] and an altered elution profile from ion-exchange resins[9–11]. Munck and Foley have shown[12] that activated complexes isolated from thymocytes elute from DEAE-cellulose in a manner identical to complexes activated *in vitro*. We report here that DEAE-cellulose chromatography of steroid–receptor complexes from CEM-C7, a cloned human leukaemic T-cell line sensitive to the cytolytic action of glucocorticoids[13–15], and its steroid-resistant subclone 4R4 demonstrated that steroid receptors of clone 4R4 cannot form stable activated complexes. This defines a new defect in receptor action, activation lability (r^+act^l), which is unlike either the r^-, r^+nt^-, or r^+nt^i phenotypes previously described for mouse lymphoid variants[16–19].

Both the glucocorticoid-sensitive clone (C7) and the steroid-resistant subclone (4R4) contain specific, high-affinity binding sites for ^{3}H-dexamethasone, although the 4R4 sites display a somewhat lower affinity for dexamethasone than do those of its sensitive parent (Table 1). The source of this difference, which in itself cannot account for the total resistance of 4R4 to 10^{-6} M dexamethasone, may be clonal variation, or it may actually reflect subtle differences in the receptors. Since subsequent experiments indicate that glucocorticoid–receptor complexes of 4R4 are labile in the conditions of the whole cell binding assay (37 °C), the higher K_d obtained may result from non-equilibrium conditions. In fact, binding data obtained using cytosol assays performed at 0–4 °C suggest that both C7 and 4R4 receptors have the same high affinity (3×10^{-8} M) for dexamethasone (data not shown). A more striking difference in the properties of the receptor complexes of the two clones is their relative ability to translocate to the nucleus in physiological conditions (Table 1). No glucocorticoid–receptor complex was detected in the nucleus of 4R4 after incubation for 1 h at 37 °C in the presence of 5×10^{-8} M ^{3}H-dexamethasone, although 40% of the receptor complexes of clone C7 were detected in the nucleus in identical conditions. In contrast to the r^+nt^- mouse variants which generally display decreased but detectable nuclear accumulation of receptor complex (40% of the sensitive S49 wild type)[16,19], clone 4R4 exhibits no nuclear transfer.

Since glucocorticoid–receptor complexes of clone 4R4 could not be detected in the nucleus we examined the possibility that these receptor complexes were either unable to be activated (r^+act^-) or were labile (r^+act^l) in 'activating' conditions. DEAE-cellulose chromatography of glucocorticoid–receptor complexes from several cell types resolves these complexes into two forms: a high salt-eluting form which does not bind to DNA, nuclei or chromatin and probably represents the 'unactivated' form of the complex, and a low salt-eluting form which does bind to DNA, nuclei and chromatin, and which has been suggested to represent the 'activated' form of the glucocorticoid–receptor complex[11,12]. Figure 1*a* depicts the time course of activation of C7 cytoplasmic receptors which were pre-incubated for 2 h at 0–4 °C with 5×10^{-8} M [1,2,4(*n*)-^{3}H]triamcinolone acetonide (^{3}H-TA) and then activated at 20 °C in the presence of 0.2 M KCl for 0–30 min. Immediately after the 2 h incubation and removal of unbound ^{3}H-TA by gel filtration, most receptor complexes were eluted from DEAE-cellulose by 0.22 M potassium phosphate, that is in the 'unactivated' form (peak II). After activation for 15 min or 30 min there was a progressive shift of specifically bound ^{3}H-TA to a form which was eluted at 0.05 M potassium phosphate (peak I), so that after 30 min 50% of the total bound radioactivity was found in peak I with a proportional loss from peak II. The salt concentrations at which peak II and peak I were eluted are essentially the same as those for cytoplasmic receptor complexes detected in rat liver, HTC cells, LA9 cells, rat brain and adrenalectomized rat thymus (Y. Sakaue and E.B.T., unpublished data), and only activated receptor complexes from CEM cells bind to DNA-cellulose[23].

Figure 1*b* depicts the time course of attempted activation of 4R4 cytoplasmic receptors. Again the glucocorticoid–receptor complexes in the unactivated cytosol were eluted predominantly in peak II (0.21 M potassium phosphate). After activation for

Table 1 Characteristics of binding of ^{3}H-dexamethasone by sensitive (C7) and resistant (4R4) CEM cells

Clone	Binding (sites per cell)*	K_d*	% Nuclear translocation*
C7	20,000	1.2×10^{-8} M	40
4R4	5,900	7.3×10^{-8} M	0

Cells were grown in suspension in RPMI 1640 (NIH Media Unit) containing 10% heat-inactivated fetal calf serum (North American Biologicals) at 37 °C in a humidified atmosphere of 95% air, 5% CO_2. Clone 4R4 is one of 54 spontaneously derived steroid-resistant subclones of CEM-C7 selected in 10^{-6} M dexamethasone[15]. For the whole-cell binding assay cells were collected in mid-logarithmic phase and resuspended in Tricine-buffered RPMI 1640 at approximately 10^7 cells per ml. Aliquots (980 µl) of the cell suspensions were added to a series of borosilicate culture tubes (Fisher Scientific) which contained 10 µl of various concentrations of [1,2(*n*)^{3}H]dexamethasone (38 Ci mmol^{-1}; Amersham/Searle) in 95% ethanol plus either 10 µl of ethanol (uncompeted) or 10 µl of 5×10^{-3} M nonradioactive dexamethasone in ethanol (competed). Cell suspensions were incubated at 37 °C for 1 h. Following the incubation, 3 ml Hanks' balanced salt solution (BSS) at 22 °C were added to each tube, and the tubes were then centrifuged for 1 min at 1,200*g* in a clinical centrifuge. The cell pellets were then washed three times in 3 ml of BSS at 22 °C. Final cell pellets were resuspended in 1.6 ml BSS and 1.0 ml was added to 10 ml Aquasol liquid scintillation cocktail (NEN) and radioactivity was determined in a Beckman LS 9000 counter. A 0.2-ml aliquot of the cell suspension was counted (Coulter Model ZB) to determine final cell recovery. The difference between the total d.p.m. and the noncompeting d.p.m. represents specifically bound ^{3}H-dexamethasone and was expressed as sites per cell. K_d values and sites per cell were determined by analysing the data by the method of Scatchard[20]. For determination of nuclear translocation a minor modification of the procedure of Munck and Wira[21] was utilized.

* Values represent means of at least two determinations.

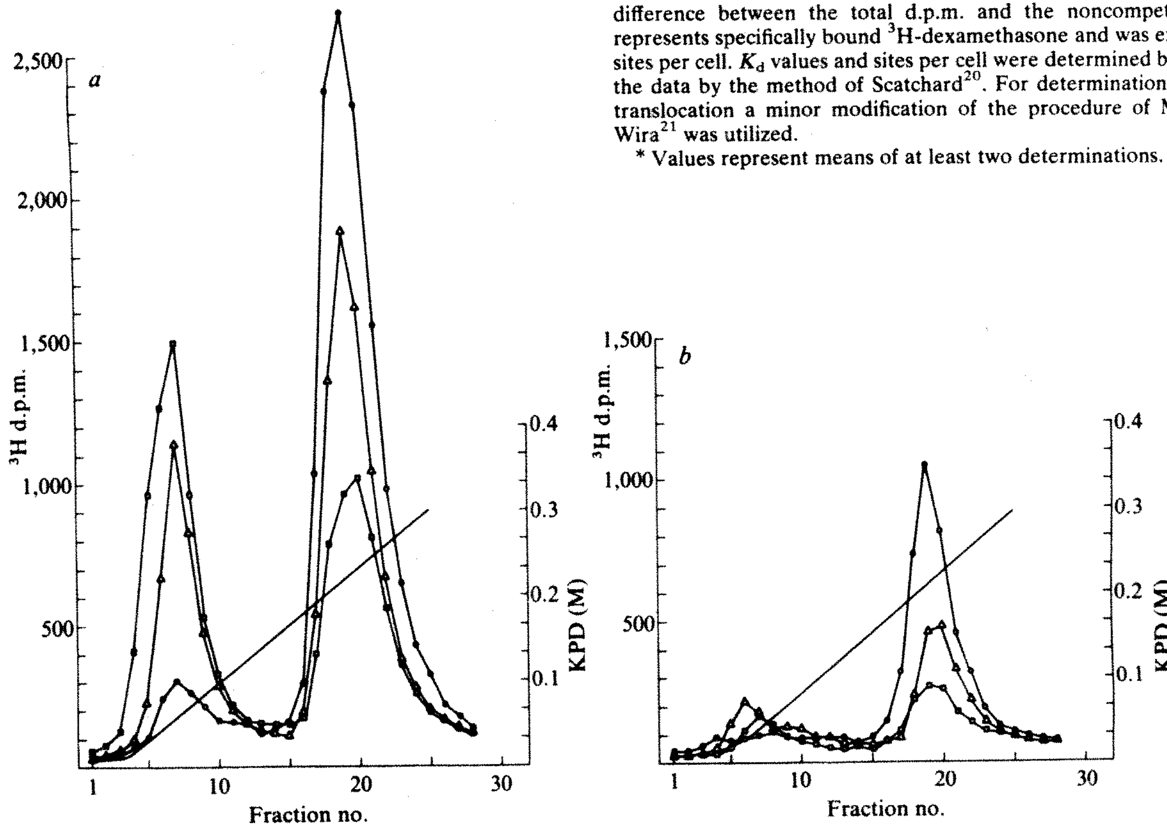

Fig. 1 Time course of activation (20 °C, 0.2 M KCl) of cytoplasmic [1,2,4*n*-^{3}H]triamcinolone acetonide–receptor complexes of CEM-C7 (*a*) and 4R4 (*b*) (○, unactivated control; △, 15 min activation; □, 30 min activation). Cells (1×10^6 cells per ml) were collected, washed once in an excess of ice-cold Hanks' BSS, and homogenized in 5 mM potassium phosphate buffer containing 0.5 mM dithiothreitol, *p*H 7.3 (KPD) at 4 °C with a Ten Broeck ground glass homogenizer. Cytosols were isolated after centrifugation for 1 h at 100,000*g* in a Spinco Model L refrigerated centrifuge. Cytosolic protein concentrations were determined by the method of Lowry *et al.*[22] and were 6 to 9 mg ml^{-1}. Cytosols were incubated for 2 h at 0–4 °C with approximately 5×10^{-8} M [1,2,4(*n*)-^{3}H]triamcinolone acetonide (29 Ci mmol^{-1}; Amersham/Searle) before activation. Following activation (20 °C, 0.2 M KCl) free steroid and salt were removed by passage over G25 columns (PD 10; Pharmacia) pre-equilibrated with 5 mM KPD buffer. 700 µl of the post-G25 cytosol were then loaded on to a DEAE-cellulose (DE52; Whatman) column (3 ml bed volume) which had been pre-equilibrated with 5 mM KPD. Bound radioactivity was then eluted by a linear 5 mM to 400 mM KPD gradient and 1.0-ml fractions collected. All chromatographic procedures were performed at 4 °C. Aliquots (400 µl) of each fraction were added to 10 ml of Aquasol and assayed for radioactivity. Salt concentrations were measured with a Radiometer electroconductivity meter. In similar experiments cytosols incubated with a 1,000-fold excess of nonradioactive TA failed to reveal any ^{3}H-TA bound to DEAE-cellulose columns. Since these lymphoid cells are devoid of progesterone receptors (J.M.H. and T.J.S., unpublished data) the binding of ^{3}H-TA can be assumed to be to glucocorticoid receptors.

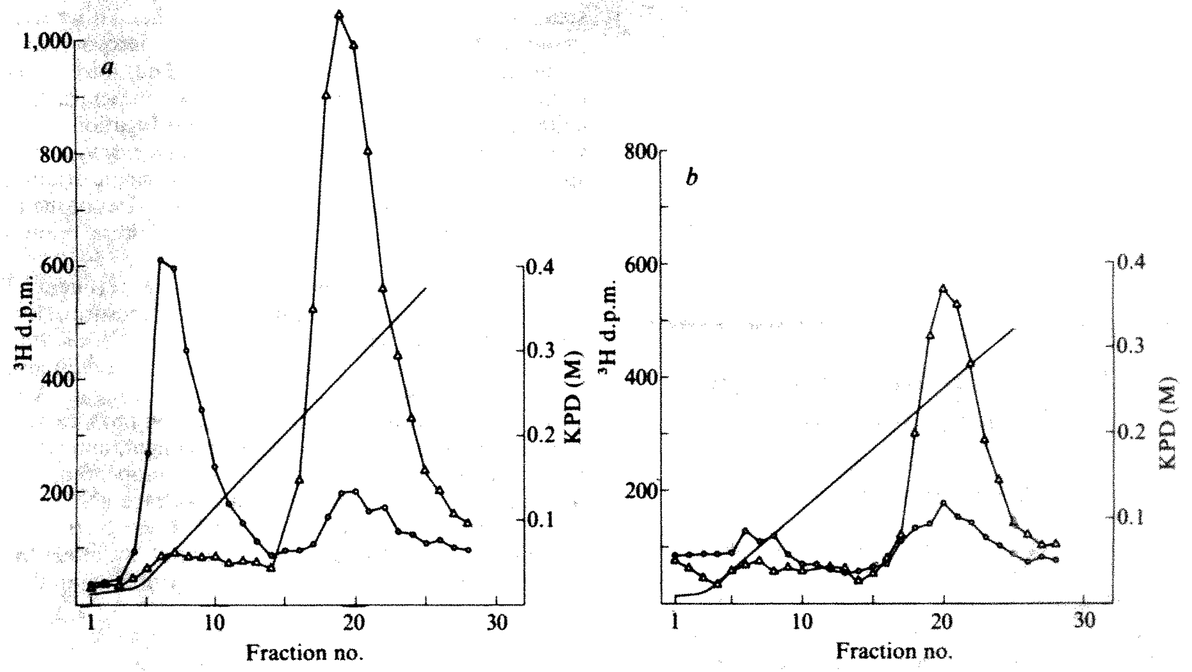

Fig. 2 DEAE-cellulose chromatograms depicting activation (30 min at 20 °C, 0.2 M KCl) of cytoplasmic [1,2,4(n)-^{3}H]triamcinolone acetonide–receptor complexes of CEM-C7 (a) and 4R4 (b) in the absence (○) and presence (△) of molybdate. Cell cytosols were prepared, incubated with ^{3}H-TA, and activated as in Fig. 1 with the exception that half of each cytosol was activated in the presence of 50 mM molybdate.

15 min there was a significant depletion in the radioactivity associated with peak II as seen for the wild type, but only a very small increase in the radioactivity associated with peak I (0.05 M potassium phosphate). Continued exposure to activation conditions for 30 min resulted in a further reduction of peak II with no further increase in the small amount of bound radioactivity eluted in peak I so that the total bound radioactivity was reduced by approximately 50%. These data clearly suggest that glucocorticoid–receptor complexes from 4R4 are labile in activation conditions. The small increase in peak I seen in the time course of activation of 4R4 receptor complexes after 15 min (Fig. 1b) suggests that at least some activation is possible. The subsequent disappearance of this peak after prolonged (30 min) activation suggests that it may be the activated form of the receptor complex which is labile. This instability could result from actual denaturation of the receptor protein or from dissociation of the steroid from receptor.

Sodium molybdate (Na_2MoO_4) inhibits the activation of glucocorticoid receptors from rat liver, rat thymus, mouse L cells and human leukaemic cells (T.J.S., unpublished data)[24,25]. It also inhibits the activation of avian oviduct progesterone receptors[26,27]. When 50 mM molybdate was incubated with C7 cytosol receptors during activation, the characteristic shift of steroid–receptor complex from peak II to peak I was not observed (Fig. 2a), demonstrating the ability of this compound to inhibit the activation of human lymphoid receptors. Attempted activation of 4R4 steroid–receptor complexes in the presence of 50 mM molybdate produced the result shown in Fig. 2b. In contrast to the loss of binding in the absence of molybdate, all of the binding was retained and eluted in peak II. This retention of binding most probably reflects the failure to generate a labile activated form of the 4R4 steroid–receptor complex in the presence of the inhibitor of activation, molybdate. Alternatively molybdate may have another, as yet undefined effect, whereby it is capable of stabilizing an otherwise unstable 'unactivated' form of the steroid–receptor complex.

Mouse lymphoid variants of S49 and W7, resistant to the cytolytic action of glucocorticoids, either lack receptor (r^-) or have receptor with diminished ability to enter the nucleus with reduced affinity for DNA-cellulose (r^+nt^-) or receptors which paradoxically bind more avidly to DNA cellulose (r^+nt^i)[16–19]. In the case of the r^+nt^- and r^+nt^i phenotypes it is presumed that activation is normal since it is the affinity of steroid–receptor complexes for DNA and not their ability to bind which is altered. We have identified a new phenotype, r^+act^l, in a steroid-resistant variant of a human leukaemic cell line. DEAE-cellulose chromatography of the glucocorticoid–receptor complexes of this resistant variant failed to demonstrate the formation of stable activated complexes. This result explains our failure to detect ^{3}H-dexamethasone–receptor complexes in 4R4 nuclei in physiological conditions and indicates an additional mechanism for the acquisition of steroid resistance. These results suggest that the predominant mechanism(s) of steroid resistance in human and mouse lymphoid cell lines may differ and the steroid-resistant variants of CEM-C7 may provide a more useful model system for the study of glucocorticoid resistance in human T-cell leukaemia.

Insertion of *E. coli* photoreactivating enzyme into V79 hamster cells

Betsy M. Sutherland & S. G. Hausrath

Biology Department, Brookhaven National Laboratory, Upton, New York 11973

Photoreactivating enzyme mediates the specific repair of UV light [220–300 nm, (UV)]-induced cyclobutyl pyrimidine dimers in DNA[1]. It binds to dimer-containing DNA, and on absorption of light in the wavelength range 300–500 nm monomerizes the dimer, restoring biological activity to DNA[2]. The specificity of the enzyme for pyrimidine dimers in DNA allows its use as an analytical tool. If UV-induced biological damage is photoreactivable, dimers are probably a major cause of that damage. Thus dimers have been implicated in producing death and mutation in prokaryotes and in simple eukaryotes[3]. Although this photoreactivation test has great potential value in assessing the role of dimers in UV-induced damage in mammalian cells, its use in cultured mammalian cells has been limited by the dependence of photoreactivating enzyme levels on the cell species[4], genotype[5] and culture medium[6,7]. We have developed a method for insertion of *Escherichia coli* photoreactivating enzyme into mammalian cells, and show here that the inserted bacterial enzyme can mediate photoreactivation of pyrimidine dimers in V79 rodent cells.

We selected V79 Chinese hamster cells as a mammalian cell line with minimal endogenous photoreactivating enzyme (rodent cells contain no more than about 10% as much photoreactivating enzyme as do human cells[4]; also, V79 cells undergo excision repair very slowly[8–10]). Cells were grown in a minimal essential medium known to be unfavourable for photoreactivating enzyme production[6]. We also required an effective insertion agent which did not inactivate the *E. coli* enzyme. Polyethylene glycol (PEG) 6000 proved satisfactory in all these respects.

We first examined dimer monomerization in V79 cells treated with PEG, *E. coli* photoreactivating enzyme and visible light. Cells were grown in 60-mm plastic culture dishes overnight; the medium was removed, the cells were washed twice with 2 ml phosphate-buffered saline (PBS; 0.171 M NaCl, 3.4 mM KCl, 10.1 mM Na_2HPO_4, 1.9 mM KH_2PO_4), and 1 ml PBS was layered over the cells. They were exposed to UV light from a low pressure mercury bulb; UV exposures were measured with a Jagger meter[11] calibrated against a Yellow Springs Instrument Company radiometer. All procedures were carried out under Sylvania F40G0 safe lights. After exposure to UV light, the PBS was removed, and the cells treated for 2 min with 3 ml of insertion mixture[12] [prepared by mixing 30 g of PEG 6000, Biological Laboratories (which had been autoclaved for 30 min) with 60 ml of medium without serum at 45 °C. The mixture was then cooled to 37 °C]. The insertion mixture was removed, the cells drained briefly, rinsed with 1 ml PBS and 0.1 ml (1.1 mg) of partially purified photoreactivating enzyme from *E. coli* W 3350 λ *phr* (ref. 13) [fraction III (ref. 14), specific activity ~600 units mg^{-1}] was layered over the cells. The cells were allowed to stand at room temperature for 15 min, then either exposed to photoreactivating light from a 60-W incandescent bulb, or kept in the dark. Small amounts of PBS (~0.2 ml) were added to the dishes as required to prevent drying of the cells. Cells were collected by scraping into PBS, and centrifugation; their DNAs were extracted, then treated with the *Micrococcus luteus* dimer-specific UV-endonuclease (which makes a single-strand scission adjacent to each dimer)[15], and the relative sizes of the resulting DNAs determined from their electrophoretic mobilities in alkaline agarose[16,17].

Figure 1 shows the result of such an experiment. Trace *a* represents DNA from unirradiated cells. Exposure of the cells to $10\ J\ m^{-2}$ of UV radiation (trace *b*) produces UV endonuclease-sensitive sites (dimers) in the DNA, and thus a reduction in the size of the DNA after endonuclease treatment. After UV-irradiated cells were treated with insertion mixture and *E. coli* enzyme, followed by photoreactivating light, almost all of the UV endonuclease-sensitive sites disappeared, implying substantial monomerization of dimers (trace *c*). Treatment of the cells with insertion mixture plus photoreactivating enzyme in the absence of photoreactivating light did not affect the dimer content of the DNA (trace *d*), nor did incubation in the light of

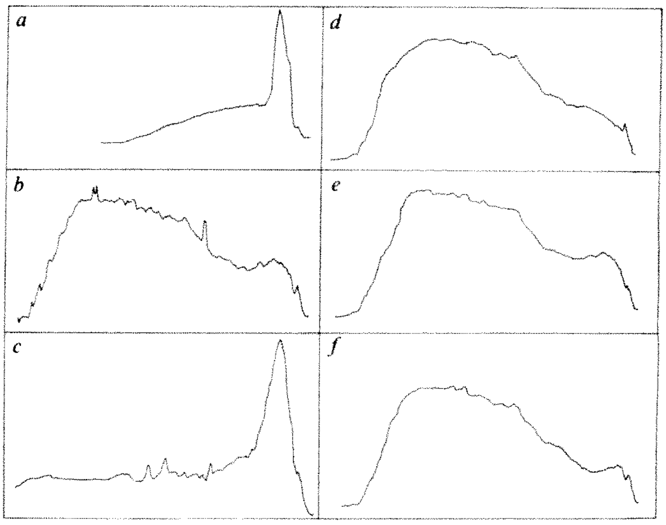

Fig. 1 Alkaline agarose gels of DNA from V79 cells which were: *a*, unirradiated; *b*, exposed to $20\ J\ m^{-2}$ of 254 nm radiation after treatment with PEG and photoreactivating enzyme and killed immediately; *c*, UV irradiated and treated with PEG, photoreactivating enzyme, then 60 min of photoreactivating light; *d*, UV irradiated, treated with PEG, photoreactivating enzyme and kept in the dark for 60 min; *e*, UV irradiated, treated with PEG (but no photoreactivating enzyme) and then 60 min photoreactivating light; *f*, UV irradiated and treated with photoreactivating enzyme (but no PEG) and 60 min photoreactivating light. Cells were collected by scraping into PBS, centrifuging at 5,000 r.p.m. in the SE12 rotor of the Sorvall RC2B for 5 min, resuspension in 0.25 ml buffer A-1 (50 mM Tris, *p*H 8, 10 mM EDTA, 0.4 M NaCl) and addition of 6 μl of freshly prepared 5% sodium lauryl sulphate, followed by 0.25 ml of redistilled phenol equilibrated with buffer A-1. The samples were rotated gently for 30 min, centrifuged, the upper layer removed and ethanol-precipitated. The precipitated DNA was centrifuged for 2 min in a Brinkman Microcentrifuge, drained briefly and resuspended in 20 μl of reaction buffer (30 mM Tris *p*H 8, 40 mM NaCl, 1 mM EDTA). To samples (10 μl) of the mixture was added 15 μg of a *M. luteus* dimer-specific endonuclease preparation[15]. The mixture was incubated at 37 °C for 20 min. A stop mixture (2 μl of 0.5N NaOH, 25% glycerol containing 0.125% bromocresol green) was added, and the mixture applied to a 12 × 14 cm agarose gel containing 0.29 g agarose, 59 mM NaOH and 4 mM Na_3EDTA. The gels were electrophoresed at 16V for 22 h, neutralized in 500 ml 0.1 M Tris, *p*H 8, stained in 0.1 M Tris *p*H 8 containing $0.5\ \mu g\ ml^{-1}$ ethidium bromide. The gels were photographed using Polaroid type 55 positive/negative film, and the negatives scanned using a Joyce–Loebl densitometer.

Table 1 Fate of dimers in UV irradiated V79 cells

	Treatment	% Radioactivity in dimers $[(TT+UT)\times 10^2/\text{total}]$
1	No UV	0.009, 0.005
2	+UV, kill immediately	0.740
3	+UV, 90 min incubation in dark	0.722, 0.682, 0.702, 0.621
4	+UV, 40 min illumination	0.670, 0.650
5	+UV, 90 min illumination	0.562, 0.713
6	No UV, 90 min illumination	0.02

V79 cells were labelled for 24 h in a minimal essential medium containing 10% dialysed fetal calf serum (inactivated at 55 °C for 30 min), and 2 μCi ml^{-1} ^{3}H-thymidine (specific activity 60 mCi mmol^{-1}). Cells were washed with PBS, exposed to 500 J m^{-2} from a germicidal lamp with most of its emission at 254 nm, then killed immediately, kept in the dark or exposed to photoreactivating light from a 100-W incandescent bulb at 20 cm. Cells were collected by scraping into PBS and centrifuging at 15,000 r.p.m. in the Sorvall SE-12 rotor. The DNA was hydrolysed with 88% formic acid, chromatographed on silica gel thin-layer plates in ethyl acetate/H_2O/n-propanol (4 : 2 : 1)[24], sliced and counted in a LKB scintillation counter. Similar determinations for cells exposed to 50 J m^{-2} gave no indication of substantial excision or photoreactivation in the times used in the PEG insertion experiments.

cells treated with insertion mixture (but without photoreactivating enzyme) (trace *e*) or incubation in the light of cells treated with enzyme and photoreactivating light (but no PEG) (trace *f*).

As these experiments showed the apparent monomerization of cellular dimers by exogenous *E. coli* photoreactivating enzyme, it was important to show that the cells did not contain endogenous enzyme which might be mediating the reaction. We thus examined cellular photoreactivation and photoreactivating enzyme in three series of experiments. We first labelled the cells with ^{3}H-thymidine, and collected them without irradiation (Table 1, line 1), exposed them to UV (Table 1, line 2), kept them in the dark (line 3) or exposed them to photoreactivating light (lines 4, 5). Dimer photoreactivation in V79 cells grown in minimal essential medium was not detectable after either high (500 J m^{-2}) or low (50 J m^{-2}) UV exposures. We also examined the loss of UV-endonuclease sensitive sites in V79 cells untreated with insertion mixture or photoreactivating enzyme in experiments similar to those in Fig. 1. Exposure of UV light-irradiated cells to photoreactivating light did not affect the number of endonuclease sensitive sites in the DNA, thus indicating an absence of detectable endogenous photoreactivation. We also tested cell extracts directly for the presence of photoreactivating enzyme activity. No enzyme activity could be detected in standard photoreactivating enzyme assays[18]. We thus conclude that it is likely that the disappearance of dimers seen in Fig. 1 is mediated by *E. coli* photoreactivating enzyme inserted into the cells rather than by endogenous V79 enzyme.

This method for inserting *E. coli* photoreactivating enzyme into mammalian cells extends the range of cells in which photoreactivation of pyrimidine dimers can be examined. Several types of cells are especially suited for these studies. For example, rodent cells, in which excision and post-replication repair have been studied extensively[19], contain low levels of endogenous photoreactivating enzyme and have thus not been amenable to photoreactivation studies. In addition many cell strains derived from patients with xeroderma pigmentosum are deficient in photoreactivating enzyme and cellular photoreactivation[5,20]. Finally, even those mammalian cells which are capable of producing photoreactivating enzyme (presumably *Phr*$^+$) must be grown on suitable medium for expression of the *Phr* gene. The development of this method lifts this restriction and should allow examination of photoreactivation in a variety of media. Insertion of an enzyme which can specifically reverse pyrimidine dimers will allow a determination of the role of dimers and of other photoproducts in the induction of cellular damage.

Two other systems have been developed for insertion of exogenous repair enzymes. Smith and Hanawalt studied the action of the phage T4 endonuclease V in isolated nuclei of human cells[21]. Tanaka *et al.* used Sendai virus to insert the T4 endonuclease into intact human cells[22,23]. They both increased unscheduled DNA synthesis and survival (about a fivefold increase) on addition of Sendai virus plus the endonuclease.

Our attempts to insert *E. coli* photoreactivating enzyme into V79 cells with UV light inactivated Sendai virus were unsuccessful; we thus developed the PEG insertion method [Yarosh (personal communication) has used a similar method for insertion of *M. luteus* UV endonuclease into V79 cells], which has several advantages: (1) PEG is available commercially, and is stable, (2) it is not a potential biohazard and does not yield productive or latent infection of treated cells, and (3) it is gentle to the photoreactivating enzyme, which is inactivated by many reagents. Finally, because the *E. coli* photoreactivating enzyme is larger (monomer molecular weight 35,000; the enzyme also aggregates to form higher multiples) than enzymes inserted by the Sendai method (the molecular weight of the T4 endonuclease is 20,000), it may offer a general method of insertion of enzymes into mammalian cells.

Innocuous biological freezing during warming

W. F. Rall*‡, D. S. Reid† & J. Farrant*

* Clinical Research Centre, Watford Road, Harrow HA1 3UJ, UK
† Unilever Research, Colworth House, Sharnbrook, Bedford
MK44 1LQ, UK

Intracellular freezing during the cooling of living cells is reported to reduce or abolish their recovery on thawing[1]. In microscopical and microprobe studies, low-temperature techniques may induce intracellular ice artefacts[2]. The amount of intracellular ice can be reduced either by selecting a slow cooling procedure that allows extracellular crystallization and cellular dehydration before the intracellular ice forms or by the ultrarapid cooling of very small samples to minimize the nucleation and growth of ice[3]. However, a few reports suggest that in some

conditions intracellular ice may be either innocuous[4] or even sometimes beneficial[5] for the survival of function. We have therefore used here the technique of low-temperature light microscopy to examine the relationship between intracellular freezing and cell injury. We followed the morphological appearance of eight-cell mouse embryos during cooling and warming in medium containing dimethyl sulphoxide (DMSO; 1.5 M) and correlated it with their functional survival after thawing. Unexpectedly, we found that ice formed in the cytoplasm of embryos during slow warming in conditions when it did not form during cooling. Death of embryos, however, did not correlate with the temperature during slow warming at which intracellular ice appeared (−85 °C). The occurrence in some conditions of freezing at these low temperatures during warming has important implications both for the preservation of function of cells and for the preservation of morphology in electron microscopy.

The mouse embryo system was chosen because of the availability of a stringent *in vitro* survival assay (development to expanded blastocyst)[6] and the ease of observing the large blastomeres during cooling and warming on the low-temperature stage of a light microscope[7]. The embryos were cooled slowly (~0.5 °C min^{-1}) to −40 °C and then rapidly to < −150 °C. In these conditions, they exhibit high survival after rapid warming (~500 °C min^{-1}) but are dead after slow warming (<20 °C min^{-1})[5]. Injury following slow warming is believed to be associated with the migratory recrystallization of intracellular ice that formed during rapid cooling[8].

Figure 1 shows the typical microscopical appearance of two eight-cell embryos in DMSO (1.5 M) during cooling and warming. The formation of intracellular ice is usually characterized by the sudden blackening or 'flashing' of the cytoplasm when viewed using phase contrast optics[9]. This blackening is believed to result from the scattering of light by the surfaces of ice crystals and possibly gas bubbles[10]. During the slow cooling of the embryos to −40 °C (Fig. 1*a*–1*f*), extracellular freezing occurred and the blastomeres shrank as reported for other cells[11–13]. During the subsequent rapid cooling to ~ −150 °C (Fig. 1*g*), the appearance of the embryos did not change, indicating the absence of visible intracellular ice. However, when the embryos were then warmed slowly, they 'flashed' (Fig. 1*j*), suggesting the formation of intracellular ice when the temperature reached −85 °C. On continued slow warming, a complex series of phenomena was observed. Changes included: the gradual appearance (−85 to −70 °C; Fig. 1*j*–*l*) and disappearance (−70 to −40 °C; Fig. 1*l*–*q*) of a dark crystalline material outside the zona pellucida and perhaps within the perivitelline space, an abrupt increase in the mobility of this material at −70 °C (not visible in Fig. 1, but discernible in videotape recordings), the sudden appearance of the zona pellucida at −65 °C (Fig. 1*m*), a second darkening of the cytoplasm at −55 °C (Fig. 1*o*) and finally, the disappearance of the dark intracellular material at −40 °C. After thawing, the embryos appeared morphologically abnormal (Fig. 1*r*). When similarly cooled embryos were warmed rapidly (~250 °C min^{-1}) from −120 °C or below, both videotape and visual observations revealed none of these changes in appearance during warming. Furthermore, if slow warming was converted to rapid warming at ~ −75 °C, the second darkening of the embryos was not observed. In both these instances, the embryos were morphologically normal after thawing.

The critical temperature range associated with injury during slow warming was found from parallel survival studies. The embryos were cooled slowly to −40 °C and then rapidly to −196 °C. They were first warmed slowly (~2 °C min^{-1}) to various temperatures and then rapidly (~500 °C min^{-1}) to 20 °C (Fig. 2). The data demonstrate that the embryos survived slow warming providing conversion to rapid warming was done before the temperature reached −70 °C. Slow warming to −60 °C or above resulted in the death of the embryos. Functional injury therefore only occurred if slow warming was continued some 15–20 °C above the temperature (−85 °C) at

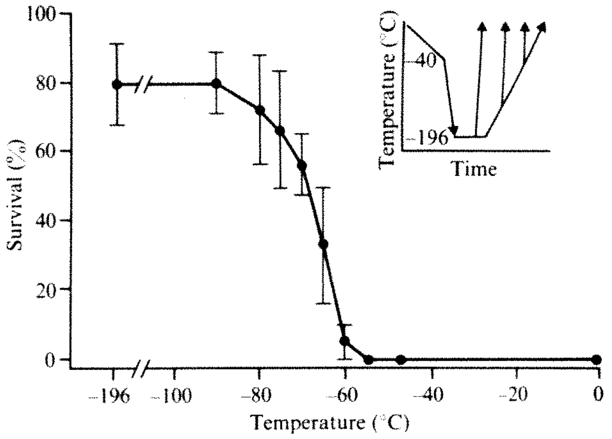

Fig. 1 Microscopical appearance of two eight-cell mouse embryos during cooling and warming. Embryos were flushed from the oviducts of superovulated TO (Crc: TO) or MF1 (Ola: MF1) female mice that had been mated ~64 h earlier with TO males. Embryos were collected and handled as described previously[18]. The embryos were placed into phosphate-buffered saline (PB1)[19] containing DMSO (1.5 M) for at least 20 min at ~20 °C to allow complete permeation of the DMSO[20]. Approximately 10 embryos were then placed into a small drop of the PB1–DMSO solution on a 13-mm diameter coverglass and immediately covered with another coverglass. A hole reinforcer for loose-leaf paper (WEB self-adhesive reinforcements, Westwood Stationery) on one of the coverglasses prevented the embryos from being crushed. The coverglass sandwich was then placed onto the temperature-controlled slide of a low-temperature microscope stage[7]. The appearance of the embryos was recorded on time-lapse videotape and photographed onto Ilford Pan-X film using phase-contrast optics on a Leitz Ortholux II microscope. The embryos were cooled slowly (~0.5 °C min^{-1}) from +4 to −40 °C and photographs *b*–*f* were taken at the indicated temperatures. Photograph *b* shows the extracellular ice front as it passes the embryos. The embryos were then cooled rapidly (~250 °C min^{-1}; photograph *g*). Subsequently, the embryos were warmed rapidly to −120 °C and then slowly (~2 °C min^{-1}) to ambient temperature (photographs *h*–*r*). Scale bar, ~50 μm.

Fig. 2 Survival of eight-cell mouse embryos cooled slowly to −40 °C and then rapidly to −196 °C as a function of the temperature at which slow warming was converted to rapid warming (see insert diagram). Embryos were collected as noted in Fig. 1 legend, and 10–15 embryos were transferred into glass test tubes (10 × 75 mm) which contained 0.1 ml PB1. The embryos were held at ~20 °C and an equal volume of PB1 containing DMSO (3.0 M) was added and mixed (final DMSO concentration 1.5 M). The embryos were held at ~20 °C for 20 min to allow complete permeation of the DMSO[20]. The samples were then placed into a −7 °C bath and 2 min later were nucleated with an ice crystal. After ~5 min, the samples were transferred into an alcohol bath at −7 °C that was cooling at ~0.5 °C min^{-1} (ref. 18). When the temperature of the bath reached −40 °C, the samples were quickly transferred into liquid nitrogen (−196 °C) and held for 15 min to 48 h. The samples were warmed either by direct transfer into a +37 °C water bath (~500 °C min^{-1}) or by transfer into stirred alcohol (300 ml in a 1-l beaker) initially at ~ −110 °C and allowed to warm in air (~2 °C min^{-1}). At different temperatures, samples were removed and warmed rapidly in a +37 °C water bath until the ice disappeared. After thawing the samples were diluted rapidly[5] and the embryos were washed in PB1 and cultured in Brinster's BMOC-3 medium[6]. Survival was measured as a percentage of cultured embryos developing to the expanded blastocyst stage in 48 h. Approximately 90% of the embryos frozen were recovered and cultured. Temperature was measured using copper–constantan thermocouples and a potentiometric recorder. Each data point represents five replicate tubes.

which intracellular ice was first observed to form. We also examined whether the functional injury was reversible, by repeating the experiments described in Fig. 2 legend, except that instead of warming the embryos rapidly from various temperatures during slow warming, they were recooled rapidly from those temperatures into liquid nitrogen and then rewarmed rapidly in a +37 °C water bath. The survival was not significantly different from that in Fig. 2. This suggests that the injury resulting from some event that occurs during slow warming could not be reversed by a return to a lower temperature before rapid warming.

These results indicate that the absence of intracellular freezing during cooling is no guarantee that freezing will not occur within the cells during warming. This finding has important implications for those using low-temperature techniques for preservation of either structure or function. The initial formation of intracellular ice at −85 °C during slow warming clearly did not result in cellular injury, as injury occurred only when slow warming was continued for a further 20 °C (to about −65 °C). Furthermore, the embryos were injured before the second darkening of the cytoplasm at −55 °C and the melting of the intracellular ice at −40 °C. If the three events of flashing at −85 °C, darkening at −55 °C and disappearance of the dark crystalline material in the cytoplasm at −40 °C correspond, respectively, to devitrification (crystallization)[14,15], migratory recrystallization[15] and melting of ice in the cytoplasm, then our data showing injury at ~ −65 °C do not support a correlation of injury with these phase transitions of intracellular ice. This conclusion contradicts previous suggestions of the mechanism by which intracellular ice injures. Mazur has suggested that injury from intracellular ice and its migratory recrystallization is a direct physical consequence of the ice and the effect is on intracellular membranes[8,16]. If this were so, the injury should occur at the same temperature as, or soon after, migratory recrystallization. Farrant has suggested instead that injury results from osmotic forces mediated by the imbalance between the melting of intra- and extracellular ice[17]; with this idea most injury should occur after the intracellular ice melts. Three alternatives may account for the discrepancy between our survival data and the phase changes of intracellular ice. First, an invisible event may occur at −65 °C (for example, recrystallization of ice) that leads to injury. Second, one of the visible changes of intracellular ice (recrystallization at −55 °C) may be the damaging event and become inevitable once slow warming reaches −65 °C. Finally, the presence of intracellular ice may be innocuous and functional injury result from a change in another component of the system.

We thank Dr C. R. Coid for providing research facilities and Miss C. Evans for the photographic processing.

Precursor complement protein (pro-C4) is converted *in vitro* to native C4 by plasmin

Gabriel Goldberger & Harvey R. Colten

Division Cell Biology, Department of Medicine, the Ina Sue Perlmutter Cystic Fibrosis Research Center, Children's Hospital Medical Center and the Department of Pediatrics, Harvard Medical School, Boston, Massachusetts 02115

The fourth component of complement (C4) is a constituent of the classical serum complement pathway, one of the principle effectors of inflammatory reactions. A single chain protein (molecular weight (MW) 200,000), presumed to be the precursor of C4 (pro-C4), was first identified as a product of cell-free translation on polysomes from guinea pig liver homogenate[1]. Pro-C4 has since been detected in human[2,3] and guinea pig[4] plasma and intracellularly in macrophage[5] and liver cultures[1]. Native C4 is composed of three polypeptide chains of unequal size and linked by disulphide bridges—the α, β, and γ chains which have MWs of approximately 95,000, 75,000 and 31,000 respectively (ref. 6). Kinetic studies of C4 biosynthesis in tissue culture, a comparison of peptide maps from tryptic digests[7] and identity of the amino-terminal segments of guinea pig pro-C4 with β chain of guinea pig and human C4 (ref. 8) suggested that pro-C4 was a precursor of C4. However, conversion of pro-C4 to native C4 has not been demonstrated directly. We now report that the addition of plasmin to radiolabelled pro-C4 (in cell lysates of guinea pig macrophages) generated a protein with the characteristic size and subunit structure of native C4, establishing the precursor–product relationship between these proteins. These data also suggest that a plasmin-like enzyme is responsible for post-translational conversion of this procomplement (pro-C4) protein to C4 *in vivo*. Another enzyme, the C1s subunit of the first component of complement, cleaved pro-C4 at a single site, distinct from the plasmin cleavage sites, to generate fragments of approximate MWs 112,000 and 91,000. This experiment indicated that β-α-γ is the sequence of subunits in pro-C4.

A previous study[8], using a microradiosequencing method, showed that the β chain is the amino-terminal segment of pro-C4; the carboxy-terminal segment had not been ascertained. Hence, a preliminary study of pro-C4 structure was required to interpret results of experiments designed to convert the procomplement protein to native C4. Guinea pig macrophage cultures from starch-induced peritoneal exudates were incubated for 5 h in medium containing ^{35}S-methionine. The cell monolayers were then washed extensively and the intracellular radiolabelled protein containing pro-C4 was recovered in the supernatant following 100,000g centrifugation of a 0.5% Triton X-100 lysate of the cells. Culture medium served as the source of radiolabelled native C4.

The C1s subcomponent of the first component of complement is an enzyme that cleaves the amino terminus of α-chain of native C4 at a single site, liberating a fragment of MW 9,000 (C4a). To test whether this enzyme would be of use in deducing the sequence of subunits in the precursor protein, purified C1s was mixed in excess with radiolabelled pro-C4 in cell lysate or with ^{35}S-methionine-labelled native C4 secreted by macrophages in culture. After incubation for 60 min at 37°C the products were subjected to SDS-polyacrylamide gel electrophoresis (Fig. 1). In confirmation of published data[6], C1s treatment of native C4 resulted in alteration of the mobility of α chain (generation of α') due to loss of a 9,000-MW fragment. There was no apparent change in mobility of either β or γ chain. C1s also cleaved pro-C4 at a single site to generate two polypeptides of approximate MWs 112,000 (α'-γ) and 91,000 (β chain + 9,000-MW (9 K) fragment of α chain); no free α' chain

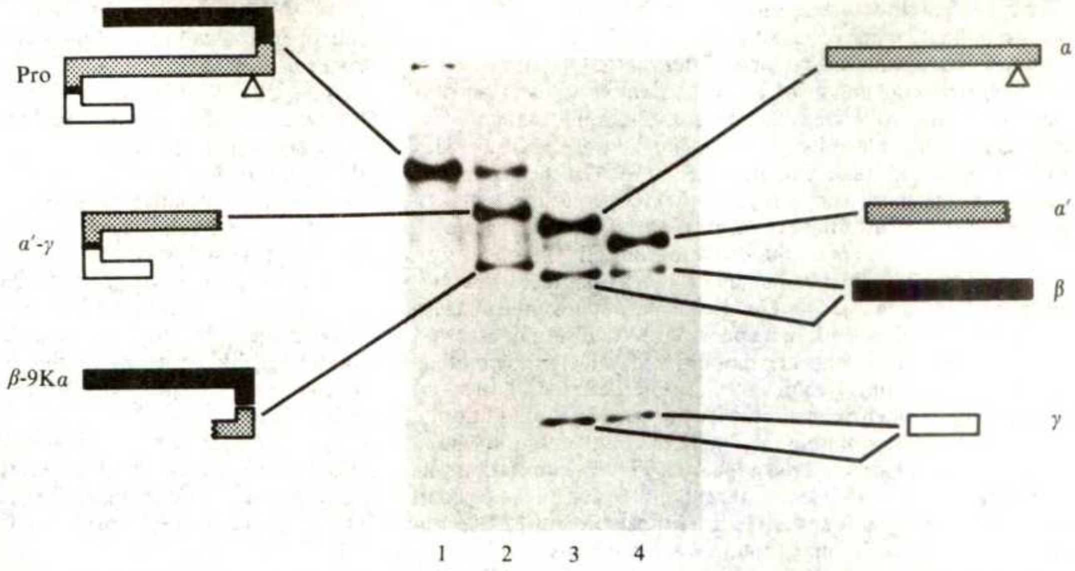

Fig. 1 Cleavage of pro-C4 and native C4 by C1s. Cell lysate (as a source of ^{35}S-methionine-labelled pro-C4) prepared as described in Fig. 3 legend and medium from the same cultures (as a source of radiolabelled native C4) were each mixed with purified C1s (140 μg ml^{-1} final concentration)[12] and the mixtures were incubated at 37 °C for 60 min. Controls consisted of lysate or medium incubated in identical conditions except that C1s was omitted. C4 antigen was isolated by precipitation[9] and the products of C1s action on pro-C4 and C4 were analysed by 1% SDS/9% polyacrylamide gel electrophoresis[13]. Lane 1, pro-C4; lane 2, pro-C4 treated with C1s; lane 3, native C4; lane 4, native C4 treated with C1s. The two fragments generated from pro-C4 by C1 cleavage were stable on prolonged incubation with the C1s enzyme. Their sizes (MWs 112,000 and 91,000) were estimated in a parallel experiment on cylindrical 1% SDS/5.6% polyacrylamide gels as described by Fairbanks *et al.*[14]. Δ, C1s cleavage site.

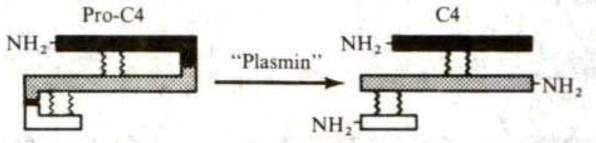

Fig. 2 Model of Pro-C4 with β chain (■) as the amino-terminal segment linked to α chain (▨) followed by γ chain (□) at the carboxy terminus. Conversion of pro-C4 to C4 mediated by plasmin or a plasmin-like enzyme according to data in Fig. 3 legend. The position and number of disulphide bridges are not known.

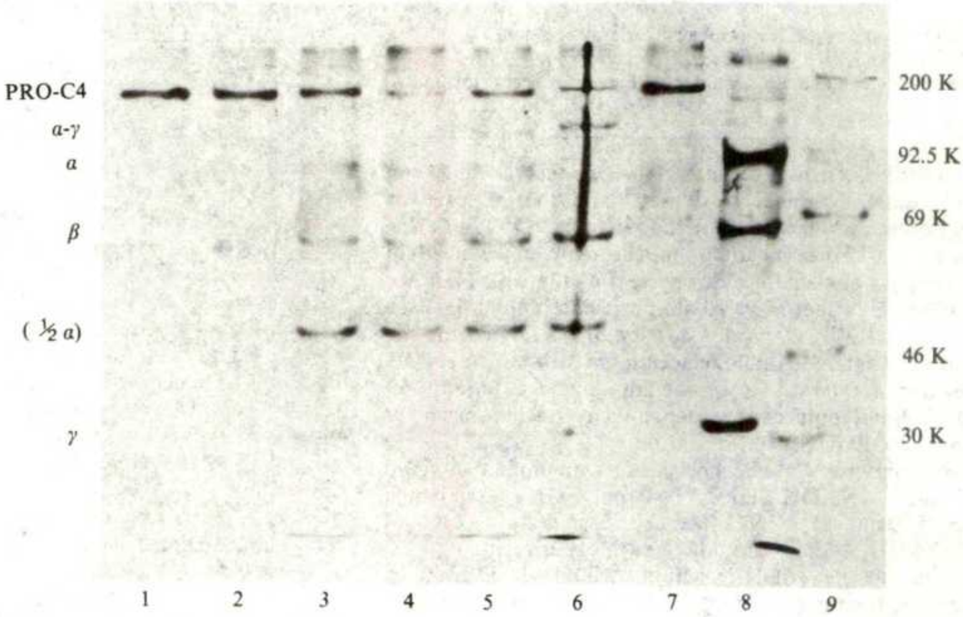

Fig. 3 Kinetics of pro-C4 cleavage by plasmin. Confluent cultures of macrophages from starch-induced peritoneal exudates in Hartley guinea pigs were established by plating 3 × 10^7 cells in 100-mm plastic Petri dishes (Falcon Plastics) with 10 ml Medium 199 containing 10% heated fetal bovine serum (FBS), 50 U ml^{-1} penicillin and 50 μg ml^{-1} streptomycin (P/S). After 2 h incubation at 37 °C in humidified 5% CO_2/95% air atmosphere, the monolayers were washed thrice with Hank's balanced salt solution (HBSS) then fed with 6 ml of supplemented (10% dialysed heated FBS, P/S and glutamine 2 mM) Dulbecco's modified Eagle's medium in which ^{35}S-methionine (>500 Ci mmol^{-1}) 85 μCi ml^{-1} was substituted for the corresponding unlabelled amino acid. Culture medium was removed after 5 h and the cells were washed extensively with HBSS then lysed in 6 ml KCl 100 mM, Tris 50 mM, *p*H 7.5 buffer with 0.5% Triton X − 100. Following one freeze–thaw cycle, the lysate was centrifuged at 100,000 *g* for 2 h at 4 °C and the supernatant stored at −90 °C. The cell lysate (1.7 ml) was mixed with 34 μl plasmin stock solution prepared as described below. An aliquot (300 μl) was immediately removed, mixed with benzamidine (20 mM final concentration) and stored at 0°C. The remainder was incubated at 37 °C and at timed intervals 300-μl aliquots were removed, benzamidine added and the samples stored at 0 °C. Controls consisted of lysate alone stored at 0 °C, and lysate alone incubated at 37 °C for 55 minutes. Sodium EDTA (2 mM final concentration) and a pseudoglobulin fraction of guinea pig serum[9] were added to each sample, then the mixture was centrifuged 10,000 *g* for 5 min at 4 °C. C4 antigen was precipitated from 250 μl of the supernatant according to the method in ref. 9. The precipitates were washed, dried and dissolved in 50 μl of a solution containing 10 mM Tris, 1 mM Na_2EDTA, 1% SDS, 10% glyerol, 60 μg pyronine-y, 4% 2-mercaptoethanol, boiled for 4 min then applied to a 1% SDS/9% polyacrylamide gel and electrophoresed[14]. The gel was stained, fixed and dried and an autoradiograph developed after 2 weeks at −70 °C. Lane 1, lysate untreated; lanes 2–6, lysate treated with plasmin at 37 °C for 0, 5, 10, 20, 55 min, respectively; lane 7, lysate incubated at 37 °C for 55 min in the absence of plasmin; radiolabelled native C4 from medium (see Fig. 1 legend) in lane 8 and MW markers in lane 9. Note the disappearance of pro-C4 following plasmin treatment and appearance of α, β and γ chains of native C4. Note also the 130,000- and 50,000-MW fragments. Plasminogen (2 mg ml^{-1}) purified on lysine Sepharose[15] was activated by incubation with urokinase (Abbot) 10% w/v for 30 min at room temperature. Plasmin activity was measured spectrophotometrically by hydrolysis of chromogenic substrate S-2251 (Ortho Diagnostics); 5 μl of the stock solution liberated 4.7 mM s^{-1}. MWs (K = × 10^3) are given on the right-hand side.

was seen. These data are consistent with the model of pro-C4 shown in Fig. 2 with β chain, the amino-terminal segment, then α chain and γ chain at the carboxy-terminus.

Enzymatic conversion of pro-C4 to native C4 was accomplished in the following experiment. Plasmin (human plasminogen and plasminogen activator) was mixed with radiolabelled cell lysate and incubated at 37 °C. At timed intervals, aliquots were removed and the reaction stopped with benzamidine (20 mM final concentration). C4 antigen was precipitated[9], and the precipitates were washed, dissolved and subjected to SDS-polyacrylamide gel electrophoresis in reducing conditions (Fig. 3). Treatment with plasmin resulted in a loss of pro-C4 protein and the appearance of disulphide-linked peptides with electrophoretic mobilities identical to the mobilities of the α, β and γ chains of unlabelled carrier C4 protein, mixed and co-electrophoresed with the samples. In addition, a protein of approximately 50,000 MW, interpreted to be a fragment of α chain ($1/2\ \alpha$), appeared. This interpretation was supported by the observation that the intensity of the α-band decreased, whereas β and γ chains were stable during plasmin treatment. An additional protein fragment consistent in size (MW 130,000) with an α–γ segment was also generated. The rate of cleavage of pro-C4 by plasmin was a function of enzyme concentration and temperature, and was inhibited by benzamidine (20 mM). Cleavage of pro-C4 was not observed in cell lysates alone, that is, those lacking plasmin, nor in the presence of plasminogen activator (human urokinase) alone. Moreover, the C1r subcomponent of C1, properdin factor D and urinary kallikrein each failed to generate C4 protein from pro-C4. Trypsin extensively degraded pro-C4 to a mixture of small molecular weight peptides.

The possibility that a plasmin-like enzyme converts pro-C4 to C4 *in vivo* is of interest in view of evidence that levels of plasminogen activator in monocytes[10] and macrophages[11] are modulated by a variety of stimuli, thus providing a potential mechanism for post-translational control of complement production.

We thank Drs Brian Tack for supplying plasminogen, Judy Andrews for purified C1s and C1r, Jocelyn Spragg for purified human urinary kallikrein, and A. E. Davis III for purified factor D. This work was supported by USPHS grants AI15033 and HL22487.

A specific enzyme is not necessary for vanadate-induced oxidation of NADH

F. Vyskočil*, J. Teisinger† & Hana Dlouhá*

* Institute of Physiology, Czechoslovak Academy of Sciences,
142 20 Prague 4-Krč, Vídeňská 1083, Czechoslovakia
† Institute of Hygiene and Epidemiology, Prague 2, Czechoslovakia

It has recently been found that ortho- or metavanadate can effectively block $(Na^+ + K^+)$ATPase[1–4] and that it loses its blocking potency when reduced to the vanadyl (VO^{2+}) ion[5]. The question arose whether vanadate could be involved (reduced) in an NAD-linked enzymatic redox system of the cell. Here we have studied the effect of vanadate on malate dehydrogenase (MDH, EC1.1.1.37) catalysed oxidation of NADH during the formation of malate from oxalacetate *in vitro*. The MDH reaction was accelerated by vanadate, but we found that vanadate does not require the presence of any specific enzyme or substrate to mediate NADH oxidation.

Unless otherwise stated, the reaction medium contained 1×10^{-4} mol l^{-1} NADH and 8×10^{-4} mol l^{-1} Na_3VO_4 [stock solution: 500 mg of $NaVO_3$(Merck) dissolved in 1 ml of 1 mol l^{-1} NaOH] at the beginning of each experiment.

The rate of the MDH reaction (MDH 0.033 U ml^{-1}), measured continuously on an Eppendorf photometer at A_{366} as the amount of NADH lost in 0.1 mol l^{-1} Tris-HCl buffer (*p*H 7.2) at 37 °C, was accelerated in the presence of vanadate. The loss of NADH was, however, observed even without MDH, if only vanadate and NADH (and oxalacetate 0.5 mmol l^{-1}) were present in the reaction medium. The vanadate-accelerated MDH reaction (loss of 4.14 μmol of NADH per min) is thus the result of the sum of the MDH reaction (loss of 1.75 μmol of NADH per min) plus the vanadate–NADH (loss of 2.29 μmol of NADH per min). Vanadate can thus induce the oxidation of NADH (probably by accepting electrons itself), and this process does not require any further enzymatic support. According to our preliminary observations in the UV spectrophotometer, vanadate immediately forms a complex with NADH, within which the NADH reduction subsequently proceeds. This redox system might be masked in biochemical experiments in which buffers with EDTA (or biological samples containing this

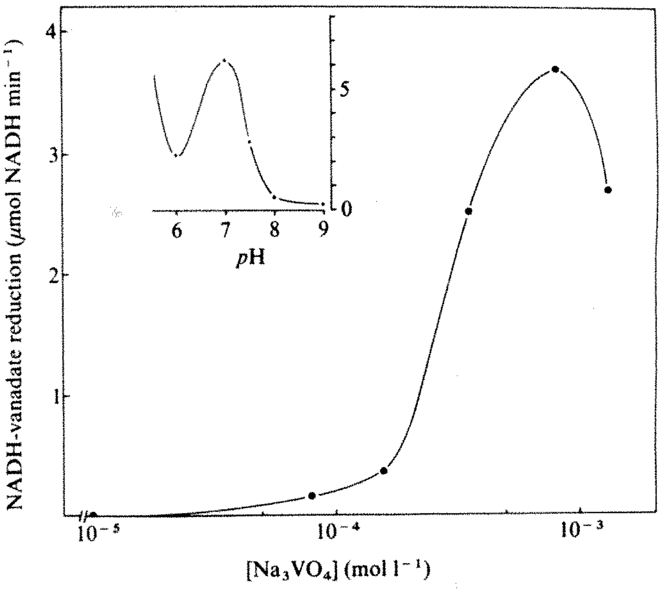

Fig. 1 Effect of vanadate on NADH oxidation in 0.1 mol l^{-1} phosphate buffer (*p*H 7.3) at 37 °C. Abscissa, concentration of vanadate [Na_3VO_4] in mol l^{-1}. Ordinate, the rate of NADH–vanadate reduction expressed as loss of NADH in μmol min^{-1} (see Erdmann *et al.*[7], Fig. 1). Inset, *p*H dependence of NADH loss (in μmol NADH per min, ordinate) in 0.1 mol l^{-1} phosphate buffer at 37 °C. Concentrations of vanadate and NADH at the beginning of experiments were 8×10^{-4} and 1×10^{4} mol l^{-1}, respectively. All results presented here are the means of 5–10 experiments. The s.e.m. values were always smaller than 5% of the mean and are therefore not indicated.

0028-0836/80/310516—02$01.00

Table 1 The rate of NADH oxidation in the presence of 8×10^{-4} mol l^{-1} vanadate in different reaction media

	mol l^{-1}	T(°C)	pH	−ΔNADH
Na-phosphate	0.1	17	7.3	2.18
Na-phosphate	0.1	27	7.3	2.41
Na-phosphate	0.1	37	7.3	3.84
Na-phosphate	0.1	37	7.0	6.15
Tris-HCl	0.1	37	7.2	5.20
HEPES-NaOH	0.01	37	7.0	1.70
Liley's solution	*	37	7.3	0.92
Histidine–NaOH	0.01	37	7.1	0.09
Imidazole-HCl	0.01	37	7.0	0.00

The rate of NADH oxidation is expressed as the loss of NADH in μmol min^{-1}, −ΔNADH. The concentration of NADH at the beginning of experiments was 10^{-4} mol l^{-1}.

The composition of Liley's solution[9] was (mol l^{-1}): Na^+ 149.8; K^+ 5.0; Ca^{2+} 2.0; Mg^{2+} 1.0; Cl^- 148.0; HCO_3^- 12.0; $H_2PO_4^-$ 1.0; glucose 11.0.

chelating compound) are used; in the presence of 1×10^{-3} mol l^{-1} EDTA no oxidation of NADH was observed, probably because inactive complexes are formed with vanadate[6].

A recent report[7] described the vanadate–NADH reductase activity of cardiac cell membranes. Because these authors claimed that there was no vanadate-induced NADH oxidation unless membrane proteins were present, we looked for the probable sources of this discrepancy. The only difference between our experiments and those of Erdmann *et al.*[7] was the buffer used in the reaction medium. When we started the vanadate–NADH reaction in a 0.01 mol l^{-1} imidazole-HCl buffer[7], we also found no oxidation of NADH. Contrary to the findings of Erdmann *et al.*[7], we observed no vanadate-dependent oxidation of NADH in the presence of membrane fractions isolated from rat and golden hamster heart[8] and other tissues (skeletal muscle, brain and liver). Subsequently, we checked several other buffers used for biochemical experiments (Table 1) and Liley's extracellular medium[9]. With the exception of the imidazole and histidine buffer, the vanadate–NADH reaction proceeded in all media.

The vanadate–NADH reaction in Tris-HCl medium was slowed to 50% by either 2.5 mmol l^{-1} Ca^{2+} or 20 mmol l^{-1} Mg^{2+}. The presence of Ca^{2+} and Mg^{2+} might therefore explain the rather slow rate of NADH oxidation in Liley's medium. The reaction is dependent on the concentration, pH (Fig. 1) and temperature (Table 1).

Similar results were obtained in the NADPH–vanadate reaction medium. Thus, 2.95 μmol NADPH was oxidized within 1 min in the presence of 8×10^{-4} mol l^{-1} vanadate and 7×10^{-5} mol l^{-1} NADPH at 37 °C in the Tris-HCl buffer.

Further examples can be presented concerning the more generalized role of vanadate in living redox systems. Vanadate–NADPH reduction was accelerated by 80% after the addition of 1 μmol l^{-1} β-hydroxy-β-methyl-glutaryl-CoA (HMGCoA). However, it is not clear whether the reduction of HMGCoA to mevalonate is triggered in this particular case by vanadate in the absence of hydroxylmethylglutaryl CoA reductase or whether HMGCoA only accelerates the transfer of electrons from NADH to vanadate within the complex. Whatever the explanation, this effect of vanadate might be of particular interest because the HMGCoA reductase is generally considered to be the rate determining enzyme for the conversion of acetate to cholesterol[10].

Visualization of the structural polarity of microtubules

Steven R. Heidemann* & **J. Richard McIntosh†**

* Department of Physiology, Michigan State University, East Lansing, Michigan 48824

Microtubules (MTs) are intrinsically polar fibres[1–8]. Many models for the mechanism of MT-mediated transport and mitosis postulate an important role for MT polarity[7,9–12] because a symmetric fibre could not generate force in one direction along its surface. The lack of a convenient method to determine the polar orientation of cellular MTs has hindered experimental testing of these ideas. We report here a convenient technique for visualizing MT polarity based on conditions for tubulin assembly *in vitro* whereby MT elongation occurs with the associated formation of hooked, protofilament appendages on the MT wall (see Fig. 1). There is polarity information in such junctions between MT walls[13–15]; our method reveals the polarity of the cellular MT by the handedness of the hooked appendage as seen in cross-section (Fig. 1).

Microtubule protein (MTP) was prepared from porcine brain by the method of Shelanski *et al.*[16] After three cycles of polymerization, the protein was resuspended in 0.5 M PIPES pH 6.9, 2.5% dimethyl sulphoxide, 1 mM EDTA, 1 mM $MgCl_2$, and 1 mM GTP (hereafter called polymerization buffer (PB)) at 0 °C and spun at 250,000g for 3 h. The polymerization of MTP in PB is similar in its magnesium and GTP requirement and in its cold, calcium and colchicine lability to that which occurs in other polymerization buffers[17]. MTP will assemble to the same extent in PB in the presence of a strong detergent mixture, 1% Triton X-165, 0.5% deoxycholate, 0.2% SDS. MTP assembly in PB also shows the biased polar growth characteristic of other *in vitro* assembly conditions[5,7,18]. One end of isolated *Tetrahymena* ciliary axonemes elongated about twice as fast as the other at the protein concentrations tested. Elongation at each end of the axoneme was about three times as fast as growth at the comparable end in 0.1 M PIPES buffer.

The polymer initiated *de novo* in PB consists primarily of ribbons of laterally associated protofilaments, as previously reported for similar conditions[14,15], not true MTs. However, when true MTs nucleate the polymerization, the elongated polymer usually has an evident lumen, and ribbons of protofilaments join the MT wall, forming hooked appendages (Fig. 1). We have examined such polymers to see if one handedness of hook predominates by nucleating MT growth from basal bodies. The MTs of the basal body are known to be oriented with the fast growing end of their MTs pointing away from the cell[6]. When lysed and deciliated *Tetrahymena* were used to nucleate the assembly of MTP in PB, polymerization occurred largely as elongation from the basal bodies (Fig. 2a). Pellicles in MTP fixed before polymerization was initiated showed no MT growth (Fig. 2b). After polymerization, the organized geometry of basal bodies in the pellicle allowed us to observe the elongated polymers in known orientations with respect to the basal bodies that initiated them (Fig. 2c). We found that about 95% of the newly grown MTs had the hook-shaped appendages. Figure 2d is a composite of several such images as seen looking toward the basal body from outside the pellicle. Figure 2e shows MTs growing inward as seen from the basal body. We confirmed both in longitudinal sections and by negative staining that the hooks are protofilament sheets which make a junction with the MT wall. The cross-section images demonstrate that when the elongated MT is viewed from its fast growing end or '+end' towards its slow growing end or '−end'(ref. 8) the hooks are commonly right handed. On polymers growing outward from the basal body (those initiated at a fast end) we counted 562 MTs with right-handed hooks and 62 with left-handed hooks when viewed from +end to −end. On

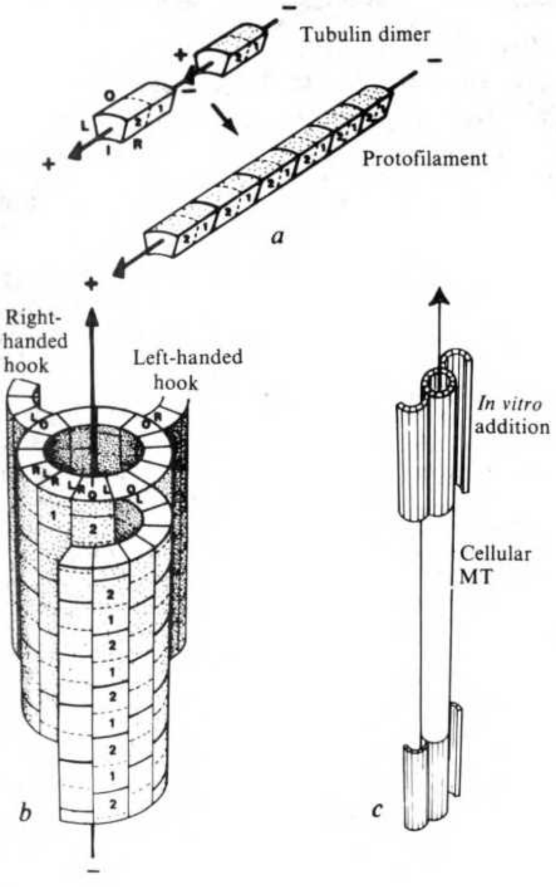

Fig. 1 Different associations of MTP. The tubulin dimer is pictured as having six dissimilar surfaces. + and − correspond to the distal and proximal ends, respectively, of a flagellar MT[22]. I and O are the surfaces which would be on the inside and outside of a normal MT, L and R are the two surfaces which associate laterally in the wall of a normal MT. The numbers 1 and 2 denote the different subunits of the tubulin dimer. The intradimer bonds are suggested by dashed line, interdimer bonds by solid ones. *a*, The head-to-tail association of dimers to form protofilaments. *b*, Protofilaments have associated laterally to form MT wall (L–R interactions) or in two alternative geometries to form junctions between MT walls, which also occur naturally[23,24]. Wall junctions and concomitant hooks of two possible hands are made by associating either the R or L surface of a protofilament with the O surface. A tacit assumption is made that the protofilament polarity of the hook wall is the same as that of the tubule itself. *c*, In our conditions neurotubulin adds *in vitro* to a cellular MT to form predominantly right-handed hooked MTs. The polarity orientation of a MT end can be determined from the observed hook-handedness of newly grown MTs.

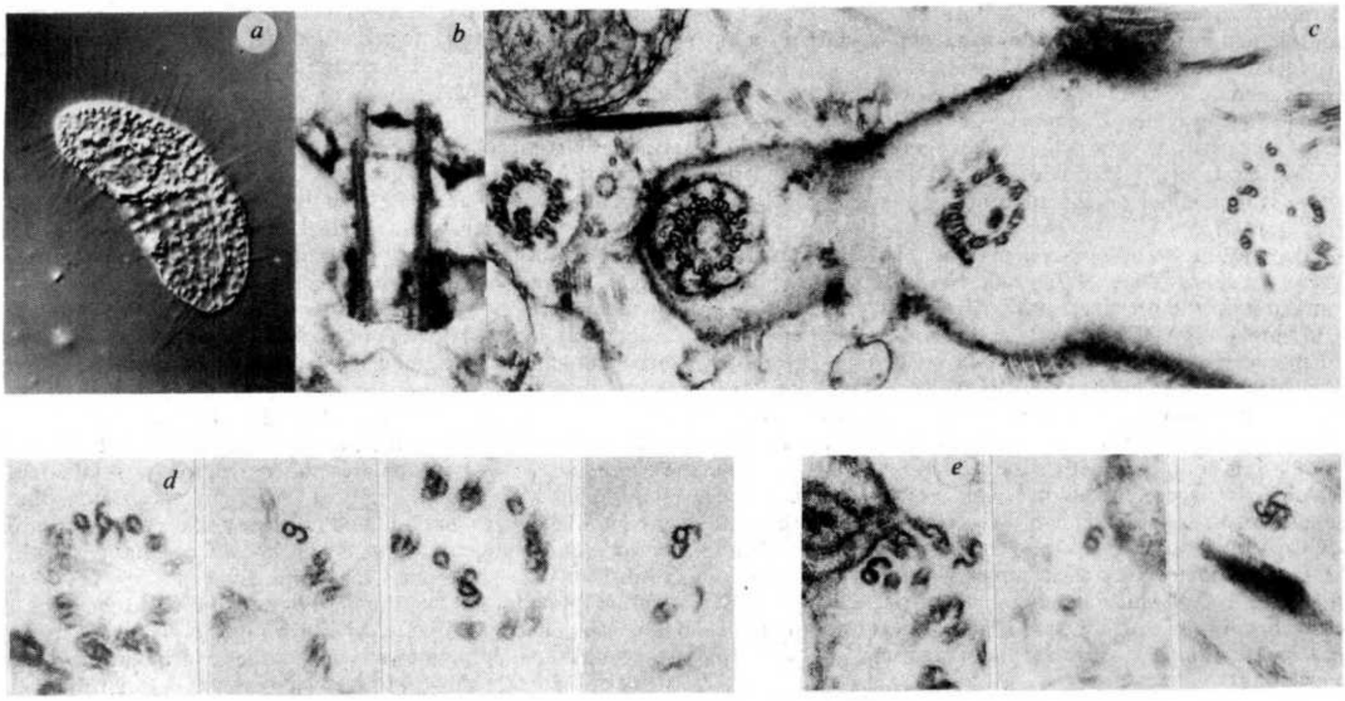

Fig. 2 *Tetrahymena* pellicles were used to nucleate growth of 1 mg ml^{-1} microtubule protein in PB at 37 °C for 6 min, then fixed by addition of an equal volume of 2% glutaraldehyde in 0.1 M PIPES. Fixed pellicles were allowed to settle onto polylysine-coated slides and were then treated with 0.2% tannic acid, rinsed in phosphate-buffered saline, post-fixed in $\frac{1}{2}$% OsO_4 for 2 min, dehydrated in 2-methoxyethanol and flat embedded in Epon. Individual pellicles were excised, serially sectioned and stained with uranyl acetate and lead citrate. Microscopy was performed on a Phillips 300 equipped with a goniometer stage to facilitate orientation of the tubules. *a* Is a Nomarski image of MT polymerization from such a pellicle after 6 min at 37 °C, ×600. *b* Was fixed at 0 °C (no growth), ×55,000. *c* Is 6 min of growth. The orientation of the growing MTs may be deduced from pellicle geometry, ×55,000. *d* Is a composite of MT images seen looking from the outside of the pellicle towards the basal body. *e* Shows MTs growing inward from the basal body; *d* and *e*, ×92,000.

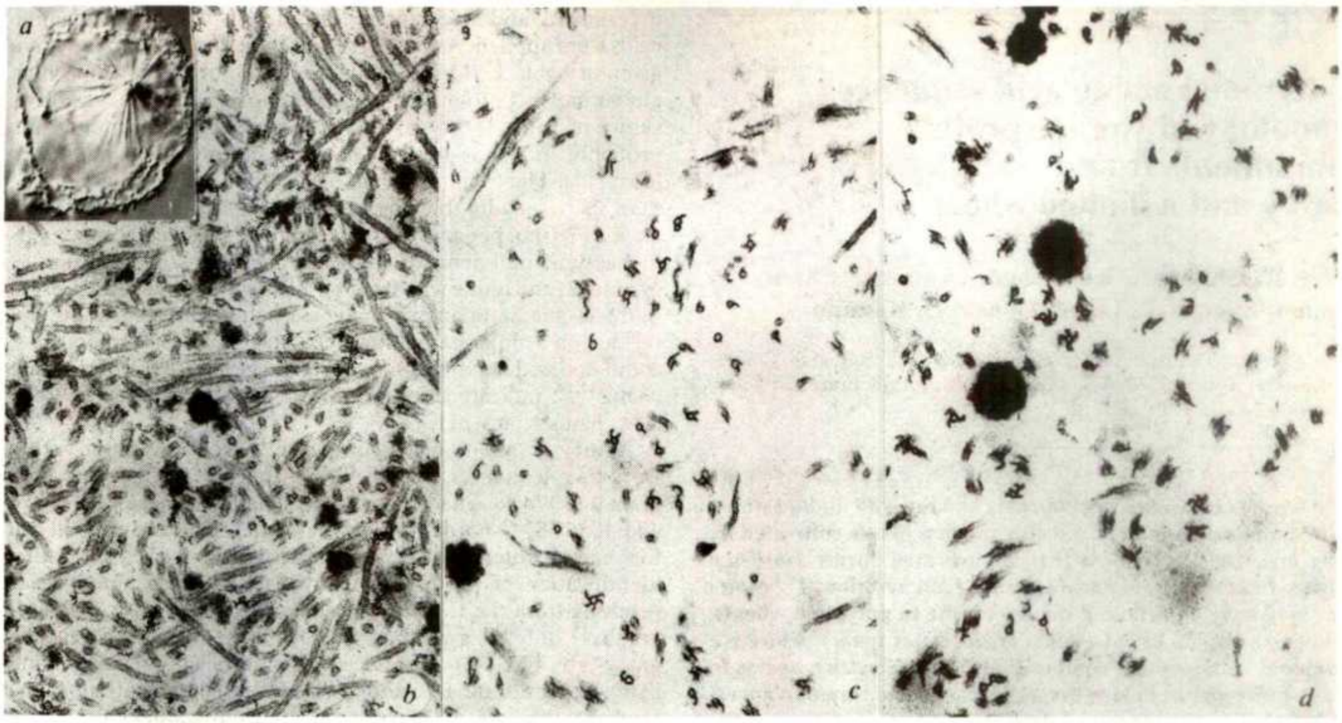

Fig. 3 Microtubule polarity in the mitotic aster of the HeLa cell. *a*, Nomarski image of a metaphase-arrested HeLa cell lysed in detergent-containing PB with 2 mg ml^{-1} MTP, ×750. *b*, An electron micrograph from a section approximately at the centre of an aster. Note that MTs are generally of normal morphology. *c*, The periphery of an aster in a section 'before' the aster centre. Note that most MTs have right-handed hook appendages. *d*, The periphery of an aster in a section 'beyond' the aster centre. The hooks are now left handed; however, the apparent observation point for these hooks is now proximal to the centre, in contrast to the distal vantage point of *c*; *b*, *c* and *d*, ×40,000.

MTs growing inward from the basal bodies, viewed from the same direction, we found 135 MTs with right-handed hooks and 25 MTs with left-handed hooks. Eight MTs displayed hooks of both handedness.

We next studied the polarity of mitotic MTs by using a remnant of the mitotic apparatus from HeLa cells. Hela cells stably blocked in metaphase with 0.04 μg ml $^{-1}$ of the microtubule poison nocodazole[19] contained large numbers of MTs with typical mitotic organization[20]. Lysis of nocodazole-poisoned cells in PB containing the detergent mixture described above preserved metaphase aster structures approximately 5 μm in diameter surrounded by a thin, fibrous cell remnant. These asters consisted of normal MTs, presumably those which existed in the drug-poisoned cell. Inclusion of 2 mg ml^{-1} MTP in the PB lysis buffer produced asters up to 20 μm in diameter (Fig. 3*a*). In these large asters, 85% of the MTs were normal within a 5 μm radius of the aster centre (Fig. 3*b*). In the area beyond a 5 μm radius, 80% of the MTs displayed the hooked appendages (Fig. 3*c*,*d*). Our interpretation is that exogenous brain tubulin added to the distal ends of pre-existing HeLa MTs to form hooked MTs. Serial sections from four such asters reveal predominately right-handed hooks when viewed looking toward the aster centre: 1752 MTs showed only right-handed hooks, 121 MTs bore only left-handed hooks and 66 MTs displayed hooks of both handedness.

Close to 90% of all hooks on neurotubules elongated from both basal body and astral MTs displayed a consistent handedness relative to the MT on which they formed. As the same predominant handedness of hook was seen on MTs growing in both directions from the basal body, we conclude that our method reveals the molecular polarity of a MT, not its direction of growth. For the same reason, we infer that the MTs which grew from the basal body have the same polarity as the A subfibre in the basal body itself. Hook handedness on the elongated MT therefore reflects the polarity of the MT which nucleated elongation. The preponderance of right-handed hooks on MTs extending from both asters and basal bodies indicates that the astral MTs have the same polarity relative to the mitotic centre as do the outer nine flagellar MTs relative to the basal body. That is, the fast or +end of the HeLa MT is distal to the mitotic centre. This is the same polarity as that of neurotubules initiated from the mitotic centres of lysed CHO cells[21,22]. This agreement supports our assertion that hook handedness is a valid marker of MT polarity. The observed bias toward right-handed hooks on MTs grown from both basal bodies and asters was strong (about 9:1) but not complete. Further, MTs with hooks of both hands were occasionally observed, so we conclude that left-handed wall junctions are not excluded. Our method reveals and uses a biased formation of right-handed wall junctions to visualize the molecular polarity of the MT.

This investigation was supported by Biomedical Research Support funds from the Colleges of Osteopathic Medicine and Natural Science, Michigan State University, and grants CD 8D from the American Cancer Society and PCM-77-14796 from the NSF to J.R.M. S.R.H. would like to thank the Department of Microbiology, M.S.U. for the use of their electron microscope.

N-terminal amino acid sequence homology of storage protein components from barley and a diploid wheat

Peter R. Shewry*, Jean-Claude Autran†, Charles C. Nimmo, Ellen J.-L. Lew & Donald D. Kasarda

Food Proteins Research Unit, Western Regional Research Center, Agricultural Research, SEA, US Department of Agriculture, Berkeley, California 94710

Wild barley (*Hordeum spontaneum*) and the wild diploid wheat *Triticum boeoticum* were possibly the first plants cultivated by early man[1], giving rise to the domesticated forms *Hordeum vulgare L.* and *Triticum monococcum L.* In addition, *T. boeoticum* may have contributed the A genome to polyploid wheats, including common bread wheat (*Triticum aestivum*)[2] which is a hexaploid with genome composition ABD. *Hordeum* seems to be the older genus, having diverged from some common ancestor before the divergence of *Triticum* and other genera of the subtribe Triticinae[3]. Prolamins constitute the major storage protein fraction of both barley and wheat; they are located in the endosperm of the caryopsis and are soluble in alcohol–water solutions[4]. Barley and wheat prolamins (hordeins and gliadins, respectively) contain large amounts of glutamine and proline, which together make up 50–75 mol per cent of total amino acids[4,5]. The hordeins and gliadins are complex mixtures of components[6–8] that seem to be encoded by clusters of duplicated genes that have diverged to produce many distinguishable protein components. Despite the complexity of the gliadin mixture, the components retain considerable homology in their N-terminal region[9,10] and this has been reported for zeins, the prolamins of maize (*Zea mays*)[11], as well. Here, we report that a purified C-hordein component from barley is homologous in amino acid sequence with a purified ω-gliadin component from *T. monococcum* at 23 of 27 residues at the N-terminus. This result is in accord with the close relationship between the two species and indicates that, despite the propensity of prolamin genes to tolerate mutations, a significant portion of their sequences can be conserved over a period of time, which, although not accurately known, probably amounts to millions of years.

Prolamins were extracted from barley (*H. vulgare* Julia) and *T. monococcum* (from the University of Manitoba) as described previously[10,12]. The C-hordein component was obtained by ion exchange chromatography of the hordein mixture on CM-cellulose followed by gel filtration on Sephacryl S–300 (ref. 12). The ω-gliadin component from *T. monococcum* was obtained by ion exchange chromatography of the gliadin mixture on CM-cellulose according to the procedure of Booth and Ewart[13] except that the gradient ranged linearly from 5 to 43 mM in sodium acetate; this component was not purified further. Electrophoretic patterns of the purified components in aluminium lactate buffer, pH 3.2, where separation is based on net charge, are compared with those of the prolamin mixtures in Fig. 1. We estimated molecular weights of 57,000 for the C-hordein and 44,000 for the ω-gliadin by SDS polyacrylamide gel electrophoresis[6].

Amino acid analyses were carried out on a Durrum analyser, model D–500. Hydrolyses were for 24 h, tryptophan was not determined, and no corrections for destruction of labile amino acids were applied. Averaged results from duplicate analyses are given in Table 1. Both components were notable for their high glutamine and proline content (although glutamic acid only is shown in Table 1, this amino acid is present in C-hordein[12] and probably in the ω-gliadin[14] almost entirely in its amidated form[12,14]). The C-hordein had more proline and less glutamine than the ω-gliadin, but the sum of these two amino acids was close to 70 mol per cent for both components. Both components had about 9 mol per cent phenylalanine, only trace amounts of cystine/2, and lysine was absent from the C-hordein and present in the ω-gliadin in an amount corresponding to only about 0.5 residue on a molar basis. Low percentages of basic amino acids, combined with equivalent low percentages of free carboxyl side chains[12,14], indicate that these proteins will have few charged side chains at any pH.

Automatic amino acid sequencing[15] was carried out with a Beckman sequencer, model 890B, and DMAA peptide program 111374 (ω-gliadin) or 0.1 M Quadrol programs 011576 and 121178 (C-hordein). Duplicate analyses were carried out for each protein. In the first analysis of the ω-gliadin, identification of the phenylthiohydantoin (PTH) amino acids resulting from the Edman degradation[15] was by gas chromatography[16] only; this method was supplemented in the second analysis by TLC on polyamide sheets[17] and silica gel plates[18] and by hydrolysis to the free amino acid followed by analysis on the Durrum analyser. PTH amino acids from sequencing of the C-hordein were identified by HPLC[19], which clearly resolved and quantified all the PTH amino acids found in the first 28 cycles. The N-terminal sequences obtained are compared in Fig. 2. Initial yields in sequencing ranged from 50 to 76% of molar

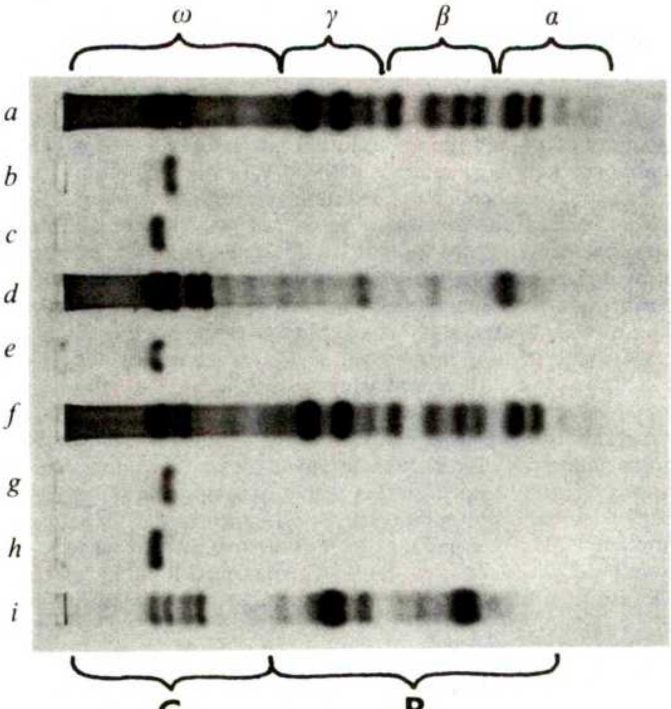

Fig. 1 Polyacrylamide gel electrophoresis[27] of purified protein components and the whole prolamin mixtures from which they were prepared, aluminium lactate buffer, pH 3.2, 3 M urea, migration from left (+) to right (−): *a*, prolamin mixture from *T. monococcum*; *b*, purified ω-gliadin from *T. monococcum*; *c*, purified C-hordein; *d*, prolamin mixture from barley (var. Julia); *e*, same as *c*; *f*, same as *a*; *g*, same as *b*; *h*, same as *c*; *i*, prolamin mixture from barley (Julia), but treated with 2% 2-mercaptoethanol to dissociate B-hordeins. The α-, β-, γ- and ω-regions (top) correspond to the usual assignments of electrophoretic mobilities for gliadin patterns of common wheats[5] and the B- and C-regions (bottom) correspond to the hordein patterns.

Fig. 2 N-terminal amino acid sequences of the ω-gliadin component from *T. monococcum* (ω) and the C-hordein component from barley (C). Sequences are ordered from the first arginine residue to emphasize homology. Glycine was a minor residue at cycle 1 in the sequence of the ω-gliadin. Positions where the ω-gliadin and C-hordein sequences differ are marked.

amounts applied. The highest yield of 76% for one of the C-hordein analyses indicates there was no significant N-terminal blocking.

No important minor residues were noted in sequencing the C-hordein, but three amino acids were identified in the first cycle of the ω-gliadin sequence and two amino acids at each subsequent cycle. Alanine was the major residue at cycle 1 in the ω-gliadin, but glycine and arginine were clearly identified; in subsequent cycles it became clear that the second sequence appearing at about half the level of the major sequence was the same as that of the major sequence displaced by one cycle. It evidently resulted from a protein component without the terminal alanine (or glycine) residue. Electrophoresis of the purified ω-gliadin did not show any minor components in sufficient amount to account for the second sequence; however, it is unlikely that a component differing by only one neutral amino acid would be resolved. The extra residue could mean that at least two genes code for the proteins in our preparation, but post-translational modifications might modify a single component in such a way as to produce the 2:1 ratio of components we observed.

Comparison of the amino acid sequences of our two components (Fig. 2) shows that they differ only at four positions if we do not consider the N-terminal alanine residue that is present in part of the ω–gliadin preparation. This demonstrates a close relationship between *H. vulgare* and *T. monococcum*. No fossil evidence provides a measure of the time since divergence of *Hordeum* and *Triticum*. If we assume for purposes of speculation, however, that the rate of evolution of the N-terminal regions of our proteins is equivalent to that of one of the fastest evolving peptide systems characterized so far, the fibrinopeptides (9.0 amino acid substitutions per site per 10^9 yr)[20], then the time since divergence of our two species would be 16 Myr.

Table 1 Amino acid compositions (mol%) of the ω-gliadin protein from *T. monococcum* and the C-hordein protein from barley (var. Julia)

	ω-Gliadin	*C*-hordein

Cys/2	Trace	Trace

The similar sequences we obtained for our C-hordein and our ω-gliadin from *T. monococcum* show little homology with any other N-terminal sequences reported for α-, β- or γ-gliadins of common wheat[9,10,21,22], rye prolamins[13] or maize prolamins[11]. Our sequence is the first reported, however, for any ω-gliadin component. Autran *et al.*[10] did not note evidence of our ω-gliadin sequence in sequencing of the whole prolamin mixture from the same accession of *T. monococcum*, but this is not surprising as ω-gliadins probably constitute less than 10% of the total mixture. Our C-hordein sequence is closely similar to sequences recently obtained for the total hordein mixture[23], the C-hordein mixture[24] and a partially purified C-hordein component[25].

In common bread wheat, which is hexaploid (genomes A, B and D), gliadin proteins are encoded by genes located on homoeologous (partially homologous, but non-pairing in the polyploid) chromosomes 1 and 6 of each genome[7,26–28]. Shepherd[29] has suggested that all gliadin genes were located originally on one chromosome and that translocation of part of this chromosome to another gave rise to the common ancestor that, in turn, differentiated into the progenitors of the common wheat genomes A, B and D. This common ancestor must have already differentiated from the line that gave rise to *Hordeum* as all the prolamin genes of barley are located on chromosome 5 with the B-hordeins and C-hordeins being coded by two separate, but linked, loci[30]. Our results suggest that the C-hordein locus of barley and the ω-gliadin loci located on homoeologous chromosomes of group 1 in common wheat are homologous. It is also possible that the B-hordein locus is homologous with the gliadin loci coding for α-, β- and γ-gliadins that are located on homoeologous chromosomes of group 6 in common wheat but this is more difficult to establish as B-hordein is blocked at the N-terminus[12,25].

We thank A. Noma for amino acid analyses, B. J. Miflin for barley samples, and B. L. Jones for the sample of *T. monococcum*. P. R. Shewry and J.-C. Autran are visiting scientists in receipt of NATO postdoctoral research fellowships. Ferredoxins are iron–sulphur proteins with either one or two [4Fe-4S] clusters or one [2Fe-2S] cluster and they function as electron carriers in diverse metabolic systems. Extensive comparative studies on the primary structures of ferredoxins with low oxidation–reduction potentials from a wide variety of organisms have provided information on the structure–function and evolutionary relationships of these proteins[1,2]. In addition, the three-dimensional structure of *Peptococcus aerogenes* 2[4Fe-4S] ferredoxin has been elucidated[3]. However, nothing is known about the three-dimensional structure of [2Fe-2S] ferredoxins such as those of chloroplasts. Here we report the three-dimensional structure of a [2Fe-2S] ferredoxin of *Spirulina platensis*, a blue-green alga, determined by X-ray crystallography at 2.5 Å resolution, and discuss the characteristic features of the molecule in relation to the molecular evolution of ferredoxins of this class.

We will give only a brief description of our study, because full details of the analytical procedures and crystal structure of ferredoxin will be reported elsewhere. The crystals were orthorhombic with a space group C222$_1$ of $a = 62.32$, $b = 28.51$, $c = 108.08$ Å and $Z = 8$. Intensity data, including both reflections of each Friedel pair, were collected for native and uranium derivative crystals on a Rigaku four-circle diffractometer with Ni-filtered CuKα radiation by an ω scan procedure. After correction for absorption[4] and radiation damage, the intensities of equivalent reflections were averaged. The heavy-atom parameters[5] were refined by the F_{HLE} method[6] with empirically determined values of the real/imaginary scattering ratio to give an R value ($R = \sum |F_{\mathrm{HLE}} - f_{\mathrm{H}}| / \sum |F_{\mathrm{HLE}}|$) of 0.398 for 1,956 reflections (55% of total reflections). The best phase angle was calculated by the single isomorphous replacement method[7] coupled with the anomalous dispersion method[8], where the anomalous dispersion effect of the two iron atoms was taken into account. The mean figure of merit at 2.5 Å resolution was 0.58 for 2,182 reflections (61% of total reflections). A Kendrew-type skeletal model was built up using a Richards box[9] on the basis of the best electron density map. The molecular structure is shown in Fig. 1.

The sulphur atoms of Cys 41 and Cys 46 coordinate to one iron atom, and those of Cys 49 and Cys 79 to the other iron atom[5]. The coordination geometry around each iron atom is tetrahedral, judging from the electron density distribution around the atoms. The cluster is located near the molecular surface and is mainly surrounded by hydrophobic residues, leaving only one side, the sulphur atoms of Cys 41 and Cys 46, exposed to the solvent. In *P. aerogenes* ferredoxin and *Chromatium* HiPIP, electron transfer was suggested to be achieved through aromatic side chains in close contact with the [4Fe-4S] cluster[3,10]. However, in *S. platensis* ferredoxin there are no invariant aromatic side chains in close contact with the [2Fe-2S] cluster. An alternative possibility is that electron transfer may occur via the orbitals of cysteinyl sulphur atoms, as these residues are directly bonded to the cluster and two of them are located outside the molecule, as described above. Comparison of the amino acid sequences of various chloroplast-type ferredoxins[2] shows that several ferredoxins, particularly those of higher plants, have deletions at positions 10 and 14 and, in this case, proline at position 11. The segment of residues 9–14 in *S. platensis* ferredoxin without the two deletions corresponds to the loop at the end of the antiparallel β-sheet. The overall structure of this region is probably very similar in the two types of ferredoxin, because the segment in ferredoxin without the two residues may take a 3_{10} turn by forming a hydrogen bond between the CO of residue 9 and NH of residue 13. In other words, the change in chain length of this region merely shifts the nature of turn without causing any major structural variation.

Figure 2 shows variations in the 26-amino acid sequence of chloroplast-type ferredoxins[2]. The substitution frequencies of amino acids among 26 chloroplast-type ferredoxins are plotted against the distances between each α-carbon atom and the cluster, and Fig. 3 demonstrates that the carbon atoms distant from the cluster have higher substitution frequencies.

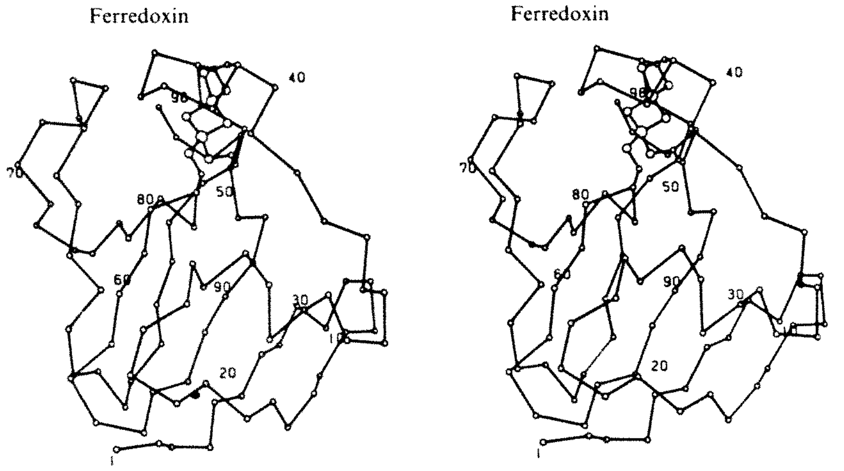

Fig. 1 The polypeptide chain of *S. platensis* ferredoxin shown by stereo pair drawing. The cluster is located at the top of the molecule. Residues 3–9 and 14–20 form an antiparallel β-sheet, and residues 5–8 and 87–89 form a parallel β-sheet. A short helical segment occurs at residues 25–31. There is a relatively large cavity in the interior of the molecule surrounded by the β-sheets and helix. The heavy-atom binding site is at Asp 36.

0028–0836/80/310522—03$01.00

There are 22 invariant and 14 variant positions, defining a variant position as a site occupied by more than 6 different amino acid residues in various ferredoxins. Structurally and functionally essential portions of the molecule must be occupied by invariant residues. For example, the four cysteine residues, Cys 41, Cys 46, Cys 49 and Cys 79, binding the two iron atoms are invariant and are most important in electron transfer function. The sites of the other invariant residues in the three-dimensional structure of *S. platensis* ferredoxin are shown in Fig. 4. As can be seen, most of the invariant residues are around the [2Fe-2S] cluster. The segments from Pro 38 to Cys 49 and from Thr 78 to Ala 81 must be important in stabilizing the cluster cavity. Note also that the segment from residues 65 to 69 consists almost entirely of invariant and semi-invariant residues (that is, chemically similar amino acid residues) located near the cluster. These observations suggest that invariant and semi-invariant residues surround the cluster cavity, making an evolutionarily conserved environment for the cluster in all the widely divergent ferredoxins isolated from various organisms, including blue-green algae and higher plants, which diverged more than 15 billion years ago. Some of the invariant glycine residues are located at the corners of the main chain: Gly 13, Gly 56 and Gly 74 must be necessary for chain folding.

Fig. 2 The amino acid sequence of *S. platensis* ferredoxin[2,11] and the distribution of various amino acid residues present in chloroplast-type ferredoxins. The sequence of *S. platensis* ferredoxin (top row) is shown by the one-letter code. The different amino acid residues found in the sequences of 25 other chloroplast-type ferredoxins are shown below the sequence. –, Represents a deletion.

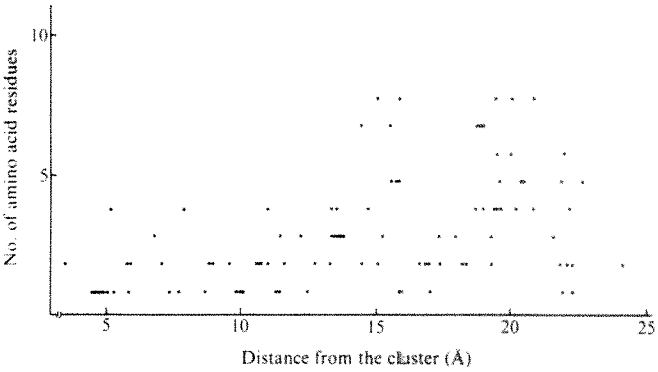

Fig. 3 The relationship between the number of amino acids substituted in 26 chloroplast-type ferredoxins and the distances between each α-carbon atom and cluster.

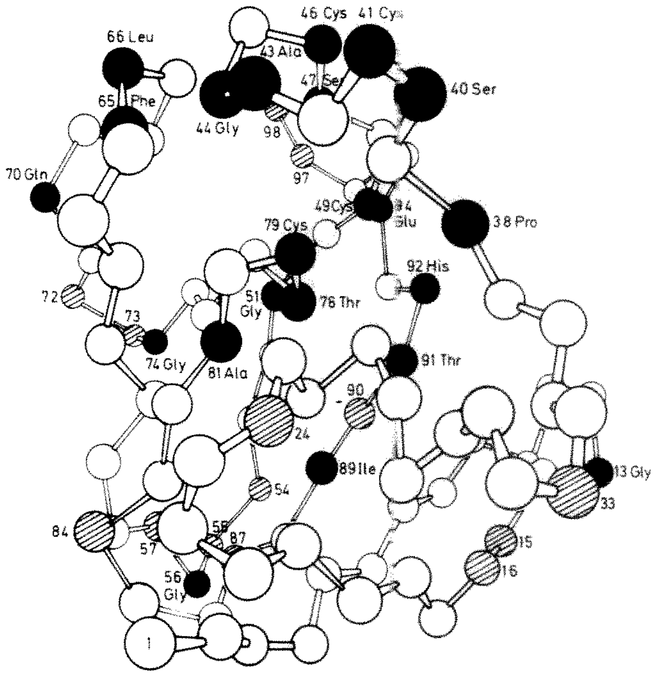

Fig. 4 The distribution of invariant and variant positions in ferredoxin sequences in the three-dimensional structure of *S. platensis* ferredoxin. ● And ▨ represent invariant and variant positions, respectively. The [2Fe-2S] cluster is not shown.

There is no remarkable feature about the distribution of variant positions in the primary structure, except that they are not near the functionally important cysteine residues. However, as shown in Fig. 4, it is obvious that they occur in the lower part and on the surface of the three-dimensional structure, producing a remarkable compartmentation between variant and invariant positions in the molecule. We have given a brief account of the relationship between the three-dimensional structure and variation in the amino acid residues in terms of evolution based on preliminary results on the structure[2].

Prevalence of amber suppressor-containing coliforms in the natural environment

Bonnie Marshall & Stuart B. Levy

Departments of Molecular Biology and Microbiology and of Medicine,
Tufts University School of Medicine, Boston, Massachusetts 02111

Amber suppressible genes have been introduced into vectors[1,2] and proposed for use in recombinant DNA studies. Such genes can be expressed only in a host bacterium with amber suppressors. To assess the biological containment of this kind of mutation we have now examined the frequency of bacteria with amber suppressors in faecal samples from humans and animals in different environments. This approach allowed us to evaluate the number of individuals in an environment bearing bacteria with amber suppressor mutations and the frequency of these bacteria within the faecal samples of each individual. Of all individuals sampled 30.5% contained detectable levels of bacteria with amber suppressor activity. In >75% of these samples, the level of suppressor-containing bacteria was <10%, about half of which were <1%. Most of these were *Escherichia coli*: however, *Citrobacter* and *Klebsiella* were also found. In three samples, essentially all coliforms had suppressor activity. Excluding these three samples, the estimated frequency of amber suppressors among faecal coliforms was 1.5%; however, if the data from these individuals were included, the overall frequency among faecal samples could be as high as 10%. By itself, the finding suggests that amber suppressor mutations in recombinant DNA vectors may not offer as great a safety feature as originally considered. These data, however, must be considered together with the known low sensitivity of wild-type *E. coli* to laboratory phages[3,4] and their low recipient ability for some plasmids.

To perform these studies we required a genetic vector which could be introduced into wild-type host cells. Different phages proved unsuccessful. Because *inc*P1 plasmids have a wide host range, we chose this as a vector for our study. We were greatly aided by the availability of plasmid pLM2 (ref. 5) (developed by Leonard Mindich) which contains amber suppressible mutations[6] in tetracycline and ampicillin resistance determinants while encoding a wild-type kanamycin resistance gene.

Samples of intestinal coliforms were obtained from five populations: hospital patients, laboratory workers, urban residents, rural residents and farm animals. A fresh faecal swab (Culturette; Scientific) was obtained from each donor, inoculated on to a MacConkey agar plate (Mac) and diluted by two-dimensional spreading on to four quadrants of the plates. These 'master' plates were then incubated at 37 °C overnight and refrigerated at 4 °C or tested immediately.

For mating studies with these coliforms, two *E. coli* strains were used as donors of plasmid pLM2: Ca274[6] bearing pLM2 (from L. Mindich)[5] and D15–12, a bile-salt sensitive, 'rough' *E. coli* produced in our laboratory by mating pLM2 into our host *E. coli* DO-19. The use of minimal agar eliminated the auxotrophic Ca274 from matings, while D15–12 was removed due to its death on the bile-salt-containing Mac agar.

The scheme for identification of endogenous suppressor-containing bacteria was as follows: a lawn of the donor organisms (Ca274 or D15–12) was inoculated on to a non-selective nutrient plate. The master plate, containing colonies of coliforms from each faecal sample, was replica-plated[7] on to the lawn of donor bacteria. After overnight incubation, the 'mating' plate was replica-plated on to media (minimal media for mating with Ca274; Mac agar for mating with D15–12) which would not allow the donor organism to grow and which contained either kanamycin (Kan) ($40\ \mu g\ ml^{-1}$) or ampicillin (Amp) ($50\ \mu g\ ml^{-1}$) + tetracycline (Tet) ($10\ \mu g\ ml^{-1}$) + Kan ($40\ \mu g\ ml^{-1}$).

The Kan replica plate assessed the efficiency of transfer of pLM2 to the wild-type coliforms; the Amp–Tet–Kan replica plate identified which of the recipient bacteria carried a suppressor mutation. Initially the master plate was replica-plated on to Mac+Kan ($40\ \mu g\ ml^{-1}$) and on to Mac+Tet ($10\ \mu g\ ml^{-1}$) + Amp ($30\ \mu g\ ml^{-1}$) + Kan ($40\ \mu g\ ml^{-1}$) to identify endogenous coliforms with resistance to Kan and/or resistance to Tet + Amp + Kan. Faecal samples bearing large numbers of bacteria resistant to Kan or a combination of Tet–Amp–Kan were excluded from analysis. pLM2 mating using either Ca274 or D15–12 showed 100% transfer efficiency of plasmid when known, good recipients were used in this replica-plating method. The observed frequency of transfer of pLM2 from both hosts was similar. Thus, the presence of any naturally occurring auxotrophic coliforms, which could have been missed in the Ca274 matings, was presumably small. The frequency of auxotrophic wild-type *E. coli* has been recently reported at about 9% (ref. 4).

Bacterial colonies, positive (Su^+) and negative (Su^-) for suppressor activity, were picked from the master plate, purified and retested by the plate method with the same or an alternative donor organism to confirm the presence or absence of amber suppression. Furthermore, some of the identified suppressor strains containing pLM2 were isolated and used to mate pLM2 into DO-11, an Su^-, Nal^R strain (this laboratory) or into a Su^+, streptomycin-resistant B40 (*supD*) strain. In all tests the intactness of the amber mutations on the plasmid was confirmed, with the exception of those few in which the presence of lytic phage prevented conjugation.

Faecal samples from 190 individuals from the five populations were tested. Of these, 30.5% had Su^+ bacteria present, all among the lactose fermenters. Biotyping (Analytab, API 20E) of 36 Su^+ isolates identified 33 as *E. coli*, 2 as *Citrobacter freundii* and 1 as *Klebsiella pneumoniae*. Most (>75%) of the faecal samples containing Su^+ bacteria showed them at a frequency of < 10%; in about 30% of samples, Su^+ bacteria occurred even

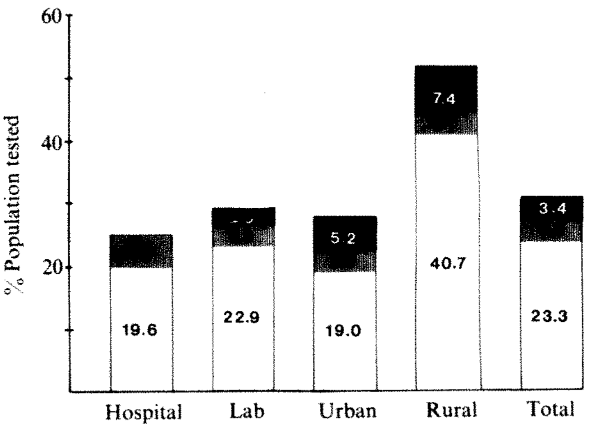

Fig. 1 Frequency of suppressor coliforms in faecal samples of four different human populations. The percentage of all samples containing any suppressor bacteria is represented by the whole bar. Frequencies (f) of suppressor occurrence within individual samples are shown by bar subdivisions as follows: open, $0 < f < 10\%$; hatched, $10 \leq f < 50\%$; closed, $f \geq 50\%$. The number of individuals sampled from each population was: hospital, 56; laboratory, 35; urban, 58; rural, 27.

0028–0836/80/310524—02$01.00

more rarely (<1.0%). Six samples showed a high level (>50%) of bacteria with suppressor activity (Fig. 1). Of note, we found three samples (from a laboratory worker and two urban dwellers) in which ~100% of the bacteria bore amber suppressors. Over 95% of the bacteria on these plates were recipients of the plasmid and Su$^+$.

The frequency of Su$^+$ bacteria in faecal samples from males and females showed equal distribution both overall and within environments. Su$^+$ bacteria occurrence, however, was twice as common in the human rural population as in humans tested in the other three environments. Fourteen non-human faecal samples were also tested (six fowl, five cows, one fly, one goat, one kitten). Of these, four (28.6%) showed the presence of Su$^+$ bacteria (at levels of <10%). This is in keeping with the frequency found in samples from the total human population.

The frequency of Su$^+$ bacteria among the entire pool of faecal coliforms tested was estimated by dividing the approximately $3.5–5 \times 10^3$ Su$^+$ bacteria identified by the estimated $3.5–5 \times 10^4$ transconjugants on the 190 plates examined. This calculation gave an estimated frequency of Su$^+$ *E. coli* of ~10%. This figure, however, is elevated considerably by the three individuals whose samples were essentially all Su$^+$. By excluding these individuals, the estimated frequency drops to roughly 1.5%.

The colonies that were not recipients of plasmid pLM2 obviously could not be evaluated for suppressor activity; however, there is no evidence to indicate that Su$^+$ bacteria have a different recipient ability from Su$^-$ bacteria. Furthermore, the ability of the faecal bacterial colonies to mate with the test organism, in the conditions described, was generally high. In 40% of the samples, 90% or more of the colonies accepted pLM2, allowing a relatively complete examination of the available flora. In only 15% of the faecal samples were less than 20% of the total colonies able to receive the plasmid; in all cases, at least 10 colonies per sample were evaluable.

Our data show that lactose-fermenting bacteria with amber suppressor activity are not uncommon in nature, and seem to be more frequent than has been previously recorded. All were lactose fermenters, *E. coli* being predominant. Using the same plasmid, Robeson *et al.*[4] found a level of about 0.4% suppressor-containing bacteria in 443 independently isolated wild-type *E. coli* from faecal and non-faecal sources. Our study, which examined whole faecal flora of different individuals, gave an estimated frequency of 1.5% in the majority of faecal samples. This value does not differ greatly from previous estimates[4]; however, the finding of 3 in 190 individuals with large amounts of Su$^+$ bacteria suggests that a much larger pool of these bacteria may exist in nature.

Given this frequency of Su$^+$ bacteria, the amber suppressor mutations in themselves, while providing some biological containment, may not be as effective as previously believed. The real effectiveness, however, must be considered in relationship to the actual ability of the mutant vector to propagate in wild-type coliforms. We and others have noted that some plasmids are poorly maintained in wild-type coliforms. In the case of λ vectors, the probability of vector rescue is greatly diminished because of the very low susceptibility of wild-type *E. coli* to this phage[3]. As an indication, we tested 27 isolates of our suppressor-containing coliforms with λ *vir*. None could be productively infected. Thus the degree of biological containment achieved by the introduction of suppressor mutations is greatly dependent on the choice of phage or plasmid vector used.

This study was supported by NIH contract no. NO1AI72529. We thank Toni Keller and Stanley Miller for help with the analyses.

DNA cloning in *Streptomyces*: resistance genes from antibiotic-producing species

C. J. Thompson, J. M. Ward & D. A. Hopwood

John Innes Institute, Colney Lane, Norwich NR4 7UH, UK

The biochemical and morphological differentiation of actinomycetes makes them academically and economically interesting. Their secondary metabolites provide the majority of medically and agriculturally important antibiotics[1] (streptomycete genes may also be the primary source of clinically important antibiotic resistance[2]); their complex morphological developmental cycle involves a series of changes from vegetative mycelial growth to spore formation[3]. Recombinant DNA technology would add a powerful new dimension to the analysis of these various aspects of actinomycete biology and would also facilitate the development of industrial strains with increased antibiotic yield, or capable of making new antibiotics[4]. For most of these purposes, cloning of genes within and between actinomycetes is required to study the expression of particular genes in genetic backgrounds defined by mutations of the characters under study. To achieve this, we have now developed a method for molecular cloning involving the transfer of genes between unrelated streptomycetes.

For initial interspecific cloning experiments we chose *Streptomyces lividans* strain 66 (ref. 5) as host, since no restriction-modification systems are known in this strain and because a potential plasmid vector (SLP1.2) was available for it; all cleavage sites for the restriction endonucleases *Bam*HI and *Pst*I lie in a dispensable region of SLP1.2(ref. 6). Into these sites we attempted to insert resistance genes from two antibiotic-producing streptomycetes. *Streptomyces fradiae*, which makes neomycin, contains a neomycin phosphotransferase (APH) and a neomycin acetyltransferase (AAC) (ref. 7 and J. Davies, personal communication). *Streptomyces azureus*, which makes thiostrepton, contains a ribosomal RNA methylase capable of protecting ribosomes from binding thiostrepton[8].

Foreign DNA was inserted into the vector in two ways. The first approach used ligation of *Mbo*I genomic DNA fragments, of length 2–20 kilobase pairs, into the *Bam*HI site of SLP1.2 (ref. 9). *Mbo*I, which recognizes a sequence of only four base pairs (GATC), generates the same single-stranded termini (GATC) as *Bam*HI (recognition sequence GGATCC). The numerous *Mbo*I sites expected in *Streptomyces* chromosomal DNA (about 1 per kilobase pair; unpublished data) allowed us to generate a suitably random population of donor fragments by partial digestion with *Mbo*I (about 10% of the sites were cleaved). This seemed advisable as we knew nothing about the positions of restriction enzyme targets within genes or promotors, or about possible fragment size selection during ligation and transformation. The second approach used double digestion of SLP1.2 with *Bam*HI and *Pst*I to excise a 2.6-kilobase pair sequence of non-essential DNA and generate non-homologous single-stranded ends (one from the *Bam*HI and the other from a *Pst*I site). Recircularization required the insertion of a segment of DNA having corresponding termini. Such fragments were generated by partially cleaving donor chromosomal DNA with *Mbo*I to 5–28 kilobase pairs and then completely with *Pst*I (giving an average of one *Pst*I cut per *Mbo*I fragment).

Ligation mixtures containing SLP1.2 and fragments of *S. fradiae* or *S. azureus* total genomic DNA were transformed into *S. lividans* protoplasts. The original procedure[10] was modified to increase the transformation efficiency approximately 20-fold. Transformation was indicated by the appearance of 'pocks' (circular zones of sporulation inhibition associated with plasmid transfer, sometimes called the *ltz* (*lethal zygosis*) phenotype[11] in the lawn of *S. lividans* growth arising from the regenerated

Table 1 Properties of the six recombinant plasmids

Strain	Plasmid	Size kilobase pairs		Method of construction		Presence of restriction fragment F	Site at vector–insertion junctions		Enzyme specified
		Plasmid	Insertion	Vector cleavage	Donor DNA cleavage		J1	J2	
M180	SLP1.2	14.4	0	—	—	+	—	—	None
TC7	pIJ1	24.8	13.0	*Pst*I/*Bam*HI	*Pst*I/*Mbo*I	—	Not *Bam*HI	*Pst*I	AAC
TC8	pIJ2	17.8	3.4	*Bam*HI	*Mbo*I	+	*Bam*HI	*Bam*HI	APH
TC9	pIJ3	22.1	10.3	*Pst*I/*Bam*HI	*Pst*I/*Mbo*I	—	Not *Bam*HI	*Pst*I	APH
TC10	pIJ4	23.4	11.6	*Pst*I/*Bam*HI	*Pst*I/*Mbo*I	—	Not *Bam*HI	*Pst*I	AAC
TC11	pIJ5	19.0	4.6	*Bam*HI	*Mbo*I	+	Not *Bam*HI	Not *Bam*HI	23S rRNA methylase
TC14	pIJ6	21.3	6.9	*Bam*HI	*Mbo*I	+	*Bam*HI	*Bam*HI	23S rRNA methylase

The recombinant plasmids were constructed by inserting genomic fragments containing genes for antibiotic resistance enzymes into SLP1.2. Neomycin resistance, due to AAC or APH, was cloned from *S. fradiae* (a variant of ATCC 10745 selected for high level resistance to neomycin and provided by Dr J. Davies); thiostrepton resistance (23S ribosomal RNA methylase) was cloned from *S. azureus* ATCC 14921. pIJ1, pIJ3 and pIJ4 were generated from *Pst*I and *Bam*HI cleaved SLP1.2 ligated to fragments of donor DNA double digested with *Mbo*I and *Pst*I; they therefore do not contain the small *Pst*I fragment F of SLP1.2 (see Fig. 3). pIJ2, pIJ5 and pIJ6 were constructed by ligation of SLP1.2 cleaved with *Bam*HI to *Mbo*I fragments of donor DNA. Plasmid and insert sizes (relative to the *Hin*dIII fragments of bacteriophage λ: 23.5, 9.59, 6.76, 4.44, 2.28, 1.94 and 0.58 kilobase pairs) were determined from the combined molecular weights of fragments in *Bam*HI/*Hin*dIII double digests, allowing for the presence or absence of fragment H (see Fig. 3). Insertion of DNA fragments having *Mbo*I termini into the *Bam*HI site of SLP1.2 reconstituted a *Bam*HI site in four out of nine hybrid junctions (J1 and J2 in Fig. 3) as deduced from the presence of fragments D and/or E (Fig. 3) in *Bam*HI/*Hin*dIII double digests (reconstitution was expected on random grounds in about one-third of junctions since one-half of each hexanucleotide junction contains half the original *Bam*HI sequence of the vector and the other half, coming from an *Mbo*I site in 73% G+C DNA, has a 36.5% (73% × 0.5) probability of having *Bam*HI specificity). The expected reconstitution of the *Pst*I site at J2 in plasmids pIJ1, pIJ3 and pIJ4 was confirmed by the presence of restriction fragment G (Fig. 3).

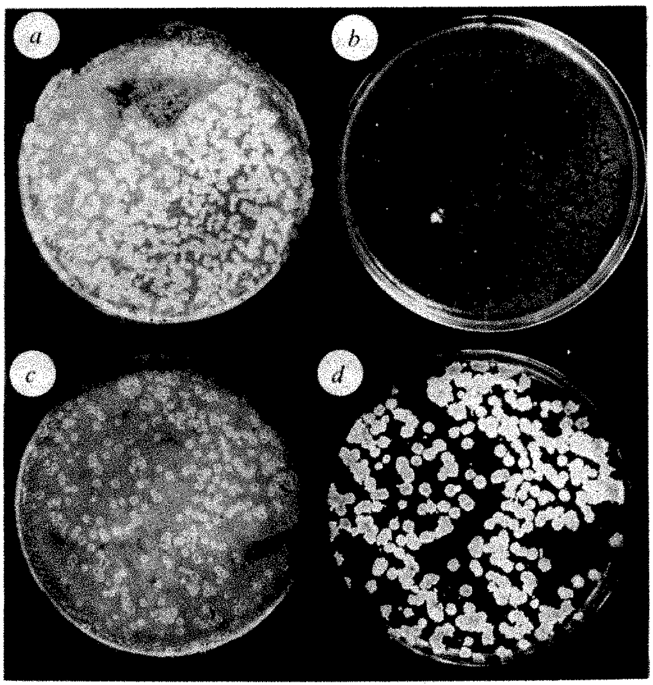

Fig. 1 The isolation of a clone carrying drug resistance. *S. azureus* genomic DNA (2.5 μg) was partially cleaved with *Mbo*I into fragments of 2–20 kilobase pairs; SLP1.2 (0.5 μg) was cleaved with *Bam*HI. Vector and genomic fragments were mixed and ligated (4 h at 10 °C followed by 72 h at 4 °C in ligation salts which contained 66 mM Tris-HCl (pH 7.5), 1 mM EDTA, 10 mM $MgCl_2$, 10 mM 2-mercaptoethanol and 0.1 mM ATP) at a total DNA concentration of 40 μg ml^{-1} with T4 DNA ligase (prepared according to ref. 16). Ligation products were introduced to 3×10^9 *S. lividans* strain 66 protoplasts (haemocytometer counts) by a modification (unpublished results) of the PEG-mediated transformation procedure[10]. These protoplasts gave rise to 5×10^7 colonies and 4×10^4 pocks (see *a*) after regeneration on 20 plates of R2 agar[17] containing 0.5% Difco yeast extract (R2 YE). When these lawns were replica-plated to R2 YE plates containing 50 μg ml^{-1} thiostrepton, two spots of drug resistant growth appeared (one is shown in *b*). After purification of this strain, its plasmid DNA was isolated by CsCl–ethidium bromide centrifugation[18] and used to re-transform *S. lividans* protoplasts. Non-selected regeneration (*c*) followed by replication to thiostrepton (*d*) demonstrated 100% correlation between pocks (*c*) and thiostrepton-resistant growth (*d*).

protoplast population (Fig. 1). When such lawns were replicated to plates containing antibiotic (50 μg ml^{-1} thiostrepton, or 1 μg ml^{-1} neomycin), patches of growth appeared corresponding to certain pocks on the regeneration plates (2 thiostrepton-resistant out of 40,000 pocks in an experiment with *Mbo*I-generated fragments, 2 neomycin-resistant out of 10,000 pocks in a similar experiment, and 3 neomycin-resistant out of 10,000 pocks when the donor DNA was cleaved with *Mbo*I and *Pst*I). The drug resistance and ltz phenotypes of these clones were transferred coincidentally at high frequency (10–100%) in matings with genetically marked *S. lividans* derivatives, indicating that they contained drug resistance genes inserted into SLP1.2. This was confirmed by transformation using the CCC plasmid DNA which could be isolated from each clone; the plasmids conferred drug resistance (Fig. 1) on all (>95%) transformants (that is, pocks).

Agarose gel electrophoresis of the hybrid plasmids revealed that each was larger than SLP1.2 (Fig. 2). *Hin*dIII digestion of each plasmid yielded SLP1.2 fragments B and C, as expected (Fig. 3). *Hin*dIII fragment A, which contained the cloning sites, was, however, invariably increased in size (Fig. 2). Since the inserted fragments came from DNA which had been only partially digested with *Mbo*I, they could not be excised in one piece with *Mbo*I. Moreover, ligation of *Streptomyces* (73% G+C) *Mbo*I fragments into a *Bam*HI site should alter the sequence at about two-thirds of the *Bam*HI–*Mbo*I junctions to eliminate the *Bam*HI site. The fact that a *Bam*HI recognition site was found at four out of nine recombinant junctions (Table 1) confirmed this prediction, and will allow the precise removal of the neomycin-(APH) and thiostrepton-resistance genes from the recombinant plasmids pIJ2 and pIJ6 for recloning purposes. The increased size of *Hin*dIII fragment A was used to calculate the amount of inserted DNA in each clone (Table 1). The sizes of the inserts (4–13 kilobase pairs) agreed with the molecular weight range of the donor DNA fragments.

Interspecific gene transfer was confirmed biochemically. The four neomycin-resistant clones were assayed for APH and AAC activities; two contained APH and two AAC. Extracts from both thiostrepton-resistant clones were found to contain thiostrepton-resistant ribosomes and the expected ribosomal RNA methylase activity. Thus the availability of *S. lividans* clones containing the ribosomal RNA methylase of *S. azureus* confirmed its potential to confer thiostrepton resistance on the producing organism[8]. In the case of neomycin resistance, the *S. lividans* clones established that the presence of either of the two neomycin modifying enzymes of *S. fradiae* is sufficient to give

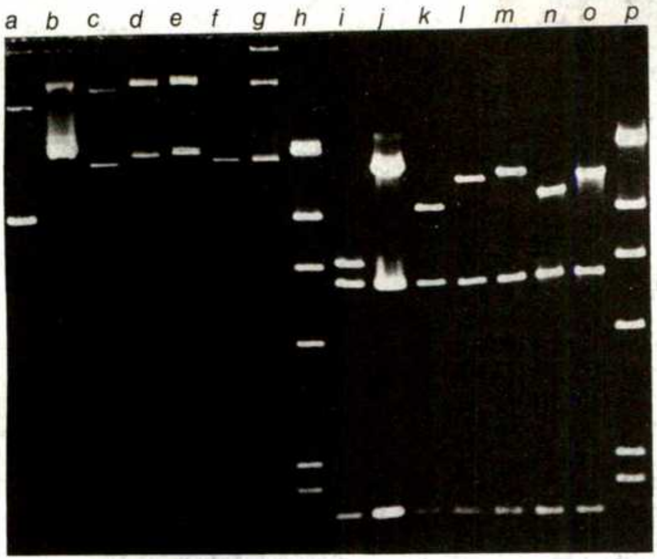

Fig. 2 Agarose gel electrophoresis of recombinant plasmids and their cleavage fragments produced by *Hin*dIII. The DNA species were separated by electrophoresis in 0.8% agarose using a Tris-acetate buffer[19] for 15 h at 1 V cm^{-1}. *h* and *p*, bacteriophage λ DNA cleaved with *Hin*dIII; *a*, the parent SLP1.2 plasmid and *b–g*, the recombinant plasmids PIJ 1–6 respectively, uncleaved (the fastest migrating band in each track is the CCC plasmid species); *i*, SLP1.2 and *j–o*, pIJ1-6 respectively, cleaved with *Hin*dIII. Note the indistinguishable sizes of the two smaller *Hin*dIII fragments in SLP1.2 and the series of recombinant plasmids and the increased size of the largest fragment in each recombinant.

resistance to neomycin. Comparable clones promise to be valuable in understanding the resistance mechanisms of other antibiotic-producing actinomycetes and perhaps the origins of clinically important drug resistance genes[2].

The results, in conjunction with those of Bibb *et al.*[12] on the cloning of methylenomycin resistance from *S. coelicolor* into *S. coelicolor* and *S. lividans*, and our unpublished results showing that two randomly chosen genes for amino acid biosynthesis could be cloned from the chromosome of *S. coelicolor* A3(2) on to the SCP2* plasmid of that strain, indicate that molecular cloning in streptomycetes on existing plasmid vectors is quite practicable. We feel that our cloning of three genes conferring resistance, by known mechanisms, to stable and readily available antibiotics augurs well for the further development of cloning vectors for streptomycetes. Possible resistance enzymes for many aminoglycosides[7], macrolides[13], chloramphenicol[14] and other antibiotics are available in the actinomycetes. It should therefore be relatively straightforward to build a streptomycete vector bearing more than one resistance gene in order to: select for the presence of the vector[15], detect clones by insertional inactivation[15], and achieve high level expression of cloned genes (highly efficient promoters for some of these genes are being sought among mutant strains showing increased drug resistance). Such a vector would facilitate, for example, the cloning of genes involved in antibiotic biosynthesis or differentiation, on which this laboratory is now embarked.

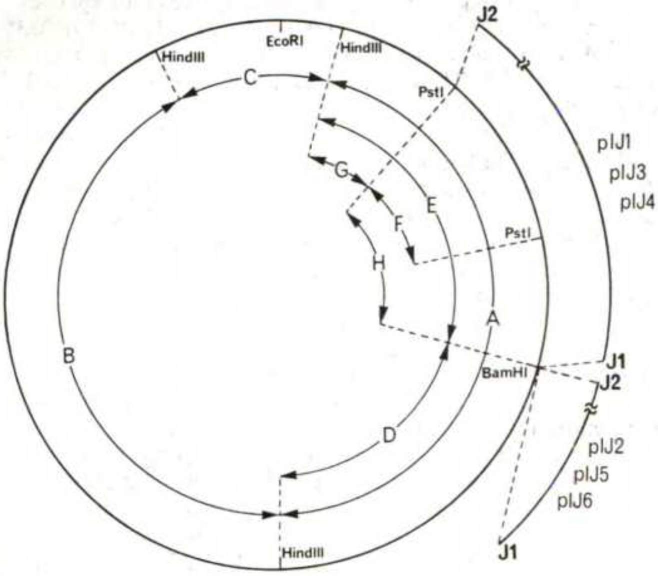

Fig. 3 Restriction map of the SLP1.2 plasmid for enzymes *Eco*RI, *Hin*dIII, *Pst*I and *Bam*HI[6] (continuous circle) and positions of insertions in recombinant plasmids pIJ1-6 (Table 1).

We thank Dr Eric Cundliffe for the *S. azureus* strain and the RNA methylase assays, Dr Ken-ichi Komatsu for the assays of AAC and APH, Drs Keith Chater, Julian Davies and Tobias Kieser for helpful discussions, and the National Research Development Corporation for financial support.

DNA cloning in *Streptomyces*: a bifunctional replicon comprising pBR322 inserted into a *Streptomyces* phage

J. E. Suarez & K. F. Chater

John Innes Institute, Colney Lane, Norwich NR4 7UH, UK

The Gram-positive, mycelial, differentiating streptomycetes are responsible for the production of many important antibiotics. The availability of gene cloning systems in this microbial group would have many industrial applications[1] besides allowing more penetrating study of the genetics of *Streptomyces coelicolor* A3(2) (which, as the best understood streptomycete genetically, serves as a model for much other *Streptomyces* genetics)[2]. Recent successes[3,4] (see previous paper[4]) in introducing *Streptomyces* DNA into *S. coelicolor* and *Streptomyces lividans* on plasmid vectors would be nicely complemented by the availability of *Streptomyces* bacteriophage vectors (discussed in ref. 5): for example, many phages have wide and easily defined host ranges; heat-inducible prophages might be used to give high copy number of cloned DNA; efficient phage promoters might be used to increase gene expression; there may be differential stabilities for particular DNA sequences cloned in plasmids *vis-à-vis* phages; selective insertion of DNA, utilizing packaging constraints, may be possible with phages; and *in situ* hybridization[6] of radioactive probes to DNA in plaques is likely to be simple. We describe here the use of the moderately wide host range temperate phage, ΦC31[7], for this purpose.

Although ΦC31 DNA (39 kilobases) is not known to have single targets for any restriction enzymes, it possesses six *Eco*RI sites[5] which might be used for inserting DNA. Viable deletion mutants have been obtained[5] that should allow the insertion of fragments of foreign DNA without interfering with packaging of DNA into maturing phage particles. DNA of ΦC31 efficiently transfects *Streptomyces* protoplasts in the presence of polyethylene glycol[8]. The particular phage strain chosen was ΦC31*cts*Δ23, which has about 8% (3.25 kilobases) less DNA than the wild-type ΦC31 (J.E.S. and K.F.C., unpublished observations). The small *Escherichia coli* plasmid pBR322 (4.362 kilobases)[9,10], which has single *Eco*RI, *Bam*HI and *Pst*I sites, was selected as the DNA for insertion.

The ΦC31*cts*Δ23 vector DNA was treated[11] with T4 ligase to close its cohesive ends covalently[5,12], precipitated with ethanol and partially cleaved with *Eco*RI to give an average of about one cut per molecule. After a second ethanol precipitation, the DNA was ligated in the presence of a 25-fold molar excess of completely *Eco*RI-cleaved pBR322, and the DNA mixture was used to transfect *S. lividans* protoplasts[8]. Of 1,500 plaques obtained with a sample of DNA mixture containing 100 ng ΦC31*cts*Δ23 DNA (about 30-fold fewer plaques than expected for 100 ng ΦC31 *cts* DNA in a normal transfection)[8] one hybridized to ^{32}P-labelled pBR322 probe DNA in a filter–hybridization test[6].

DNA was isolated from the purified presumed hybrid phage and analysed by digestion with restriction enzymes (Fig. 1). An *Eco*RI fragment of 4.36 kilobases, present in the hybrid DNA but not in DNA of ΦC31*cts*Δ23, co-migrated with *Eco*RI-cleaved pBR322. Single sites for *Bam*HI and *Pst*I, absent from the control DNA, were present in the hybrid DNA, and were both within the novel *Eco*RI fragment (not shown). In digestions with single enzymes, the smaller *Bam*HI fragment was 10.8 kilobases, and the smaller *Pst*I 7.4 kilobases. These data were consistent with insertion of pBR322 into ΦC31*cts*Δ23 in the position and orientation shown in Fig. 2.

Fig. 1 Restriction enzyme analysis of DNA of ΦC31 derivatives using electrophoresis in 1% agarose gels. Tracks *a* and *k* are molecular size standards of λ DNA treated with *Sal*PI (ref. 13). Phage DNA was prepared by conventional procedures (ref. 16). Note that the DNA in tracks *c*, *d* and *e* is indistinguishable from that in tracks *i*, *j* and *h*, but that (as expected) in the plasmid form of the hybrid DNA (track *g*), *Eco*RI fragment A' (the fusion product of *Eco*RI fragments B and F, the cohesive ends of the phage DNA[5]) completely replaces B and F. Fragment C^{23} (3.4 kilobases (kb)) is the reduced form present in ΦC31*cts*Δ 23, of the wild-type fragment C (6.6 kilobases, absent from this gel) (ref. 5).

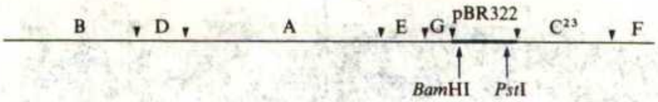

Fig. 2 Structure deduced for ΦC31*cts*Δ23–pBR322 hybrid DNA from data in Fig. 1, based on the *Eco*RI restriction map of ΦC31 DNA given in ref. 17. Letters above the map are *Eco*RI fragment designations.

Wild-type ΦC31 DNA contains no sites for the *Pst*I isoschizomer *Sal*PI present in *Streptomyces albus* P: consequently, ΦC31 is not restricted by *S. albus* P[13]. However, phage from the plaque containing pBR322 sequence homology was restricted and modified by *S. albus* P: its efficiency of plating on *S. albus* P was 20-fold lower (data not shown) when the previous host was *S. lividans* than when it was *S. albus* P (using *S. lividans* as a standard host). A similar level of restriction by *S. albus* P was previously seen with phage R4, which has one *Sal*PI target site in its DNA[14]. Presumably, introduction of the *Pst*I (=*Sal*PI) site of pBR322 into ΦC31 was responsible for the observed restriction. This property provided a supplementary way of identifying the hybrid clone.

The *Eco*RI site of pBR322 is not within a region needed for plasmid replication or expression of its tetracycline or ampicillin resistance genes in *E. coli*. Therefore, assuming that the ΦC31DNA would be largely unexpressed in *E. coli*, the hybrid molecule should replicate in *E. coli* as a plasmid and express both drug resistances. This was found to be the case: very similar efficiencies of transformation[11] of a *recA* derivative of *E. coli* 803 (*metB hsdS*) to tetracycline resistance were obtained with supercoiled pBR322 DNA and ligated or non-ligated hybrid DNA. (The similarity between the efficiencies with ligated and non-ligated DNA probably reflects the high stability of hydrogen bonding between the cohesive ends of ΦC31 DNA[5,12].) The colonies obtained were all Met$^-$ and resistant to both tetracycline (25 μg ml^{-1}) and ampicillin (200 μg ml^{-1}) when tested by replica plating. Plasmid DNA isolated from nine colonies transformed with hybrid DNA gave an *Eco*RI digestion pattern which was distinguishable from that obtained with the original hybrid DNA isolated from phage particles only by the expected covalent joining of the cohesive ends of the phage DNA (Fig. 1). (Plasmid DNA isolated from two of the *E. coli* colonies transformed with pBR322 DNA was indistinguishable from pBR322 using *Eco*RI digestion.)

We next tested whether *S. lividans* protoplasts could be transfected by the hybrid plasmid DNA isolated from *E. coli*. About 250 ng hybrid plasmid DNA gave 1,100 plaques—a frequency 10–100-fold lower than that obtained with DNA isolated from the hybrid phage. DNA from phages obtained from five of these plaques was indistinguishable by restriction enzyme analysis from the DNA of the original hybrid (Fig. 1).

The data reported here demonstrate the following: (1) the plaque hybridization technique[6] is applicable to the *Streptomyces* phage ΦC31; (2) pBR322 DNA can be inserted into ΦC31*cts*Δ23 DNA at an *Eco*RI site 6.35 kilobases from one end of the molecule without obvious effects on the ability of the phage to form plaques, proving the feasibility of using this phage as a DNA cloning vector and providing single dispensible *Bam*HI and *Pst*I target sites which will be important in the future use of derivatives of the hybrid as cloning vectors;(3) the presence of the *Pst*I (= *Sal*PI) site of pBR322 in the hybrid phage causes it to be restricted by *S. albus* P; (4) DNA of the ΦC31*cts*Δ23–pBR322 hybrid can easily be transformed into *E. coli* (even without ligation of the phage cohesive ends), and maintained there without any evidence of structural instability during subculture for at least 30 cell generations; (5) the supercoiled covalently closed circular DNA isolated from *E. coli* transfects *S. lividans* protoplasts at least moderately efficiently, suggesting the absence of a severe restriction barrier (which might have operated on DNA last propagated in *E. coli*); (6) the pBR322 sequence is stably inherited during propagation of the hybrid molecule as a phage in *S. lividans*.

The ability of the hybrid DNA to inhabit either *Streptomyces* or *E. coli* will be invaluable in introducing some of the powerful genetic techniques (such as transposon mutagenesis)[15] available in *E. coli* into the study of *Streptomyces* genetics. It may also be possible to turn to advantage the absence of packaging constraints on the size of the molecule when it is replicating in the plasmid mode, *vis-à-vis* the presence of such constraints during its growth as a phage.

Dr A. G. Hepburn provided not only extensive technical advice but also labelled and unlabelled pBR322 DNA. We thank Professor D. A. Hopwood and Dr C. J. Thompson for invaluable comments on the manuscript, and Celia Bruton for technical assistance. J.E.S., on leave from the University of Oviedo, Spain, was the recipient of a grant from the Vicente Canada Blanch Foundation.

Novobiocin inhibition of simian virus 40 DNA replication

Howard J. Edenberg

Department of Biochemistry, Indiana University School of Medicine,
Indianapolis, Indiana 46223

Supercoiling in eukaryotic cells can be explained by the packaging of DNA into nucleosomes in the presence of nicking–closing enzymes[1]. This does not, however, rule out the presence of a DNA gyrase. DNA gyrase[2] is involved in the introduction and maintenance of supercoiling in prokaryotic cells[3–6] and in DNA replication in *Escherichia coli*[4,6,7]. Novobiocin and coumermycin-A_1 inhibit prokaryotic DNA replication[4,7–11] by inhibiting the subunit of the gyrase responsible for its ATPase and energy transduction activities[3,4,12–14]. The inhibition of DNA synthesis in a mammalian cell[15] and in rat liver mitochondria[16] by novobiocin suggests that a gyrase required for initiation of replication is inhibited. Because the presence of a gyrase in eukaryotic cells would be of great interest, I have examined this question in a well characterized model system, the replication of simian virus 40 in its host (monkey) cell. The results demonstrate here that novobiocin and coumermycin A_1 inhibit SV40 DNA synthesis in mammalian cells and inhibit DNA polymerase α, the replicative DNA polymerase in this system[17,18]. Novobiocin, but not coumermycin A_1, reduces the degree of supercoiling of DNA pulse-labelled in its presence, probably through its inhibition of protein synthesis. Thus the inhibition of SV40 DNA synthesis by novobiocin does not alone prove the involvement of a DNA gyrase.

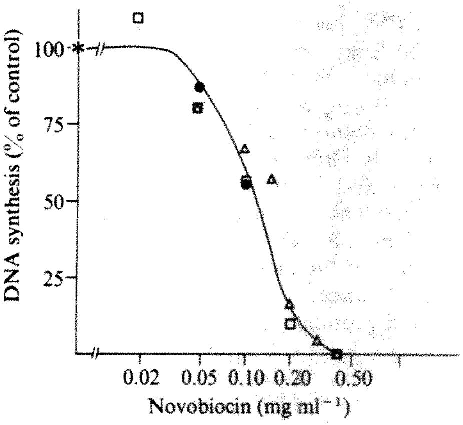

Fig. 1 Novobiocin inhibition of SV40 DNA synthesis in intact cells. CV-1 cells were grown to confluence in minimal essential medium (MEM) with 10% fetal calf serum (FCS), infected with SV40, and incubated in MEM with 2% FCS as previously described[20]. Novobiocin (Boehringer) was added from a stock solution of 10 mg ml^{-1} in 2.0 mM Tris-HCl, *p*H 7.5, as noted. Radioactive labelling was terminated by removal of medium, two rinses with phosphate buffered saline, and extraction of viral DNA by the method of Hirt[19]. □, Novobiocin was added 20 h after infection, [^{3}H]dT (1.8 μCi ml^{-1}) was added 75 min later, and incubation was continued for a further 24 h. △, Novobiocin was added 18.5 h after infection, [^{14}C]dT (0.08 μCi ml^{-1}) was added 90 min later and incubation was for a further 25 h. ●, At 39 h after infection, the medium was replaced with fresh medium containing 2% FCS and 12.5 mM HEPES (*p*H 7.1); 2 h later novobiocin was added, and 120 min after drug addition [^{3}H]dT (12 μCi ml^{-1}) was added for a 30-min pulse.

The effect of novobiocin on SV40 DNA synthesis was studied by examining the incorporation of radioactive label into viral DNA (selectively extracted from the cells by the method of Hirt[19] about 40 h after infection). As shown in Fig. 1, novobiocin inhibits SV40 DNA replication in a dose-dependent manner; 50% inhibition is achieved by ~0.1–0.2 mg ml^{-1} novobiocin. Inhibition of DNA synthesis by novobiocin is rapid (the steady-state level is reached within 90 min) and reversible. The concentration of novobiocin required to inhibit SV40 replication is about 100 times greater than that required to inhibit DNA synthesis in *E. coli*[7,9].

Since the inhibition of processes in two different systems by the same drug does not necessarily imply that the same target enzyme is involved in both systems, I tested the effect of novobiocin on the replicative DNA polymerase. We have previously shown that DNA polymerase α is responsible for SV40 DNA synthesis[17,18]. DNA polymerase α, partially purified from the host monkey cells, was tested in a standard *in vitro* assay[17] and as shown in Fig. 2 was 50% inhibited by ~0.2 mg ml^{-1} novobiocin, a concentration similar to that which inhibits replication in cells. This inhibition would suffice to explain the inhibition of SV40 DNA synthesis. Since the substrate in these studies consists of short linear segments of DNA which are extensively nicked and gapped, this inhibition cannot be related to a need to relieve supercoiling. DNA polymerase γ is also inhibited (50% at about 0.6 mg ml^{-1}); DNA polymerase β is not inhibited (data not shown). These results confirm reports that similar concentrations of novobiocin inhibit a crude DNA polymerase α of rat brain[21] and that high levels inhibit a human 7S DNA polymerase[22], but do not significantly inhibit DNA polymerase β[21,22].

Closed circular SV40 DNA made during a 30–40 min pulse in novobiocin-inhibited cells (0.1 mg ml^{-1} and above) has a greater density in CsCl–ethidium bromide density gradients than does SV40 DNA from control cells (Fig. 3), indicating that it is less negatively supercoiled[23,24]. This was confirmed by examining the dependence of sedimentation rate on ethidium bromide

0028–0836/80/310529—03$01.00

concentration[23-25]; the minimum sedimentation rate of SV40 DNA extracted from control cells occurred at about 2 μg ml^{-1} ethidium bromide, while that of SV40 DNA made in the presence of 0.1–0.2 mg ml^{-1} novobiocin occurred at about 1.0–1.5 μg ml^{-1}. Novobiocin itself does not bind to DNA[8], and would not directly alter the supercoiling. DNA made during long labelling periods in the presence of novobiocin is indistinguishable from that made in control cells (data not shown). At these levels of novobiocin, protein synthesis is also inhibited (data not shown) and the change in supercoiling could be a result merely of less packaging of the DNA into nucleosomes due to this inhibition of protein synthesis.

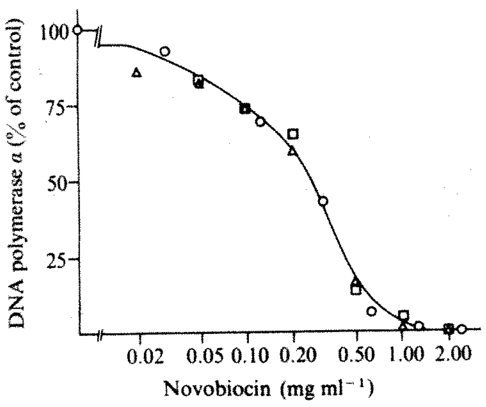

Fig. 2 Novobiocin inhibition of DNA polymerase *α in vitro*. DNA polymerase *α* assays were conducted as previously described[17]; the reaction mixtures contained (per 0.1 ml) 50 μg activated DNA and 15 μg bovine serum albumin, in 0.05 M Tris–HCl *p*H 8.5, 7.5 mM $MgCl_2$, all four dNTPs at either 15 μM (○, △) or 25 μM (□); and [^{3}H]dTTP (2 μCi). Two different preparations of DNA polymerase *α* were used, one partially purified through DEAE cellulose as previously described[17] (○) and an independent preparation purified in a similar manner and then further purified through phosphocellulose[26] (△, □). Both preparations were shown to be sensitive to *N*-ethyl maleimide, and resistant to dideoxy-TTP[17,18,27]. Incorporation was normalized to the value from reactions lacking drugs; 100% represents 235 pmol (○), 340 pmol (△), or 180 pmol (□) of dTTP incorporated in 30 min.

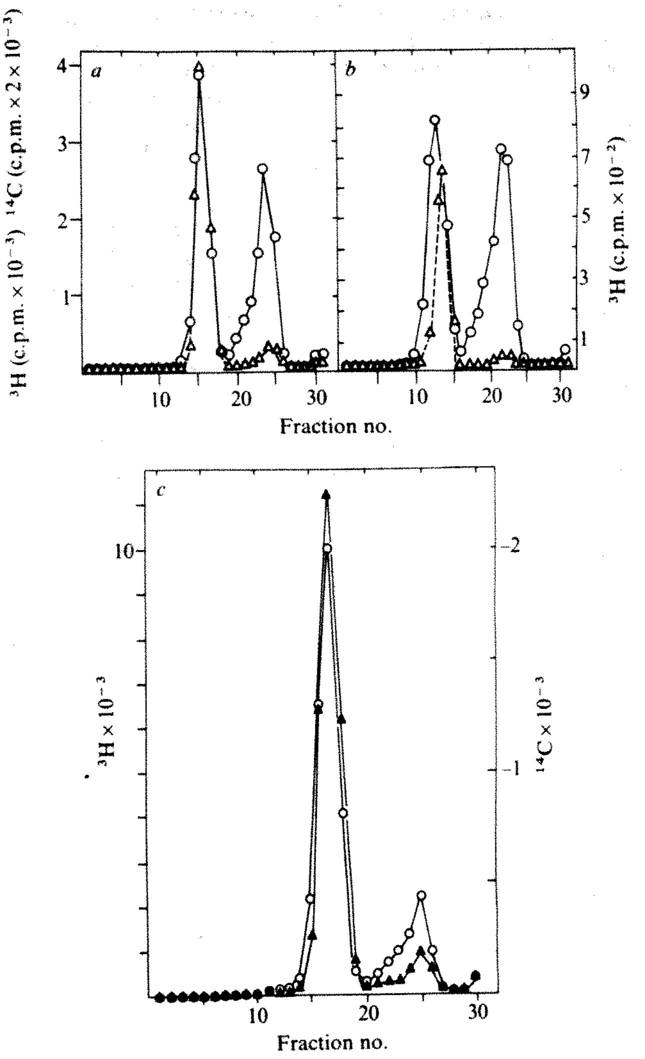

Fig. 3 Ethidium bromide–caesium chloride equilibrium gradients. Control SV40 DNA was isolated by the method of Hirt[19] from infected cells incubated with [^{14}C]dT (0.08 μCi ml^{-1}) from 22 to 45 h post-infection (△). Pulse-labelled DNA was isolated in the same manner at 40 h post infection (○). *a*, Cells were incubated for 20 min with [^{3}H]dT (25 μCi ml^{-1}), in the absence of drug. *b*, Cells were incubated for 2 h with 0.2 mg ml^{-1} novobiocin, and then [^{3}H]dT (25 μCi ml^{-1}) was added for 35 min. *c*, Cells were incubated for 2 h with 0.005 mg ml^{-1} coumermycin-A_1 and then [^{3}H]dT (25 μCi ml^{-1}) was added for 40 min. The Hirt supernates were extracted with chloroform/isoamyl alcohol (24 : 1), aliquots of ^{14}C-DNA (control) (△) were mixed with the ^{3}H-DNA (pulse) (○) from control or drug-treated cells, and each was adjusted to a refractive index of 1.388 with CsCl, buffer (0.01 M Tris–HCl *p*H 8.0, 0.01 M NaCl, 0.001 M EDTA) and ethidium bromide (0.27 mg ml^{-1} final concentration). Centrifugation was for 42 h at 38,000 r.p.m., 20 °C in a Beckman 50Ti rotor. Fractions were collected, carrier DNA was added, and the DNA precipitated with HCl and filtered through glass fibre filters, all as previously described[20]. For *a* and *b*, ^{14}C scales are the same, ^{3}H scales differ. Density decreases from left to right.

To clarify this situation, I examined the effects of coumermycin-A_1 (refs 10, 11) on SV40 DNA synthesis. Coumermycin-A_1 lyses monkey cells at concentrations above 0.01 mg ml^{-1}; at slightly lower concentrations it inhibits SV40 DNA replication, and at slightly higher concentrations inhibits DNA polymerase *α* (50% at about 0.03 mg ml^{-1}) and *γ* (50% at 0.2 mg ml^{-1}). Coumermycin-A_1, however, inhibits DNA replication without significantly altering the supercoiling of SV40 DNA, as tested both with equilibrium density gradients (Fig. 3*c*) and sedimentation rate measurements in the presence of ethidium bromide. These comparative data reinforce the suggestion that the difference in supercoiling seen with novobiocin is a secondary effect of the drug.

After submission of this manuscript, the presence of type II DNA topoisomerases in eukaryotic cells was reported[28]; no gyrase activity was reported. These topoisomerases are reported to be sensitive to high levels of novobiocin[28], and the authors relied on the previously reported sensitivity of replication to high levels of novobiocin[15] to argue that these topoisomerases might be the target enzymes. These conclusions are premature, since the data presented here demonstrate that the effects of novobiocin and coumermycin-A_1 on SV40 DNA synthesis can be explained as the results of inhibiting DNA polymerase *α* and protein synthesis. The results presented here provide no direct evidence for participation of a DNA gyrase in SV40 DNA replication, although they do not rule out the possibility.

Identification of integrated hepatitis B virus DNA and expression of viral RNA in an HBsAg-producing human hepatocellular carcinoma cell line

Prasanta R. Chakraborty, Nelson Ruiz-Opazo, Daniel Shouval* and David A. Shafritz

Departments of Medicine and Cell Biology and the Liver Research Center, Albert Einstein College of Medicine, 1300 Morris Park Avenue, Bronx, New York 10461

Alexander and co-workers[1] have developed a tissue culture cell line (PLC/PRF/5) from a primary hepatocellular carcinoma of a Mozambican male with a positive serum for hepatitis B virus surface antigen (HBsAg). This cell line produces and secretes HBsAg but no other known viral protein[1–3]. PLC/PRF/5 therefore contains at least part of the hepatitis B virus (HBV) genome in functional form. The 42-nm, spherical Dane particle in human serum is thought to represent the complete infectious agent of HBV[4]. The core of this particle contains circular double-stranded DNA in which one strand is 'nicked' (complete but not covalently closed) and the other strand is incomplete (lacking 15–45% of its sequence complement)[4,5]. Four proteins have been associated with the HBsAg, core antigen (HBcAg), e antigen and a viral DNA polymerase[4]. Several groups have now cloned Dane particle DNA in *Escherichia coli*[6–10], and both restriction maps and a complete DNA sequence have been determined. Various studies suggest that there is sequence heterogeneity in Dane particle DNA isolated from patients expressing the same or different viral subtypes, as well as sequence variation in different clones of Dane particle DNA obtained from a given individual[10,11]. Other studies[12,13] have reported HBV DNA sequences in DNA from liver cancer tissue. In none of these cases was viral DNA reported to be integrated into the host cell genome. With the improvement in techniques for characterizing viral DNA molecules, we have begun to analyse HBV genes and their expression in the PLC/PRF/5 cell line by molecular hybridization of cellular DNA and RNA to cloned ^{32}P-labelled plasmid HBV DNA. We now present evidence in PLC/PRF/5 cells for integration of HBV DNA into the host genome and expression of three RNA molecules containing HBV-specific sequences. These findings are consistent with observations in several animal virus models in which integrated viral DNA is found during oncogenic transformation.

HBV DNA contains a unique *Eco*RI site which was used for insertion of HBV sequences. Therefore, treatment of cloned recombinant λ phage or plasmid pA01 DNAs containing the complete sequence of fully double-stranded Dane particle DNA (3,250–3,300 base pairs) with *Eco*RI should release the entire sequence of HBV DNA as a single fragment, which can be identified by agarose slab gel electrophoresis, nitrocellulose filter transfer and hybridization to an appropriate ^{32}P-labelled HBV probe (Southern blot)[14]. Figure 1 shows the autoradiograph of a Southern blot of recombinant λ HBV DNA, λ HBV DNA digested with *Eco*RI and λ HBV DNA digested with *Eco*RI followed by a second restriction endonuclease to generate additional HBV fragments. *Eco*RI generates a single HBV fragment of ~3,250 base pairs (lane *b*), *Eco*RI followed by *Bam*HI generates two fragments of ~1,900 and 1,400 base pairs (lane *c*), *Eco*RI plus *Bgl*II generates three fragments of ~2,250, 700 and 100 base pairs (lane *d*), *Eco*RI plus *Hin*cII yields four fragments of ~1,800, 800, 450 and 200 base pairs (lane *e*) and *Eco*RI plus *Hin*dII (lane *f*) generates one 3,250-base pair fragment as found with *Eco*RI alone (that is, the HBV sequence in recombinant λ phage DNA contains no *Hin*dIII restriction site). In each case, the total length of HBV restriction fragments is approximately 3,250 base pairs. For reasons which are unclear, in lane *e* the hydrization signal for the 1,800 base pair band was weak and this band reproduced poorly on the photograph. For subsequent studies, restriction enzymes *Eco*RI and *Hin*dIII were used.

Figure 2 shows the autoradiograph of a Southern blot of PLC/PRF/5 DNA digested with either *Eco*RI or *Hin*dIII, using

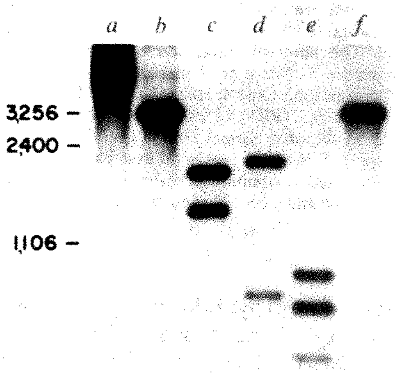

Fig. 1 Restriction enzyme analysis of cloned λ HBV DNA. Recombinant (5 μg) λ HBV DNA was digested with 5 units of *Eco*RI restriction endonuclease. Digested material (1 μg) was further digested with 1 unit of *Bam*HI, *Bgl*II, *Hin*cII or *Hin*dIII, respectively. All digestions were carried out in appropriate buffers at 38°C for 6–12 h. Aliquots (1 μg) of each digested sample were placed on a separate lane of a 0.8% agarose slab gel and electrophoresis carried out in Peacock and Dingman buffer[31] at 50 V for 5–6 h. After electrophoresis, the DNA fragments were transferred to nitrocellulose paper and the paper was hybridized with nick-translated ^{32}P-labelled pA01 HBV probe as described by Southern[15]. Nick-translation was carried out according to a modified procedure of Rigby *et al.*, using *E. coli* DNA polymerase I. Both ^{32}P-dATP and ^{32}P-dCTP (specific activity 300–800 Ci mmole^{-1}) were included in the reaction to obtain uniform labelling of high specific activity ($1-2\times10^8$ per DNA). After hybridization, the nitrocellulose paper was exposed overnight on Kodak XR-5 film for autoradiography. Lane *a*, undigested λ HBV DNA, lane *b*, λ HBV DNA + *Eco*RI; lane *c*, λ HBV DNA + *Eco*RI + *Bam*HI; lane *d*, λ HBV DNA + *Eco*RI + *Bgl*II; lane *e*, λ HBV DNA + *Eco*RI + *Hin*cII; lane *f*, λ HBV DNA + *Eco*RI + *Hin*dIII. The position of restriction fragments of plasmid pBR322 run on a separate lane are shown on the left.

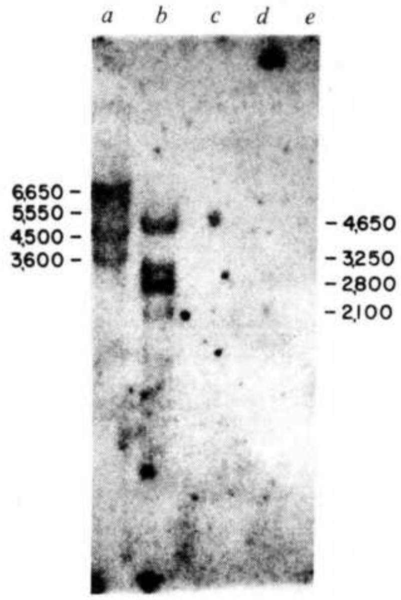

Fig. 2 Restriction enzyme analysis of total DNA from PLC/PRF/5 cells. PLC/PRF/5 cells were grown to confluence in monolayer culture using Eagle's minimal essential medium supplemented with glutamine, non-essential amino acids, 10% heat-activated fetal calf serum, penicillin, streptomycin and Fungizone. Trypsinized cells were lysed with detergent according to the procedure of Innis and Miller[33], nuclei were pelleted by centrifugation at 5,000*g* for 5 min, and DNA and nuclear RNA were obtained by SDS-phenol extraction followed by ethanol precipitation. Nuclear DNA was purified further by ribonuclease A digestion, followed by SDS-proteinase K treatment and phenol/chloroform/isoamyl alcohol extraction. DNAs from other tissues were purified essentially as described above, except that the starting material was total nucleic acids. Aliquots of 20 μg of each DNA sample were digested with *Eco*RI or *Hin*dIII in appropriate digestion buffer. To ensure complete digestion, 20 units of restriction endonuclease were used and incubation was at 37 °C. After 12 h of incubation, 20 additional units of fresh enzyme were added and incubation continued for an additional 12 h. Electrophoresis of these samples, their subsequent transfer to nitrocellulose paper and hybridization to ^{32}P-labelled pA01 HBV DNA were as described in Fig. 1 legend. The autoradiograph was developed by exposing the nitrocellulose paper for 5–7 days on Kodak XR-5 film using intensifying screens (Picker Corporation). Lane *a*, *Hin*dIII-digested PLC/PRF/5 DNA; lane *b*, *Eco*RI-digested PLC/PRF/5 DNA; lane *c*, *Eco*RI-digested rat liver DNA; lane *d*, *Eco*RI-digested normal human liver DNA; lane *e*, *Eco*RI-digested salmon sperm DNA. The length (in base pairs) of specific labelled fragments was determined by comparison with restriction enzyme fragments of plasmid pBR322 used as standards.

^{32}P-labelled HBV DNA as hybridization probe (specific activity 2×10^8 c.p.m. per μg). Lane *a* shows four HBV restriction fragments with *Hin*dIII of sequence length ~6,650, 5,550, 4,500 and 3,600 base pairs, respectively. The 5,550-base pair fragment reproduces poorly on this photograph but is present on all autoradiographs of this material. Lane *b* shows four HBV restriction bands with *Eco*RI, ranging from 2,100–2,200 to 4,650 base pairs. *Eco*RI-digested rat liver DNA (lane *c*), normal human liver DNA (lane *d*) and salmon sperm DNA (lane *e*) show no bands hybridizing with ^{32}P-HBV DNA. As one fragment with *Eco*RI and four fragments with *Hin*dIII are larger than cloned full-length double-stranded Dane particle DNA, these results suggest that HBV DNA sequences are integrated into PLC/PRF/5 cell line DNA. The possibility cannot be excluded that host or other virus-related sequences are associated with extrachromosomal HBV DNA to produce some of these bands. However, as *Hin*dIII recognizes no internal cleavage site in HBV DNA, the presence of four large fragments with this enzyme strongly favours integration of viral DNA sequences. The band migrating at 3,250 base pairs after *Eco*RI digestion (lane *b*) could represent a small amount of extrachromosomal (non-integrated) HBV DNA, and the 6,650-base pair band after *Hin*dIII treatment (lane *a*) could represent a dimer or circular concatomer of HBV DNA. Further studies will be necessary to characterize these bands fully.

The number and size of HBV restriction fragments suggest that more than one, but only a few, discrete host integration sites are involved. Although the lengths of fragments generated with *Hin*dIII are larger than those obtained with *Eco*RI, a more precise comparison cannot be made. This is especially true as HBV DNA integrated into different sites may contain deletions or rearrangements affecting the restriction pattern, and Dane particles from the original patient are not available for comparison.

To study viral RNA expression in this cell line, total cytoplasmic and nuclear RNAs were isolated and separated into poly(A)$^+$ and poly(A)$^-$ fractions. RNA samples were applied to denaturing glyoxal slab gels, blotted to diazobenzyloxymethyl (DBM)-cellulose paper and HBV sequences identified by hybridization with ^{32}P-HBV probe[15]. As shown in Fig. 3, total cytoplasmic poly(A)$^+$ RNA (lanes *a* and *a'*) reveals two bands containing virus sequences, 21.5S (3,050 nucleotides) and 19.5S (2,500 nucleotides). Total nuclear RNA (lane *b*) shows three bands of 27S, 21.5S and 19.5S (the migration of all components in this fraction is retarded slightly by the presence of high molecular weight nuclear RNA). The 21.5S and 19.5S bands in nuclear RNA probably represent the same components as found in the cytoplasm. Cytoplasmic poly(A)$^-$ RNA (lane *d*) also shows a 27S band (4,700 nucleotides). Hybridisable material in the nuclear fraction is alkaline labile (lane *c*), ruling out the possibility of DNA contamination, and poly(A)$^+$ RNA from normal human liver (lane *e*) shows no distinct radioactive bands, demonstrating the specificity of our HBV probe.

The biological activity and function of these viral RNAs are unknown. The presence of a poly(A)tail in the 21.5S and 19.5S RNA species suggests that they represent specific viral mRNAs. It has been reported that this cell line produces HBsAg[1–3], and a recent DNA sequencing study of Dane particle DNA proposes a

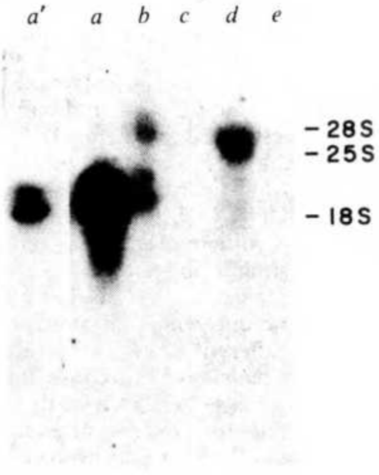

Fig. 3 Identification of RNA molecules containing HBV sequences in PLC/PRF/5 cells. Nuclei and cytoplasm from 2×10^8 PLC/PRF/5 cells were prepared as described in Fig. 2 legend. Isolated nuclei were resuspended and lysed in 50 mM Tris-HCl *p*H 7.5, 2 mM NaEDTA, 150 mM NaCl and 1% SDS. Nuclear RNA and DNA were isolated by phenol/chloroform/isoamyl alcohol extraction and nuclear RNA was recovered by repeated differential salt precipitation. Total cytoplasmic RNA was isolated from the post-nuclear supernatant fraction by SDS/phenol/chloroform/isoamyl alcohol extraction followed by ethanol precipitation. Total cytoplasmic RNA was fractionated further into poly(A)$^+$ and poly(A)$^-$ RNA by oligo(dT)-cellulose column chromatography. 15–60 μg of RNA was denatured by a glyoxal procedure[34] and electrophoresed on an agarose slab gel in Peacock–Dingman buffer[31] for 5–6 h at 50 V. RNA was blotted to DBM paper[16] and hybridized to nick-translated ^{32}P-labelled PA01 HBV DNA. After hybridization, the DBM paper was exposed on Kodak XR-5 film for autoradiography using intensifying screens. Lanes *a*–*e* were exposed for 3 days. Lane *a'* is lane *a* of the same gel exposed to autoradiography for only 17 h. Lane *a*, 15 μg of cytoplasmic poly(A)$^+$ RNA; lane *b*, 50 μg of total nuclear RNA; lane *c*, 50 μg of alkali-treated total nuclear RNA; lane *d*, 60 μg of cytoplasmic poly(A)$^-$ RNA; lane *e*, 20 μg of cytoplasmic poly(A)$^+$ RNA from normal human liver. The position of 18S, 25S and 28S ribosomal RNA markers determined in separate lanes is shown to the right.

892-base pair region as coding for this protein[9]; it is therefore surprising to find no viral RNA in the cytoplasm close to 1,000 nucleotides. Most probably, either the 21.5S or the 19.5S $\text{poly}(A^+)$ viral RNA codes for HBsAg. The finished polypeptide (molecular weight 25,000) may be derived by post-translational processing of a larger precursor. As the PLC/PRF/5 cell line produces only one known viral protein (HBsAg), the role of the other two viral specific RNAs remains unclear. These RNAs may code for nonstructural proteins which do not become incorporated into the mature virion, as observed in other systems after viral infection[16].

At present, the major evidence linking HBV to hepatocellular carcinoma is epidemiological[17]. A variety of virus–cell interactions have been described in oncogenic transformation and/or persistent viral infection in cultured cells, so the PLC/PRF/5 line provides an excellent model for studying these phenomena as related to HBV gene expression. The ability of these cells to grow rapidly in tissue culture as well as in soft agar[18], and to produce tumours in athymic *nu*/*nu* mice[19] (our unpublished observations), indicates a malignant phenotype. However, in considering the relationship between the presence of viral genes and tumorigenicity, it is important to remember that transformation may result from altered cellular gene expression rather than the function of HBV genes. Therefore, the mere presence of integrated HBV genes with limited expression of HBV proteins does not prove viral oncogenicity, although these findings are consistent with observations in other systems[19–23]. In spite of this limitation, evaluation of HBV genes and their expression in PLC/PRF/5 cells provides the first opportunity of studying the biology and pathobiology of HBV infection at the molecular level.

In the present study, viral DNA is transcribed into three specific RNAs. Although the function of these RNAs has not been determined, two are $\text{poly}(A)^+$ (21.5S and 19.5S) and presumably represent cytoplasmic viral mRNAs. The third viral RNA is $\text{poly}(A)^-$, is found in both the nucleus and the cytoplasm, and is larger than full-length Dane particle DNA. This suggests that the 27S RNA is derived by co-transcription of host and viral sequences from an integrated viral transcription unit, or that the full genome of hepatitis B virus in the cell is larger than that observed in Dane particles. Although other explanations are possible, evidence suggesting synthesis of small amounts of rapidly sedimenting RNA, containing viral and host sequences in molecules of larger apparent size than the viral genome, has been reported during integration of SV40 viral DNA[24–28]. In the present case, this material has been identified as a specific RNA molecule (27S or 4,700 nucleotides on agarose gel electrophoresis in strongly denaturing conditions) and represents a significant portion of viral sequences in both the nucleus and cytoplasm. The exact nature and role of 27S HBV RNA, as well as the other viral RNAs, remain to be determined.

After this manuscript was submitted, Marion *et al.*[28] reported similar findings of integrated HBV-DNA in the PLC/PRF/5 cell line.

We thank Dr J. Summers[30] for providing recombinant λ phage and pA01 HBV DNA, Dr I. Millman for PLC/PRF/5 cells and Dr Probir Sarkar for advice. Research was supported in part by NIH grant AM 17702, American Cancer Society Institutional grant IN-28U and the Sara Chait Memorial Foundation. D.S. is the recipient of an NIH John E. Fogarty International Fellowship. These studies represent part of a thesis by N. R.-O. to be submitted to the Sue Golding Graduate Division, Albert Einstein College of Medicine, in partial fulfillment of the requirements for the degree of D.Phil.

Hepatitis B virus (HBV) may be one of the agents involved in the aetiology of human primary liver cancer[1]. This hypothesis is supported by (1) the similarity between the geographical distribution of chronic carriers of the viral surface antigen (HBsAg) and that of hepatocellular carcinoma (HCC); (2) the increase in the prevalence of HBV markers in serum of patients with primary liver cancer when compared with the general population[1]; (3) the observation that HBV infection precedes the development of the tumour[1]. Moreover, these epidemiological indications of an association between HBV infection and hepatocellular carcinoma are supported by the detection of HBV markers such as HBsAg[2,3] or viral DNA sequences, although in a non-integrated form[4,5] in tumour tissue. To study the relationship between HBV and primary liver cancer further, we looked for the presence of free or integrated viral DNA in tumour tissue of human hepatocellular carcinomas and in a HBsAg-producing human hepatoma cell line[6]. Using the blot-transfer hybridization technique and cloned HBV DNA as a probe, we have now demonstrated that the viral DNA is integrated in the cellular genome both in tumour tissue and in a hepatoma cell line.

Tumoral tissue was an autopsy sample obtained from a 53 yr old man who lived in the savanna in the Ivory Coast (Ethnie Bete). HBsAg (subtype undetectable) and Anti-HBc were present in the serum (as tested by radioimmunoassay: AusRIA-II and Corab, Abbott Laboratories). HBV e

antigen (tested by immunodiffusion) and anti-HBsAg (tested by radioimmunoassay: Ausab-Abbott Laboratories) were absent from the serum. Immunofluorescence, using anti-HBsAg and anti HBcAg labelled with fluoresceine isothiocyanate[7], was negative in the tumour tissue. Normal liver tissue from this patient was not available.

The cellular DNA was extracted as described in Fig. 1 legend. Non-digested DNA and restriction fragments were analysed by agarose gel electrophoresis (Fig. 1*a*). We chose the restriction endonucleases *Eco*RI and *Hin*dIII because *Eco*RI cleaves the HBV genome once and *Hin*dIII does not cut any of the HBV genomes so far cloned[8,9]. Cloned P-labelled HBV DNA was used as a probe to detect viral sequences[8]. As shown in Fig. 1*a*, hybridization of non-digested cellular DNA with the HBV probe occurred only in the high molecular weight (MW) DNA. Hybridization of the *Hin*dIII restriction fragments revealed the existence of five bands (Fig. 1*a*). Three bands corresponded to DNA fragments which migrated more slowly than the HBV genome and had MWs of 25,000, 19,000 and 12,000 respectively. Two bands of weaker intensity were located at the position of DNA fragments of MWs 3,200 and 2,400. Hybridization of the *Eco*RI restriction fragments revealed the presence of several bands (Fig. 1*a*). Three bands corresponded to DNA fragments of respective MWs 14,000, 8,000 and 6,500. Another particularly intense band was located at the position of the HBV genome. A similar pattern was observed with DNA extracted from tumour tissue of two other patients (Ivory Coast) with hepatocellular carcinoma (data not shown). No hybridization signal was observed with DNA extracted from a normal liver as a control (data not shown).

We analysed in the same way DNA from the hepatoma cell line PLC/PRF/5 (a generous gift from Dr J. Alexander) which was derived from a human hepatocellular carcinoma and which produced HBsAg (subtype ad)[10]. At the 100th passage, HBsAg was produced in the supernatant at a concentration of 50 ng ml^{-1}. Hybridization of non-digested cellular DNA occurred only in high molecular weight DNA (Fig. 1*b*). Analysis of *Hin*dIII restriction fragments revealed the presence of five bands of MWs 24,000, 17,000, 12,000, 6,500 and 4,200, respectively. Analysis of *Eco*RI restriction fragments revealed the presence of eight bands; one of these was intense and corresponded to a DNA fragment of MW 3,000 (Fig. 1*b*). The DNA pattern was identical at the 100th and 140th passages.

Taken together, these results demonstrate the integration of HBV DNA sequences in the cellular DNA of both the tumour tissue and the cell line. Our results differ from those of another study of human tumour tissue in which only free viral DNA was detected[4,5]. However, our results obtained with the cell line PLC/PRF/5 are in agreement with those observed recently by Marion *et al.*[11], although the number and size of the restriction DNA fragments are different. The presence of several sharply delineated bands in the *Hin*dIII pattern of the tumour tissue (Fig. 1*a*) suggests the existence of a limited number of integration sites in the cellular DNA. These results are consistent either with the development of the liver tumour from one clone with several integration sites or with its development from a few clones each having particular integration sites. The difference in intensity of the bands could reflect a variability of the number of viral genomes or of the viral DNA length in the different integration sites. The very intense band located at the same position as that of HBV genome in the *Eco*RI pattern of the tumour tissue is not present in the non-digested DNA pattern. This result is consistent with the presence of two or more whole viral genomes inserted in tandem head-to-tail. The presence of a very small quantity of free viral DNA cannot be ruled out by our experiments.

The presence of integrated HBV DNA sequences in both the human hepatocellular carcinomas and in the cell line reinforce the interest of these two results. Indeed, the Alexander cell line produces HBsAg, possesses characteristics of malignancy[6] and induces tumours in mice that are similar to human hepatoma[12]. Demonstration of the integration of HBV genome in cellular DNA is an additional argument for HBV as a factor in human hepatocellular carcinoma. Until now, integration of viral DNA in the genome of human tumours has only been confirmed for Epstein–Barr virus in Burkitt's lymphoma and some nasopharyngeal carcinomas[13]. Our observation is another example of such a relationship between a DNA virus and human cancer. However, the demonstration of integrated HBV DNA sequences is not sufficient to assert the role of HBV in the onset of human primary liver cancer. Additional studies should compare the pattern observed in non-tumorous and tumorous liver cells.

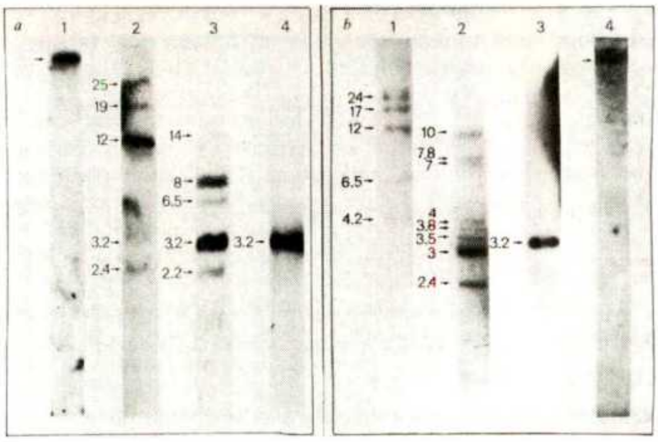

Fig. 1 The liver tumorous tissue is a postmortem sample obtained 6 h after death and kept frozen in liquid N_2. Tissue was pulverised in liquid N_2, then transferred into lysis buffer (Tris-HCl 10 mM, *p*H 7.8, NaCl 10 mM, SDS 0.5%, EDTA 10 mM) and digested with 500 μg ml^{-1} of Pronase (Boehringer) at 37 °C for 2 h. DNA was extracted with phenol/chloroform, dialysed, treated with 100 μg ml^{-1} of RNase A (Boehringer) and dialysed. Cellular DNA of the cell line was extracted by the same procedure using the same lysis buffer. The extracted DNA had an average MW of 100×10^6. Digestion with restriction endonucleases *Eco*RI (Biolabs) and *Hin*dIII (Biolabs) was carried out at 37 °C for 8 h using 2 units of the enzyme for 1 μg of DNA and the appropriate reaction mixtures. Digestion products were precipitated with ethanol, dissolved in electrophoresis buffer (Tris-HCl, *p*H 7.8, 40 mM, sodium acetate 5 mM, EDTA 10 mM) and 0.2% agarose beads[14]. Electrophoresis was carried out in 0.8% agarose gels for restricted DNA and 0.4% gels for non-digested DNA using horizontal slabs of 20 cm long and 0.5 cm thick at 1 V cm^{-1} for 24 h. DNA was then transferred to nitrocellulose filter by a modification of the Southern technique described by Wahl *et al.*[15]. The filter was hybridized using cloned HBV DNA[8] as a probe and the nick-translation procedure[16]. [α-^{32}P]dCTP (Amersham, 2,000 Ci mmol^{-1} and [α-^{32}P]dTTP (Amersham, 2,000 Ci mmol^{-1}) were used and the probe yielded a specific activity of 4×10^8 c.p.m. per μg. The hybridization procedure used dextran sulphate as described by Wahl *et al.*[15]; 5×10^6 c.p.m. of probe was added to each filter. The nitrocellulose filter was autoradiographed with preflashed Kodak X-Omat R film in the presence of a Dupont Lightning Plus screen. *a*, Tumour tissue: lane 1, 30 μg of non-digested cellular DNA; lane 2, 80 μg of cellular DNA digested with *Hin*dIII; lane 3, 80 μg of cellular DNA digested with *Eco*RI; lane 4, 30 μg of cellular DNA from normal liver cells mixed with 10 pg of cloned HBV DNA. *b*, Cell line PLC/PRF/5: lane 1, 20 μg of cellular DNA digested with *Hin*dIII; lane 2, 20 μg of cellular DNA digested with *Eco*RI; lane 3, 10 pg of cloned HBV DNA; lane 4, 20 μg of non-digested cellular DNA. Cloned HBV DNA digested with *Bam*HI and λplac5cI857S7 DNA digested with *Hin*dIII were used as molecular weight markers.

We thank Professors Attia, Beda, Loubienes and Drs Carsuzaa, Condat and Soubeyran for providing autopsy samples, Professor Benhamou and Mr Roland Nageotte for helpful discussion, and Miss Michelle Fonck for technical assistance.

Integration of hepatitis B virus sequences and their expression in a human hepatoma cell

Jeffrey C. Edman, Patrick Gray, Pablo Valenzuela, Leslie B. Rall & William J. Rutter

Department of Biochemistry and Biophysics, University of California, San Francisco, California 94143

Hepatitis derived from hepatitis B virus (HBV) infection is endemic throughout the world, but it is particularly prevalent in Asia and Africa[1]. In these areas, demographic studies show a strong coincidence between HBV infection (assayed by HBV antigenic markers) and the incidence of primary liver cancer. On these grounds, a causal link between HBV infection and primary hepatocellular cancer has been proposed[2–5]. Recently, a human hepatoma cell line (PLC/PRF/5; Alexander cells) has been shown to produce hepatitis B surface antigen (HBsAg)[6]. We show here that the Alexander cell line contains at least six (four complete and two partial) hepatitis B viral genomes integrated into high molecular weight host DNA. An analysis using specific probes to fragments of the HBV genome suggests that integration of the virus in most cases occurs at the nicked cohesive end region of the virus. Expression of viral sequences using Northern blots demonstrates the presence of RNA transcripts specific for the surface antigen sequences of HBV DNA and the absence of detectable transcripts corresponding to the hepatitis B core antigen.

The study of the possible role of HBV in cell transformation has been hampered by the lack of an *in vitro* system for propagation of the virus. However, with the Alexander cell, which is derived from a hepatoma obtained from a male individual from Mozambique, HBsAg accumulates in the media as characteristic 22-nm particles[6,7]. The HBsAg of Alexander cells is identical to that isolated from HBV carriers and contains the unglycosylated and glycosylated forms of HBsAg protein (molecular weights (MWs) 25,000 and 29,000, respectively)[8,9]. In contrast, the Alexander cells do not produce hepatitis B core antigen (HBcAg; MW 19,000[8]), the cryptic HBeAg[10] or free virus (Dane particles)[11]. The presence of the endogenous Dane particle DNA polymerase that fills in the partially single-stranded region of HBV DNA to generate a double-stranded circular structure with cohesive ends[12] has not been tested. These cells show typical epithelial cell growth and exhibit many of the functions of liver cells. They also induce HBsAg-positive tumours in nude mice[13].

We have examined the physical state and expression of the HBV sequences in Alexander cells using the techniques developed by Southern for DNA analysis[14], 'Northern' blots for RNA analysis[15] and nick-translated cloned HBV sequences as probes[16]. Figure 1 shows the hybridization with the cloned HBV DNA probe to *Hin*dIII, *Eco*RI and *Hin*dIII–*Eco*RI digestions of high molecular weight DNA prepared from Alexander cells. The autoradiograph shows the presence of several large DNA fragments that hybridize with the probe. *Hin*dIII digestion (lane 2) yields at least six hybridizing bands, ranging from 4.2 to >30 kilobases. The unit length in all six is greater than that of the HBV DNA (3.2 kilobases). As there are no *Hin*dIII sites in any of the cloned HBV sequences reported, the data suggest at least six different sites for the integration of HBV DNA into host cell DNA. There is no detectable free viral DNA at 3.2 kilobases; this is consistent with the lack of virus production of these cells. This pattern of hybridization is observed in Alexander cells after many passages in tissue culture and also in recloned populations of the cells. Thus, the multiplicity of bands does not reflect cell heterogeneity.

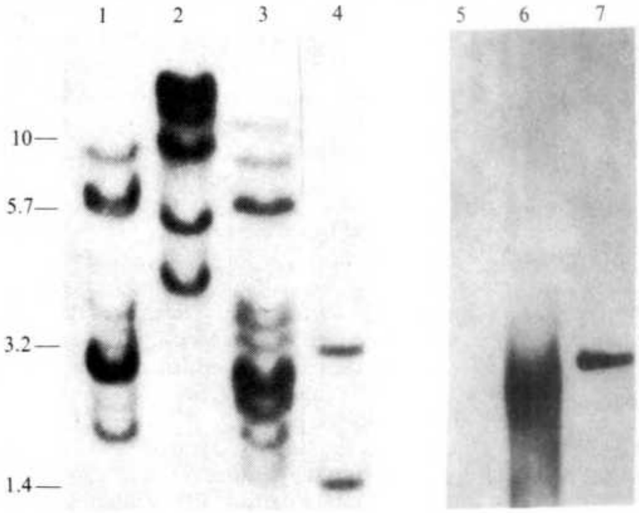

Fig. 1 Hybridization of ^{32}P-labelled HBV DNA probe to *Eco*RI (lane 1), *Hin*dIII (lane 2) and *Hin*dIII-*Eco*RI (lane 3) digests of Alexander cell DNA; standards were derived from cloned HBV DNA (lane 4, 3,200 and 1,400 base pairs), *Eco*RI-digested normal human liver DNA (lane 5), *Eco*RI-digested chronic hepatitic liver DNA (lane 6) and Dane particle DNA made double stranded by endogenous DNA polymerase reaction (lane 7). DNA was prepared from Alexander cells by suspending 0.5 ml of packed cells in 5 ml of 10 mM Tris-HCl (*p*H 7.4), 10 mM NaCl and 2 mM EDTA-Na_2. SDS and proteinase K were then added slowly to 2.5% and 0.1%, respectively. The solution was incubated for 18-24 h at 37 °C, extracted once with phenol, once with chloroform/isoamyl alcohol (24 : 1) and precipitated with two volumes of ethanol. The precipitate was resuspended in 5 ml of the same buffer, RNase A and RNase T1 added to 40 $\mu g\ ml^{-1}$ and 10 $\mu g\ ml^{-1}$, respectively, and digested for 1 h at 37 °C. The phenol and chloroform/isoamyl alcohol extractions were repeated, and the DNA precipitated with ethanol and resuspended in 10 mM Tris-HCl, *p*H 7.4, and 1 mM EDTA. DNA from liver samples was prepared in an identical manner except the tissue was homogenized briefly with a Teflon homogenizer before the addition of SDS and proteinase K. Dane DNA was made completely double stranded and extracted according to Landers *et al.*[12]. Restriction enzyme (New England Biolabs) digests were carried out according to the manufacturer's instructions. Completion of digests was monitored by addition of 1 μg of λ DNA to a small fraction of the digest and digested DNA was precipitated with ethanol. The samples were run on 1% agarose gels. DNA was transferred to nitrocellulose filters according to Southern[14] and hybridized to nick-translated[23] HBV probe in the presence of 10% dextran sulphate[24]. Numbers on the left-hand side indicate the fragment sizes in kilobase pairs.

*Eco*RI digestion (Fig. 1, lane 1) produces a series of 10 bands ranging from 2.4 to 9.5 kilobases with a particularly intense band at 3.0 kilobases. As HBV DNA contains a single *Eco*RI site, it is expected that *Eco*RI digestion would give twice as many hybridizing fragments as *Hin*dIII-restricted DNA. Ten rather than twelve bands were observed. This discrepancy may be the result of overlap of bands at the 3.0 kilobase band, as an analysis using a more highly resolving gel system shows that there are multiple bands in this region (data not shown). Figure 1 also shows the results of a similar analysis of HBV viral DNA (lane 7), normal human liver DNA (lane 5) and DNA from the liver of a chronic hepatitis patient (lane 6). No hybridization signal was detected in the DNA from normal liver; thus, there are no sequences closely related to HBV DNA in the normal human genome. Hybridization characteristic of free viral DNA was detected from the DNA of a chronic hepatitic liver.

0028–0836/80/310535—04$01.00

To determine the fraction of HBV information retained in each of the six integrated viral sites, we hybridized Alexander DNA with fragments of HBV DNA. Cloned HBV DNA was digested with a combination of restriction enzymes to yield a series of fragments each representing roughly one-sixth of the viral genome. Figure 2*a* and *b* show the source of these fragments and their positions within the viral genome. These fragments were purified by polyacrylamide gel electrophoresis, individually nick translated and hybridized with *Hin*dIII-digested Alexander DNA. Autoradiographs of these hybridization reactions are presented in Fig. 3*a* and summarized in Fig. 2*c*. *Hin*dIII digestion generates the six fragments which presumably contain full-length integrated HBV sequences. Four of the bands (30, 27, 18 and 5.7 kilobases) hybridize with all the probes; thus, each contains a major fraction of the HBV genome. However, the 10-kilobase band *Hin*dIII fragment does not hybridize with the *Bgl* 3 probe (see Fig. 2 legend) and the 4.2 kilobase *Hin*dIII fragment does not hybridize with the *Bgl* 3 and *Bgl* 2 probes and therefore contain partial HBV genomes. The absent sequences of both partial genomes are in the region of the core antigen gene. The apparent deletion of HBV information in the 10- and 4.2-kilobase fragments could also be explained by the presence of additional *Hin*dIII sites in these two integrated copies. This would generate an additional *Hin*dIII fragment hybridizing to the apparently deleted regions. No such fragments were detected.

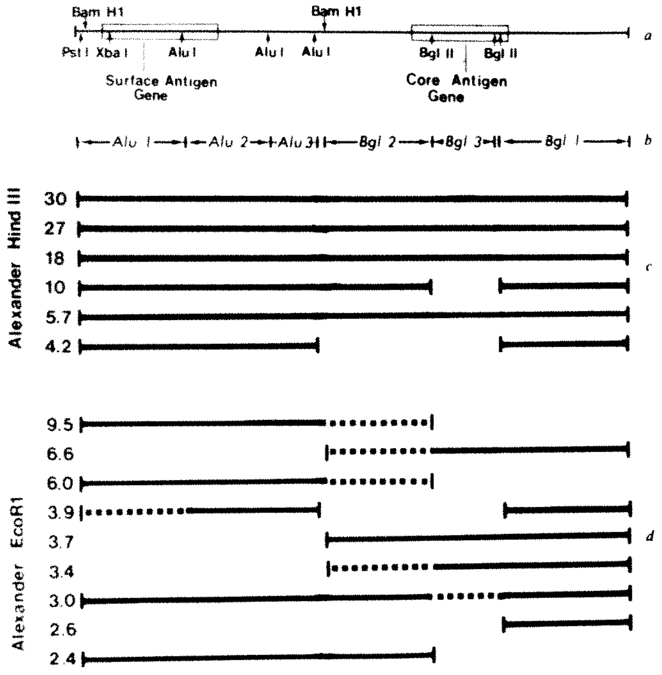

Fig. 2 Source of HBV DNA fragment probes and summary of hybridization to Alexander cell DNA digests. *a*, Restriction map of cloned HBV DNA linearized by *Eco*RI[16]; *b*, fragment probes used in the hybridization reactions. Cloned HBV DNA was digested with *Bam*H*I* and *Eco*RI, and the 1,800- and 1,400-base pair fragments purified by agarose gel electrophoresis and electroelution. The 1,800-base pair fragment was digested with *Bgl*II to yield fragments *Bgl* 1–*Bgl* 3 and the 1,400-base pair fragment with *Alu*I to yield *Alu* 1–*Alu* 3. Fragments derived from these digests were purified by polyacrylamide gel electrophoresis and individually nick translated. The sizes of the various fragments (in base pairs) are: *Alu* 1, 714; *Alu* 2, 344; *Alu* 3, 242; *Bgl* 1, 789; *Bgl* 2, 584; *Bgl* 3, 421. *c*, Summary of hybridization of fragment probes to *Hin*dIII-digested Alexander cell DNA. The sizes (in base pairs) of *Hin*dIII fragments hybridizing to the entire HBV probe are given on the left. A solid bar represents a positive hybridization result and absence of a bar represents no hybridization to the same regions as shown in *a* and *b*. For example, the 10-kilobase *Hin*dIII fragment of Alexander cell DNA does not hybridize to the *Bgl* 3 probe. *d*, Summary of hybridization of fragment probes to *Eco*RI-digested Alexander cell DNA. As in *c*, *Eco*RI fragment size is given on the left. A solid bar represents strong hybridization, a dashed bar weak hybridization. Two patterns of hybridization are evident. The 9.5-, 6.0-, and 2.4-kilobase bands hybridize from the *Eco*RI site through the surface antigen gene with the *Bgl*2 region and the 6.6-, 3.7- and 3.4-kilobase bands hybridize from the *Eco*RI site through the core gene into *Bgl*2. Anomalous hybridization is observed in the 3.9-, 3.0- and 2.4-kilobase bands.

The orientation of HBV DNA sequences within the Alexander genomic DNA has been studied by hybridizing the specific probes to *Eco*RI-digested Alexander DNA (Fig. 3*b*). As there is a single *Eco*RI site in the viral genome and assuming that integration is not random with respect to the virus, two patterns of hybridization should be observed, one hybridizing to fragments of HBV from the HBV *Eco*RI site clockwise to the region of integration, and the other pattern going counterclockwise. As summarized in Fig. 2*d* , two such patterns are obtained. One hybridizes from the *Eco*RI site through the surface antigen gene to a region approximately 1,600 base pairs from the *Eco*RI site; the other hybridizes approximately 1,600 base pairs in the opposite direction. Thus, *Eco*RI cleavage essentially bisects the integrated genome. This places the integration site in the region of the cohesive end region of Dane DNA[17]. There are three exceptions to this general pattern. One is the 3.9 kilobase fragment that hybridizes to both sides of the *Eco*RI site in one of the integrated regions. Another exception is the 2.6 kilobase band hybridizing only to a small region of HBV. This probably arises from the integration of a partial HBV genome. Finally, the 3.0 kilobase band apparently hybridizes with all regions of the genome. The hybridization intensity varies with different probes and is particularly weak with the *Bgl* 3 probe. The width of the band also varies, being nearly resolved into two bands using *Alu* 1 as a probe and appearing as a single band using *Bgl* 1. As this band may be resolved into three bands, it is possible that the anomalous hybridization in this region is due to a multiplicity of bands representing a combination of fragments having the two hybridization patterns. Other possible explanations are tandem integration of the virus or the loss of an *Eco*RI site in one of the viral copies coupled with the presence of *Eco*RI sites flanking the viral sequences.

The orientation of HBV integration may be responsible for the selective pattern of HBV gene expression in these cells. An analysis of the expression of HBV was carried out by hybridization of HBV probes to poly (A)-enriched Alexander cell RNA fractionated into size classes by electrophoresis in denaturing conditions[18]. This RNA was transferred to diazotized paper as described by Alwine *et al*[18]. and then hybridized with cloned HBV DNA probe (Fig. 4). The predominant hybridization signal is a high molecular weight RNA approximately the size of 18S ribosomal RNA(~2,000 bases). This band hybridizes specifically to the *Alu* 1 fragment (see Fig. 2 legend) of the HBV genome that contains the surface antigen gene but includes 300 base pairs 5′ to the gene (the *Bgl* A probe, see Fig. 4 legend) and 700 base pairs 3′ to the gene (the *Bgl* B probe). This major transcript does not hybridize to the *Bgl* 1, *Bgl* 2 or *Bgl* 3 probes, demonstrating the absence of core antigen-specific transcripts. These studies suggest that at least 1,500 base pairs of the HBV genome hybridize to the transcript. As this is smaller than the total transcript, additional sequences may be contributed by transcription of sequences of the Alexander genomic DNA and/or by poly (A) addition. HBV probes also hybridized to larger and smaller RNA sequences than the major transcript. This hybridization is HBV-specific as negligible background is observed in the hybridization of HBV DNA to uninfected liver RNA (data not shown). The HBV-related RNA which is larger than the major transcript is obviously of considerable significance because it must represent either a precursor to the approximately 2,000-base major transcript or an independent transcript(s). The lower molecular weight material probably represents processing or degradation of the major transcript, as is seen in other systems.

Others have previously investigated the question of HBV integration into the host cell genome. Summers *et al.*[19] studied a series of six hepatomas using nick-translated HBV DNA. They concluded that some of the tumours contained HBV DNA but that none contained integrated virus. Marion *et al.*[20] have recently reported the integration of HBV in Alexander cells. They detected only three *Hin*dIII fragments hybridizing to total

HBV probe, roughly corresponding to the lower three bands found in Fig. 1, lane 2. The source of this discrepancy is uncertain; however, it is not a result of partial cleavage by restriction enzymes in our experiments. The present experiments demonstrate that HBV sequences are integrated into a minimum of six different sites in Alexander cell DNA. The results suggest that the nicked cohesive end region of HBV DNA coincides with the region of integration of at least several of the HBV fragments. A circular structure with terminally redundant ends has been suggested as the precursor to integration in retroviruses, known integrating viruses[21,22]. Such a structure could be formed in HBV by repair of the nicked region with the endogenous polymerase activity, resulting in a structure that contains a terminally redundant sequence.

Integration of HBV in a malignant cell does not imply that the virus is the oncogenic agent. However, viral transformation is usually associated with the integration of viral sequences into host chromosomal DNA. If HBV is an oncogenic virus, the transformation event producing the Alexander cell might have involved the gene product HBsAg or be some function of the integration of HBV. Analysis of the integration of HBV in other hepatomas, as well as efforts to obtain the expression of the HBsAg gene in mammalian cells, may help to clarify this issue. However, the putative role of HBV in transformation itself will be greatly facilitated by the development of an *in vitro* cell system that is capable of propagation and integration of the virus.

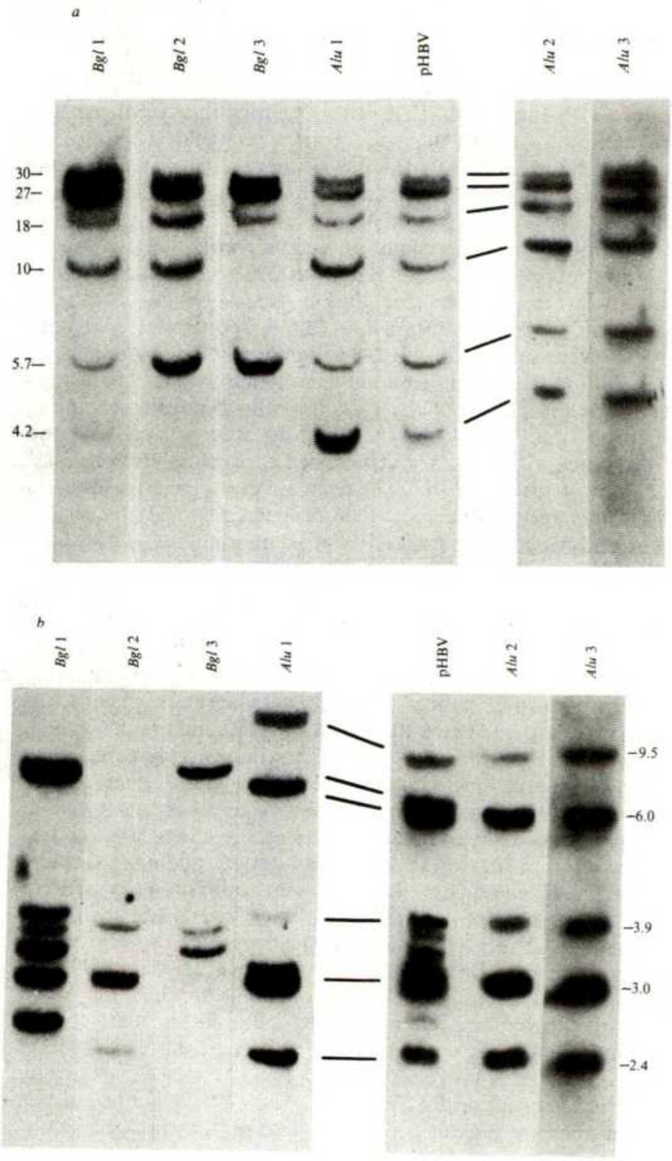

Fig. 3 Hybridization of *Hin*dIII (*a*) and *Eco*RI (*b*) digests of Alexander DNA with probes representing fragments of HBV DNA. Digestion products were run on 0.8% agarose gels and blotted to nitrocellulose filters. Individual lanes were cut out and hybridized to probes derived from cloned HBV DNA. The various probes are described in Fig. 2*a*,*b*. pHBV represents probe prepared from the entire HBV sequence. These hybridizations are summarized in Fig. 2*c*,*d*. Fragment sizes are indicated in kilobase pairs.

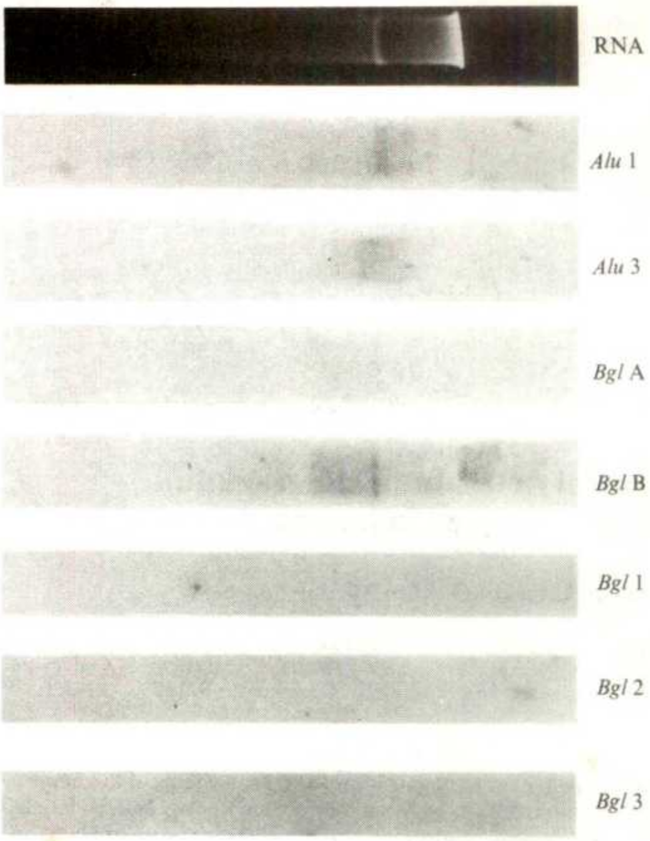

Fig. 4 Hybridization of poly(A)-enriched Alexander cell RNA with ^{32}P-cloned HBV DNA fragments. RNA was isolated from Alexander cells by the method of Chirgwin *et al.*[25] and passed once over oligo(dT)-cellulose. This RNA was run on a methyl mercury agarose gel and transferred to diazotized paper as described by Alwine *et al.*[15]. Individual lanes were cut out and hybridized to the various probes as shown in Fig. 2*b*. In addition, two other probes were used: *Bgl* A was derived from *Bgl* 1 and represents a 100-base pair fragment adjacent to the *Eco*RI site, and *Bgl* B is derived from *Bgl* 2, being 100-base pairs from the *Bam*HI site. RNA lane shows an ethidium bromide stain of the gel before transfer.

We thank Drs J. Birnbaum, M. Hilleman, R. Hirschman and A. Tytell for the initial supply of Alexander cells and Dane particle preparations, Dr E. Smuckler for human hepatitic liver, Dr H. M. Goodman for helpful discussion, and L. Spector for preparation of the manuscript. P.G. is a fellow of the Damon Runyon–Walter Winchell Cancer Fund. This research was supported by a grant from Merck Sharpe & Dohme Research Laboratories.

Partial deletion of the α-globin structural gene in human α-thalassaemia

Stuart H. Orkin & Alan Michelson

Division of Hematology-Oncology, Children's Hospital Medical Center, Sidney Farber Cancer Institute, Department of Pediatrics, Harvard Medical School, Boston, Massachusetts 02115

Defective synthesis of specific polypeptide chains of haemoglobins is the hallmark of human disorders known collectively as the thalassaemia syndromes[1]. Genetic lesions intimately linked to or within the globin genes are responsible for these conditions. Recently, the molecular basis of several forms of thalassaemia has been clarified by examination of the organization and structure of globin genes. Gene mapping studies using the gel blotting technique of Southern[2] have revealed an array of deletions involving globin structural genes in thalassaemias[3–12] and nucleotide sequencing has identified a point mutation responsible for thalassaemia in one individual[13]. In most α-thalassaemias, deletion of entire α-globin structural genes has been observed[3,4]. In specific forms of β-thalassaemia in which δ-globin chain expression is affected ($\delta\beta$-thalassaemia, $\gamma\delta\beta$-thalassaemia and hereditary persistance of fetal haemoglobin syndrome), various deletions within the cluster of closely linked γ-, δ- and β-globin genes occur[5–9]. In some Asian Indian individuals with β°-thalassaemia, an internal deletion in the DNA involving the 3′-portion of the β-globin gene has been described[10–12]. Lastly, in one Chinese patient with β°-thalassaemia, a nonsense mutation within the β-sequence has been identified[13]. We now report a new genetic lesion present in some individuals with α-thalassaemia: an extensive deletion of the 5′ portion of the α-globin structural gene. This defect has been characterized by DNA sequence analysis of cloned α-thalassaemia genes.

In normal humans the α-globin structural genes are duplicated and closely linked[14]. By gel blotting experiments these genes have been localized to a 22.5 kilobase fragment of genomic DNA generated by the restriction enzyme *Eco*RI. In α-thalassaemic DNA samples, several different alleles of the normal complex are observed. These include *Eco*RI fragments of 22.5, 18–20 and 2.6 kilobases in length[15,16]. The 22.5-kilobase fragment, grossly normal by restriction mapping, contains two structural genes, one of which is presumed to be functionally abnormal on the basis of its presence in some individuals with HbH disease α-thalassaemia, a condition in which only one functional α-globin gene exists. The 18–20-kilobase fragment contains a single α-gene that most commonly arises due to non-homologous crossing-over within the region of the duplicated structural genes. We focus here on the 2.6-kilobase fragment, identified only in several individuals with HbH disease originating from the Mediterranean basin. On the basis of DNA–DNA hybridization[15,16], this fragment seemed to contain at most a single α-globin structural sequence. To characterize this novel restriction fragment in detail, we have cloned it in bacteriophage λ vectors from two unrelated individuals with α-thalassaemia and analysed its structure by restriction mapping and DNA sequencing.

The α-specific 2.6-kilobase fragments were cloned from these two individuals by different strategies. The lymphocyte DNA of patient 1 (HbH disease genotype: 18–20 kilobases/2.6 kilobases[15]) was digested with *Eco*RI and fragments of 2.2–2.8 kilobases were isolated by preparative agarose gel electrophoresis. This enriched DNA fraction was ligated to the outer arms of phage λgtWES (ref. 17) and packaged *in vitro* into viable phage[18], and recombinants were screened by the plaque assay method of Benton and Davis[19] using total $(\alpha+\beta)$ ^{32}P-labelled globin cDNA as probe. Positive phages were then rescreened using nick-translated DNA from the plasmid α-cDNA clone JW101[20]. Among approximately 3×10^5 recombinants, one α-globin-specific phage was isolated. Analysis of its DNA indicated that, in addition to a 2.6-kilobase fragment, at least two other DNA fragments in the 2–3-kilobase size range were present. The 2.6-kilobase fragment was recloned in λ Charon 16A (ref. 21) free of these other human fragments. This phage was designated $\lambda\alpha$T1(2.6). A 'library' of the lymphocyte DNA of patient 2 (HbH disease genotype: 22.5 kilobases/2.6 kilobases) was prepared in λCharon 4A (ref. 21) by the procedure of Kemp *et al.*[22]. Screening of this library constructed from partial *Eco*RI* digestion fragments yielded several α-specific phage containing the 2.6-kilobase fragment. From one such isolate the 2.6-kilobase fragment was subcloned in λ Charon 16A and designated $\lambda\alpha$T2(2.6).

Gel blotting of these recombinant phage with α-globin probes specific for sequences either 5′ or 3′ to the *Hin*dIII site normally present at the codons for amino acids 90/91 of the α-sequence[14,23] demonstrated that coding sequences from both regions were present in the 2.6-kilobase *Eco*RI fragment (Fig. 1). Additional restriction mapping immediately raised questions regarding the nature of the cloned globin gene. For example, cleavage sites for *Mbo*II and *Taq*I located normally in the α-sequence within the 5′-untranslated region and at the codons for amino acids 46/47 (ref. 23), respectively, were not present in the anticipated positions 5′ to the intragenic *Hin*dIII site (Fig. 2). *Taq*I and *Mbo*II sites located approximately 55 and 170 base pairs 3′ to the *Hin*dIII site were located within what was found to be an intervening sequence of approximately 150 base pairs within the cloned α-thalassaemia gene (see below and Fig. 2). The presence of these latter restriction sites in this α-globin gene is in accord with recent findings regarding intervening sequences of cloned normal human α-genes[24]. In agreement with our previous mapping of genomic DNA, *Bam*HI and *Hpa*I[15], as well as *Sac*I and *Bgl*II, did not cut the 2.6-kilobase fragment.

To determine the nature of the cloned globin gene and to localize the lesion responsible for thalassaemia in this instance, DNA sequencing was carried out using the chemical degradation method of Maxam and Gilbert[25]. The sequencing strategy and a partial sequence of the gene from approximately −170 to +60 base pairs relative to the intragenic *Hin*dIII site are shown in Figs 2–4. The nucleotide sequence predicts the correct α-globin amino acid sequence from amino acids 57 to 99. An intervening sequence, the initial portion of which is shown, interrupts the coding sequence after codon 99, as is the case in the mouse α-globin gene[26] and probably also the normal human α-globin genes[24]. There is an abrupt loss of the α-globin coding sequence 5′ to codon 57 (Figs 3, 4). The DNA sequence of this region does not encode any globin-like polypeptide. In fact, it contains a termination codon (UGA) at the position expected for codon 48. Gel blotting experiments (not shown) did not reveal any hybridizable α-globin sequences 5′ to the *Hin*fI site depicted in Fig. 2, therefore indicating that the missing 5′ portion of the α-sequence is not contained within the cloned 2.6-kilobase fragment. Additional DNA sequencing, to be reported elsewhere, has revealed a complete α-globin sequence for codons 100–141 following the intervening sequence as well

0028-0836/80/310538—03$01.00

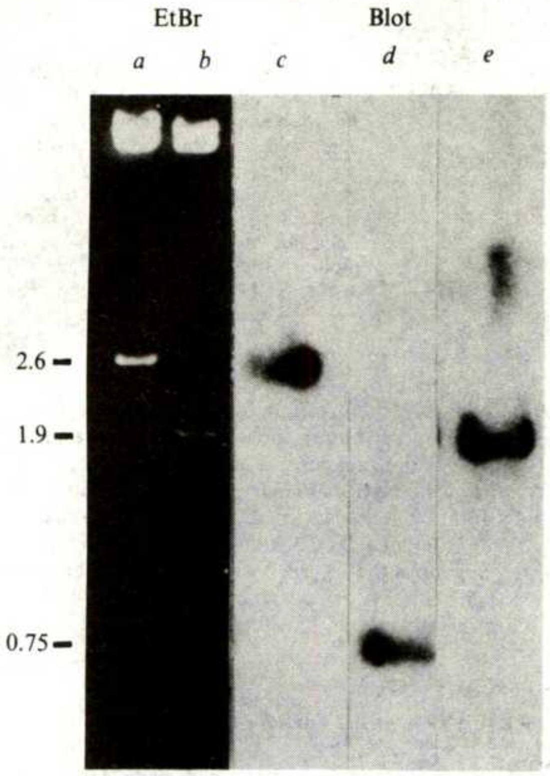

Fig. 1 Gel blotting of $\lambda\alpha$T1(2.6) DNA with 5'- and 3'-specific α-probes. Recombinant phage DNA (0.5 μg) was digested with *Eco*RI alone (lanes *a,c*) or *Eco*RI + *Hin*dIII (lanes *b, d, e*) and electrophoresed in 1% agarose. Ethidium bromide (EtBr) staining of the DNA is shown in lanes *a,b*. Lanes *c,d,e* represent hybridization to 5' + 3'-specific, 5'-specific and 3'-specific α-globin DNA probes, respectively. 5' + 3'-specific probe was prepared by nick translation of plasmid JW101 DNA[20]. Probes specific for α-sequences 5' and 3' to the intragenic *Hin*dIII site were prepared from JW101 DNA digested with *Hin*dIII, as described by Embury *et al.*[4]. The sizes of fragments resulting from digestion of the cloned segment are shown in kilobases. Gel blotting of $\lambda\alpha$T2(2.6) DNA yielded identical results.

as the presence of a 3'-untranslated region exhibiting several scattered single nucleotide changes from the published normal mRNA sequence[23]. Whether these changes reflect previously unrecognized sequence polymorphisms within α-globin genes or sequence divergence from normal in these α-thalassaemia genes is uncertain at present. Thus, the striking feature of the structure of the α-globin gene present in the 2.6-kilobase fragment is the absence of the 5'-untranslated region and codons 1–56.

Two observations show this structurally abnormal globin gene is not an artefact of cloning. First, the identical deletion has been observed in the fragment cloned from unrelated individuals by different cloning strategies. Furthermore, several independent recombinant phages with the same structure of the 2.6-kilobase fragment have been isolated from the library constructed from the DNA of patient 2. The precise reproducibility with which this fragment has been isolated argues strongly against its accidental creation during the cloning procedures. Second, in gel blotting experiments, the 2.6-kilobase *Eco*RI fragment of genomic DNA of these patients hybridizes in the presence of a vast excess of unlabelled JW101 DNA with probe prepared from the portion of the 2.6-kilobase fragment 5' to the intragenic *Hin*dIII site (not shown). Thus, sequences 5' to codon 57 in the cloned fragment reside in the same location in genomic DNA.

The 2.6-kilobase fragment, therefore, seems to have arisen by a deletion originating 5' to a normal α-globin gene. In theory, a large insertion of DNA within the coding segment of the gene might have occurred. In this case, the missing 5' portion of the α-gene would be located elsewhere in the genome and be represented in gel blotting experiments as an additional restriction fragment. As analysis of genomic DNA of individuals with the 2.6-kilobase *Eco*RI fragment has not revealed such additional hybridizing bands[15,16], a deletion rather than an insertion of DNA is the likely origin of this structurally abnormal globin gene. Note that this is the first partially deleted globin gene in which the deletion terminates within the coding region. In the partial deletion of δ-globin sequences in one form of $\delta\beta$-thalassaemia[6] and of β-sequences in β°-thalassaemia[10–12] the deletions end within the large intervening sequences. On the basis of its distance from the 3' *Eco*RI site[14,15] and the presence of specific restriction sites in its 3'-flanking region (for example, extragenic *Xba*I site[27]), the α-globin sequence of the 2.6-kilobase fragment is probably derived from the 3'-α-globin gene of the normal duplicated complex.

By gene cloning, Lauer *et al.*[24] have determined the arrangement of α-like globin genes in normal human DNA as

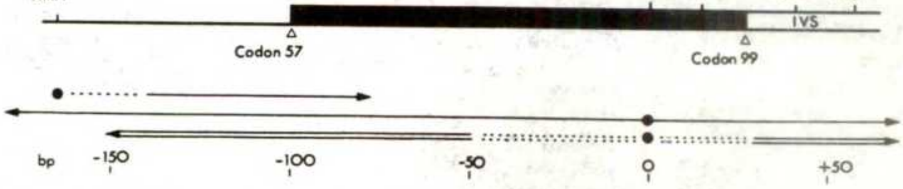

Fig. 2 Restriction map of the 2.6-kilobase cloned fragment and the strategy for DNA sequencing. The map of the cloned 2.6-kilobase fragment of $\lambda\alpha$T1(2.6) (upper portion) was constructed from the results of gel blotting and partial restriction mapping by the method of Smith and Birnstiel[28] after end-labelling of the *Hin*dIII site. The expanded segment below indicates the region of the cloned insert that was sequenced by the method of Maxam and Gilbert[25]. The solid dots indicate the fragment ends that were labelled. Single arrows indicate fragments labelled at the 5' end with [^{32}P-γ]ATP by polynucleotide kinase[25]. Double arrows indicate fragments that were 3' labelled with [^{32}P-α]dNTPs by the action of the Klenow fragment of *Escherichia coli* DNA polymerase. The solid portions of these arrows indicate those regions for which unequivocal sequences for each fragment were obtained. HdIII = *Hin*dIII; MbII = *Mbo*II; IVS = intervening sequence. The filled boxed regions indicate globin coding regions. The open boxed area represents the nearly 150-base pair intervening sequence present in the cloned gene. 3'-Untranslated sequences are shown by the cross-hatched area. The cloned fragment is orientated with its 5' end to the left.

Fig. 3 Partial nucleotide sequence of the 2.6-kilobase fragment. The nucleotide sequence of the portion of the cloned insert shown at the bottom of Fig. 2 is compared here with the amino acid and nucleotide sequences of normal α-globin and α-globin mRNA[23]. The underlined segment 5′ to the position of codon 57 does not resemble normal α- or other globin sequences. The nucleotide sequence of $\lambda\alpha$T2(2.6) was identical in the region shown here.

5′-ζ2-ζ1-$\psi\alpha$1-α2-α1-3′ where ζ1 and ζ2 are embryonic α-like genes, $\psi\alpha$1 a non-functional α-like gene, and α1 and α2 the normal adult α-genes. Restriction maps of the ζ and $\psi\alpha$1 genes and their flanking regions do not resemble the pattern of sites within our 2.6-kilobase fragments at their 5′ ends. This suggests that the 5′ extent of the deletion responsible for the creation of the 2.6-kilobase fragment lies beyond the region mapped by Lauer *et al.*[24] and therefore more than 25–30 kilobase upstream from the region of the normal α-globin genes. If this is the case, homozygosity for the 2.6-kilobase allele would result in defective embryonic haemoglobin synthesis. This lethal form of thalassaemia might go undetected due to the early time at which fetal loss would occur. The true incidence of the thalassaemia gene studied here among Mediterranean individuals is not known. As we identified this gene in 6 unrelated individuals with HbH disease among 12 cases initially analysed[15], it cannot be exceedingly rare. We should anticipate, therefore, the discovery of fetal wastage due to homozygosity for this α-thalassaemia gene in populations in which it is prevalent rather than a hydrops fetalis phenotype[1], the consequence of deletion of the adult α-globin structural genes without simultaneous deletion of embryonic α-like genes.

Fig. 4 Sequencing gel of the region containing the deletion in $\lambda\alpha$T1(2.6). The 0.75-kilobase *Eco*RI/*Hin*dIII fragment of $\lambda\alpha$T1(2.6) (Fig. 1) was 5′ labelled at the *Hin*dIII site and subjected to the chemical degradation reactions of Maxam and Gilbert[25]. The products were electrophoresed in a 0.38-mm thick 20% urea-acrylamide slab at 2,000 V for 24 h.

We thank Dr David G. Nathan for his continued support and encouragement and J. Lauer and T. Maniatis for a preprint of ref. 24. S.H.O. is the recipient of a Research Career Development Award of the National Heart, Lung, and Blood Institute-NIH and a grant from the National Foundation March of Dimes. *Note added in proof*: The 3′-untranslated region of the α-thalassaemia gene is that of the normal α1 gene. Therefore, the α-thalassaemia gene is derived from α1 and the normal α-globin genes differ in sequence in that region.

Errata

In the letter 'Mantle composition derived from the composition of lherozites' by S. Maaloe and R. Steel, *Nature* **285,** 321–322, the first line of paragraph 6 was omitted; it should read 'The composition of the mantle generating abyssal tholeiite'.

In the article 'Sequence of retrovirus provirus resembles that of bacterial transposable elements' by Shimotono *et al.*, *Nature* **285,** 550–554, in Fig. 2 legend it should read 'Labelled termini are indicated by (⊢)' not (–) as shown. In Fig. 4 legend lines 21 and 22 should be omitted.

In the News and Views article 'Extra-pituitary actions of LHRH and its agonists' by Richard M. Sharpe, *Nature* **286,** 12–14, line 9 on page 14 should be replaced by 'LHRH has taught most of us to regard'

BOOK REVIEWS

Plants, politics and empires

A.H. Bunting

Science and Colonial Expansion: The Role of the British Royal Botanic Gardens. By L.H. Brockway. Pp.215. (Academic: New York and London, 1979.) $21, £12.

THE author offers this book as an account of "botanical imperialism" and a historical-anthropological analysis of the role of the Royal Botanic Gardens, Kew, in the expansion of the British Empire. Her purpose is to demonstrate that nineteenth-century Kew was a "control centre", the directors of which conspired with the Government to press the botanical resources of the Earth, and of Latin America in particular, into the service of British imperialism and the expansion of colonial rule, especially in Asia. Since she sees no redeeming facets in imperialism and colonialism, the tone of the book is overwhelmingly critical; and since both her objectives and her raw materials are restricted in scope, her presentation is out of balance. The broad sweep of Kew's immense contribution to pure and applied botany, the foundations of which were laid in the nineteenth century, hardly emerges.

About half of the book is devoted to setting the stage. An introduction, and a brief and superficial chapter on the political and economic history of the British Empire, are followed by an essay on the diffusion of domesticated plants around the world, which is offered as the primary reason for the growth of human population since 1492.

Two chapters on the growth and organization of science in Britain in the eighteenth and nineteenth centuries in general (including its social and personal links with government), and on the evolution of Kew and the overseas botanic gardens in particular, make much of class distinction and patronage; and so it is the more unfortunate that the Darwin-Wedgwood connection did not lead the author to ponder the relative roles of the Lunar and the Royal Societies. The special train which brought Wickham's 70,000 rubber seeds from Liverpool becomes an example of the power of authority serving imperial interest.

The next three chapters, on quinine, rubber and sisal, the core of the book, are followed by a final ten pages containing a curious miscellany — the Crystal Palace as a symbol of the common interests of feudal landowners and the new industrialists (because Paxton had learnt to build glasshouses at Chatsworth), leading on to the Palm House as a symbol of Kew's overseas role, a résumé of the history of British plant exploration and the growth of plantation industries, followed by some concluding remarks on the social function of science.

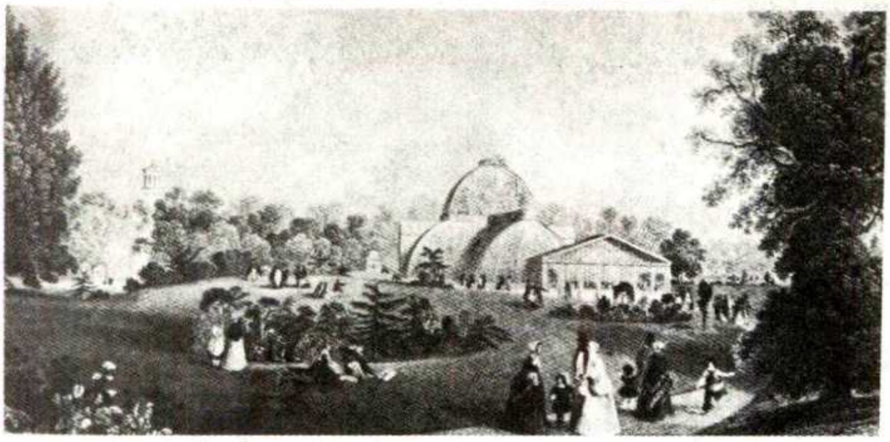
Taken as a whole, the book resembles, in structure, ideas and language, an unpolished and somewhat immature PhD thesis. It is a library study, supplemented by visits to Brazil and to Kew. Most of the references are to secondary sources, mostly from the social sciences, often written 100 years or more after the observations or events they review. A good deal of the biological comment is gauche — among much else, *Stylosanthes* is cited as a forage grass; the seed dispersal mechanism of *Hevea* cannot by itself explain the small density of trees of this genus in the Amazonian forest; *Ficus elastica* is not a vine; the significance of the monocarpic habit of *Agave* is misunderstood; and the nature of taxonomic work and the rules of priority in botanical nomenclature are misrepresented. If the biology is so unprofessional (and, moreover, written in a mixture of colloquial American and the metalanguage of an unfamiliar profession), what is the biological reader to think of the historical, economic and political material?

In fact the historical material about Kew, and the details of the transfers of plant materials in the eighteenth and nineteenth centuries, seem to be accurate enough. Much of it will be sufficiently unfamiliar to be interesting to non-specialists. The interpretation of history is something else. It makes much of smuggling and other knavish activities (though the circumstances in which Linnaeus' herbarium was transferred to Britain have escaped the author's censorious eye), and of the "conversion of knowledge to profit and power" by the British in support of imperialism. Thus *Cinchona* plantations were established in the Nilgiris, with seeds and plants spirited out of the Andean countries, to aid control of malaria in the Indian Army in the aftermath of the Mutiny. Quinine then made it easier for the British to bring their families to live in India and so to widen the social gulf between British and Indians. Kew organized the smuggling of rubber out of Brazil — though J.W. Purseglove (*Tropical Crops, Dicotyledons* p.149. Longman: London, 1968) firmly rebuts this gloss on the events — for British military, industrial, commercial and other imperialist purposes. Kew is castigated for publishing, as scientific and technical information, secrets of the botany and processing of sisal which enabled Germany to obtain materials of a Mexican plant from a supplier in Florida in order to build a sisal industry in German East Africa which fell into Britain's lap when Tanganyika was mandated to her after the First World War.

The transfer of economic plant materials from one country to another is consistently treated as expropriation. While unique artefacts, or mineral resources, can be expropriated, genetic resources are by their nature renewable. Transferred plant materials can of course be used to produce improved varieties and build plantation industries which may bring far greater advantages to foreigners than to the people of their countries of origin. This is but one of the many harsh features of the uneven development of nations. Plant resources can be expropriated only where they are also eradicated in their country of origin, as the Dutch attempted to do with the clove tree early in the seventeenth century.

The cynic could comment here that many plant species and varieties are at present unlikely to be saved for posterity unless they are in part expropriated, since they are at severe and increasing risk in their native lands.

Many people today share the author's uncompromisingly critical attitude towards conquest, the oppression of man by man, imperialism in general (including neocolonialism and the multinational companies), and British imperialism in particular, and look askance at the



Kew Gardens in the 1850s, showing the newly constructed Palm House

arrogant self-righteousness of some nineteenth-century attitudes towards Britain's civilizing role among the lesser nations. We can well imagine that the destruction of indigenous weaving and metal industries in India, by imports from Britain, helped to provide a cheap labour force for plantation industries in India (and later elsewhere in tropical Asia) when none was available in tropical America. Indeed this was advanced in the early 1830s as an argument for establishing a tea industry in India (*Tea Cultivation, India*. House of Commons Papers 63, 1839).

To most, however, this will seem an unduly eclectic view. Rubber provides a significant part of the economic basis for political independence in Malaysia and Indonesia; Indian quinine in its time saved many lives throughout the world; sisal has brought foreign exchange and some employment to Tanzania; and Kew continues to provide valued services, including third-country quarantine, for many developing countries.

Perhaps even more important are the personal and professional links, which include Kew and the Linnean Society, which hold together the large and active community of pure and applied botanists throughout the Commonwealth.

All in all, then, an unsatisfactory book; and in view of the great potential interest of its theme, a disappointing one. □

Krylov and the genesis of statistical physics

Michael Berry

Works on the Foundations of Statistical Physics. By N.S. Krylov. Pp.283. (Princeton University Press: Princeton and Guildford, UK, 1980.) Hardback $19.50, £10.80; paperback $7.50, £4.15.

RECENT YEARS have seen real progress towards answering fundamental questions in statistical mechanics, thanks largely to the Russian school led by Kolmogorov and Sinai. Their work was stimulated by the thorough and imaginative studies of N.S. Krylov, who died in 1947 at the tragically early age of 29. With the publication of this book, Krylov's works are at last available to English-speaking readers.

Krylov emphasized the importance of explaining how systems relax to equilibrium, and indeed regarded this as the central problem of statistical mechanics. He shows that a sufficient condition for relaxation is that the system's dynamics possess the property of mixing, which means that an initial patch of phase space (i.e. a group of systems) eventually spreads to cover the whole energetically available region in filamentary fashion (whilst preserving its area). Most previous work had concentrated on ergodicity, namely the property that a point in phase space (i.e. a single system) eventually passes arbitrarily close to every energetically available phase point. Ergodicity is a weaker property than mixing, and does not guarantee statistical behaviour. Krylov traced the source of mixing (at least for systems of colliding hard spheres) to instability of trajectories, i.e. the exponential divergence of neighbouring orbits. He employed this idea in an approximate calculation of relaxation times. Subsequent research has abundantly confirmed that this type of instability is indeed the source of unpredictable behaviour in causal systems.

The book is not easy to read, because Krylov's repetitious style of writing makes it hard to hold the thread of his complex argument. Nevertheless, this is an important document, which should be studied by anybody seriously interested in statistical mechanics. A valuable feature of this book is an appendix by Sinai, outlining recent developments of Krylov's ideas. □

Michael Berry is Professor of Physics at the University of Bristol, UK.

Developments in plant molecular biology

Martin R. Hartley and R. John Ellis

Nucleic Acids in Plants. By T.C. Hall and J.W. Davies. Vol.I pp.261, Vol.II pp.237. (CRC: Boca Raton, Florida/Blackwell Scientific: Oxford, 1980.) Vol. I $64.95, £48.75; Vol. II $59.95, £44.75.

THESE two volumes represent the only comprehensive treatise so far published in the area of plant nucleic acids, and reflect the upsurge in interest and the exciting new developments that have recently taken place in plant molecular biology. The aim of the books is to provide a detailed and critical appraisal of selected topics which include many current research interests in plant nucleic acids, as well as some related aspects of protein synthesis and genetic manipulation. The title "Nucleic Acids *in* Plants" has allowed the inclusion of contributions on viral, viroid and plasmid nucleic acids, which together with a chapter on gene manipulation by sexual and somatic cell techniques occupy Vol.II.

Volume I deals with nucleic acids found in 'healthy' plants, with articles on nuclear genome organization (Walbot and Goldberg), chloroplast DNA (Tewari), RNA polymerases (Becker), tRNAs (Weil), rRNA (Leaver) and mRNA (Hall). The styles of these chapters vary considerably, from epic literature reviews to more personal accounts. For example, Weil's 33-page article cites 432 references, while Tewari's 65-page contribution cites only 62 and relies largely on the author's own data. All of the articles are authoritative and are mostly easily readable, although by the very nature of some of the topics under discussion it has not always been possible to avoid a catalogue approach. Particularly impressive are Walbot and Goldberg's description of the intricacies of DNA reassociation kinetics in an intelligible fashion, and Becker's critical and reasoned account of plant RNA polymerases, in which he dispels many myths, including those about the action of plant growth substances at the transcriptional level. Most articles contain fairly detailed sections on methodology, where advice is offered on the merits and limitations of different techniques. Although these sections are not sufficiently detailed to enable the reader to repeat experiments, they do provide valuable first-hand information of a kind which is not usually given in original papers or reviews, and therefore they should prove extremely useful for researchers entering the field. As is inevitable in such books, the reviews are out of date by up to two years, especially in the field of mRNA and chloroplast DNA where little of the recent cloning work is analysed.

Volume II contains chapters on plant DNA viruses (Hull), monopartite plant viruses (Zaitlin), multipartite and satellite plant viruses (Lane), the translation of plant viral RNA (Davies), viroids (Dickson), the crown gall phenomenon (Schell) and plant gene manipulation (Bingham). All are useful summaries of the state of the art at the time of writing, which varied from 1976 to 1978 judging from the references. Studies on plant viruses have not had the same impact on biology as have studies on bacteriophages and animal viruses, but several of the chapters stress their potential importance for improvements in agriculture. However the overall impression given is that plant virology is poorly developed compared to its bacterial and animal counterparts; these articles show that there is a long way to go before such studies lead to major improvements in agriculture by direct genetic manipulation. Thus the chapter by Hull is entitled "The DNA of Plant DNA Viruses" but most of the detailed information is confined to cauliflower mosaic DNA. That by Bingham discusses the various methods proposed for the genetic manipulation of crop plants from a plant breeder's point of view, and correctly stresses the severe nature of the problems to be overcome. His case is not helped by the fact that the work referred to on p.218 on the expression of foreign DNA in cultured plant cells has not stood the acid test of reproducibility in other laboratories. The contributions by Zaitlin, Lane and Davies contain much detailed information on the isolation, characterization, synthesis and translation of plant viral RNAs. These chapters will be especially useful to those entering the field.

The message stands out clearly that much more work of high quality is what plant virology needs before its full potential can be realized, and the latter volume should contribute towards this goal by informing and interesting young research workers. In this respect it is to be regretted that each slim book is so highly priced; 19p a page will deter many people from purchasing two useful volumes. □

Martin R. Hartley and R. John Ellis are Lecturer and Professor respectively in the Department of Biological Sciences at the University of Warwick, UK.

Catalytic chemistry of palladium

M.W. Roberts

Palladium Catalyzed Oxidation of Hydrocarbons. By P.M. Henry. Pp.407. (Reidel: Dordrecht, The Netherlands, Boston and London, 1980.) Dfl. 125, $65.

IT IS perhaps surprising to someone not closely involved with the field that a book of over 400 pages can be entirely devoted to how palladium catalyses homogeneously the oxidation of hydrocarbons. However, a quick glance at this book left me in no doubt that it contains a wealth of interesting chemistry and that the idea is entirely justified. The book is aimed at three groups of people: (1) the industrialist interested in catalysis; (2) organic chemists interested in synthetic aspects; and (3) physical chemists interested in mechanistic aspects. The author is ideally suited to tackle such a task, being currently in a university post but having spent some 15 years in industry.

The book is divided into seven chapters. The author, however, having decided that there will be mainly two groups of readers — first, those largely interested in preparative chemistry, and second, those interested in both preparative and mechanistic aspects — has separated mechanistic discussions from the purely descriptive sections. Being mainly interested in heterogeneously catalysed reactions, I found this helpful.

In the first chapter we are led gently through a historical account, then some aspects of the basic inorganic chemistry of palladium in its various valence states — Pd(0), Pd(I) and Pd(III) — are described, followed by a discussion of the organometallic chemistry of palladium and finally catalysis. The two basic catalytic mechanisms considered are: (1) oxidation-addition or its reverse, reduction-elimination; and (2) the insertion reaction or its reverse.

Chapter 2 deals exclusively with the oxidation of monoolefines leading to the formation of aldehydes and ketones, esters and ethers. Over half of the book is devoted to the first two chapters, while the remaining five deal with the reaction of dienes and polyenes, π-allyl complexes, reactions of acetylenes, reactions of aromatic compounds and what are termed "miscellaneous reactions".

An excellent bibliography of approximately 40 pages lists 1124 references largely taken from papers published during the past decade. Among the references there is a good sprinkling of patents reported, reflecting the author's links with the industrial application of palladium catalytic chemistry.

There is a great deal of information in this book which will cater for a wide cross-section of chemists. The detail is impressive and indicative of the author's close involvement with the subject. I found it perhaps unusual to have a blend of detailed preparative chemistry intertwined with mechanistic argument, but possibly physical chemists are unfamiliar with this approach! The author set out to "give a survey of both the range and utility of the (homogeneous) catalytic chemistry of palladium and to discuss the basic reaction paths . . .". This, I believe, he has accomplished satisfactorily. In addition there is much of benefit in this book for those interested in heterogeneous catalysis (and its possible relationship with homogeneous systems); however, what is difficult for the non-specialist to ascertain is how much of the mechanistic discussion is 'established fact' and how much 'interesting speculation'. □

M.W. Roberts is Professor of Physical Chemistry at University College, Cardiff, UK.

Alone; the story of South American mammals

R.J.G. Savage

Splendid Isolation: The Curious History of South American Mammals. By G.G. Simpson. Pp.256. (Yale University Press: New Haven and London, 1980.) $17.50, £11.05.

FIFTY years ago Dr G. G. Simpson escaped death from revolutionaries in Argentina and undaunted carried on to lead a fossil-hunting expedition into distant Patagonia. He has returned many times to South America and has devoted a large portion of his long and very active scientific career to studying South American fossil mammals. In 1934 Simpson published a narrative of that first expedition; his deservedly popular book *Attending Marvels* (Macmillan: New York) vividly portrays the excitement of fossil hunting and the fascination of those bleak Patagonian landscapes. In *Splendid Isolation* he now addresses a wide readership with, as he subtitles the book, the curious history of South American mammals.

The book begins with chapters on the history of discovery from the time when Darwin found fossils there in 1832, on where and how fossil mammals occur, and on stratigraphical stages and mammal ages. For almost all of the past 60 million years the South American continent has been isolated without land connections anywhere — neither to Antarctica or Africa, nor to Central or North America. A land link was only re-established within the past 5 million years. Thus throughout almost the entire Cenozoic era it was in splendid isolation, receiving only periodic mammal invasions by waif dispersal from some other continent(s). The history of the faunas is retailed in three phases: the earliest faunas of the Palaeocene and Eocene have just three basic stocks (the marsupials, xenarthrans and condylarths); in the second phase during the Oligocene and Miocene, we witness the addition of rodents and primates; and the third phase begins in the early Pliocene (as defined by Simpson) with the build-up to the great American interchange of mammal faunas north-south across the continents. The book finishes with a summary chapter and a note on the restoration of extinct animals.

The book is highly factual and, as we would expect of the doyen, highly accurate and up-to-date with the latest fossil discoveries. But the facts are too often dry and indigestible. Accounts of each family with descriptions of their dental characteristics do not make easy reading, the more so as few are adequately illustrated. Indeed the illustrations are almost totally limited to elemental reconstructions — all without scale. The Plio-Pleistocene and Recent faunas are very summarily treated; much of the space here is devoted to etymological discourse. Simpson's penchant for both logodaedaly and sesquipedality are evident throughout. There are no photographs, no skeletal reconstructions and only one palaeogeographical map — and that of the mid-Cretaceous. Palaeogeography is a subject to which the author has himself made signal contributions, yet it is all but ignored in this book; it merits space only in the last three pages. Considering the tremendous impact of plate tectonics theory over the past decade, much could have been said, if only in summary, about the continent's history and its relationships to adjacent regions during the past 80 million years. The author tells us his first and second phase colonizations were waif dispersals. The centre(s) of origin of waifs has been the subject of copious debate; Simpson, fairly but very briefly, disposes of the arguments on the grounds that we have too few facts to come to definitive conclusions. The third phase colonization is certainly better documented, but Simpson refuses to be drawn into the current debates on palaeogeographical models, dispersal or vicariance — the latter originating with a Venezuelan biologist. Many scientists feel such models are useful in that they offer a challenge to discover adequate evidence to test a hypothesis. With the immense knowledge and unique experience Simpson possesses, we would all appreciate and profit from having his palaeogeographical interpretation. For without this, the history is as Hamlet without the Prince of Denmark. The task may be, to use Simpson's words, Herculean, but it is hardly Sisyphean.

There is no recent work with which *Splendid Isolation* can readily be compared. Patterson and Pascual's brilliant essay review of 1972, "The Fossil Mammal Fauna of South America" (In *Evolution, Mammals and Southern Continents*, edited by A. Keast *et al.* State University of New York Press: Albany), is still indispensable to the serious student. Yet, while the balance of topics treated in *Splendid Isolation* is sometimes too light and sometimes too heavy, there is much a student will find interesting in this curious history.

R.J.G. Savage is Reader in Vertebrate Palaeontology at the University of Bristol, UK.

Suspending time: a guide for biologists

David E. Pegg

Low Temperature Preservation in Medicine and Biology. Edited by M.J. Ashwood-Smith and J. Farrant. Pp.323. (Pitman Medical: Tunbridge Wells, UK/University Park Press: Baltimore, 1980.) £17.50, $39.50.

WHEN Polge, Smith and Parkes made the discovery, in 1948, that glycerol would enable avian spermatozoa to survive freezing at −79°C, they could scarcely have anticipated the impact their observation was to have in medicine and biology. The special value of preserving viable cells in the deep-frozen state is that this essentially suspends time: chemical reactions are arrested and even the recrystallization of ice is prevented at the generally used storage temperature of −196°C, the boiling point of nitrogen. Then, only ionizing radiation can produce damage, but as Ashwood-Smith points out in this book, it would take 32,000 years to accumulate a dose of 600 rads! The cryobiologists' trick then is to cool cells to, and recover them from, −196°C without damage. Although the conditions necessary to achieve this differ widely from cell to cell, remarkable successes have been achieved: nowadays, innumerable scientists and technicians in fields as disparate as clinical blood banking, animal husbandry, immunology, reference culture collection of bacterial, fungal, animal and plant cells, and entomology use cryopreservation as a tool in their daily work, perhaps with little knowledge of the principles upon which the techniques are based. This book sets out to provide a guide for such workers.

Farrant opens the book with a delightfully clear elementary explanation of mechanisms of freezing injury and cryoprotection. Ashwood-Smith then describes current techniques for the preservation of tissue culture cells and some mammalian tissues, and Polge, truly one of the founders of cryobiology, contributes an excellent chapter on the development of techniques for the cryopreservation of spermatozoa — full of practical detail, but also interestingly reflective on the way in which this field has developed. Whittingham gives excellent guidance from his wide personal experience of the low temperature preservation of early embryos of many mammals. The chapters on haematological applications, by Rowe and Schaefer, are essentially practical and detailed, while Knight provides an admirable critical account of work on the preservation of leukocytes, emphasizing the difficulties of obtaining valid measurements of post-thaw recovery. The chapters on protozoa and helminth parasites by James, on micro-organisms by Ashwood-Smith and on plant cells by Morris are all clear and packed with practical advice, while the contribution by Ring on the cryobiology of insects and their cells is particularly fascinating and goes beyond practical preservation to describe the fascinatingly varied adaptations found in insects that survive the extremely low temperatures occurring in Arctic regions. The book concludes with a chapter of general practical guidance.

Without doubt, this will prove to be a valuable text: it is not, however, as comprehensive as its title might suggest. Low temperatures, but without freezing, are widely used in medicine and biology for the short-term preservation of cells, tissues and organs, most importantly perhaps of blood cells for transfusion and of tissues and organs for transplantation. None of this is dealt with. Moreover the excellent introductory chapter could, I believe, usefully be supplemented by a more detailed discussion of theoretical cryobiology to help the reader digest the mass of 'cookbook' detail found in the subsequent chapters. Also, the balance of contributors seems a little strange in that it does not reflect the major contribution of workers in the USA during the past 20 years. Finally, the chapter on practical aspects would be much improved by the inclusion of greater detail of the actual equipment and procedures being discussed. (The thermocouple table on p.290 differs from the current BSI and NBS standards.) These are relatively small details, however, and the editors can be congratulated on a most useful compilation: perhaps they will consider widening the scope of future editions.

David E. Pegg is head of the MRC Medical Cryobiology Group in the Department of Surgery, University of Cambridge, UK.

Towards a more competent Civil Service

The narrow issue of how much scientists working in the British Civil Service should be paid during 1980 will no doubt be settled by this week's arbitration hearing, to which the Civil Service Department has been driven by the Institution of Professional Civil Servants (see *Nature*, 24 July). The outcome, no doubt, will be a compromise between the government's offer and the claim by the IPCS — and a further setback for the system of "pay research" by which salaries are determined. The more serious questions of how, and on what terms, scientists should be recruited to the Civil Service will however remain unasked. As a result, scientists in the public service will continue to be treated as a group apart while the public service and thus the British government will continue to be less effective than it could and should be. It is a scandal that so little attention has been paid, since the publication in 1968 of the report of the Fulton Commission on the organization of the Civil Service, to these important issues.

Traditionally, as the whole world knows, the British Civil Service has been a happy and largely successful hunting ground for gifted generalists, able to turn their attention from the administration of bits and pieces of the British Empire to the administration of, say, the publicly supported schools. It is customary to suppose that in the nineteenth century the system worked splendidly, although with hindsight it is clear that for every brilliant administrator of India thrown up by the system there was a small army of dull pecksniffs guiding the growth of the public service in unimaginative directions. How could it be otherwise, given the traditional method of recruitment into the Administrative Civil Service? Although in the twentieth century the Administrative Class has replenished its ranks with graduates from well connected universities, Oxford and Cambridge in particular, rather than from the sons of well connected families (as in the nineteenth century), the principle is unchanged. It is to take a man (or now, mercifully, a woman) of high intelligence but without particular expertise, and to let him learn the craft of public service on the job in one ministry after another, with spells of duty rarely spanning more than three years. Within the service, frequency of movement is a mark of success, with the result that the high fliers, as they are called, begin and end as generalists — intelligent, to be sure, but almost proud of having no expert knowledge of the fields of the public service they administer. Recognizing, however, that the public service increasingly requires expert knowledge in many different fields, the Administrative Civil Service has built up separate cadres of specialists — scientists and engineers but also economists and architects, for example.

The Fulton Commission was born of a suspicion that this system was increasingly an anachronism. The suspicion was confirmed by the commission's analysis. Its conclusion that generalists, sometimes rudely but properly called amateurs, had outlived their usefulness to society as public servants was understandably unpalatable to those primarily concerned. In the circumstances, it is something to be grateful for that the least radical of the Fulton Commission's recommendations have indeed been followed. The Administrative Civil Service now looks less eagerly to the products of Oxbridge courses in classics or history for its new recruits. Responsibility for recruitment has been transferred from the Treasury to the newly created Civil Service Department, while steps have been taken, as Fulton asked, to make it easier for people with experience of other walks of life to join the Civil Service in mid-career. (Even so, the flux of people into and out of the public service is not nearly as great as Fulton hoped.) Under these arrangements, there is of course no reason why scientists or people with other specialist backgrounds should not compete for places in the Administrative Civil Service alongside those with other kinds of degrees. Understandably, the numbers of those prepared to ape the generalists at such an early stage in their careers as scientists is small and likely to remain so.

The Fulton Commission acknowledged that this was likely to be the case, for which reason (among others) it urged that there should be a merger of the Science and Administrative classes. Since 1968, British governments have stolidly declined to follow this proposal. Administration, they say, no doubt on the advice of the administrators, is in itself a special skill, distinct from other kinds of skills. The one concession to the Fulton view to have been made in the past decade is a scheme by means of which scientist within the public service can apply for a transfer to the Administrative Branch. Again, understandably, the volume of transfers is a trickle. More seriously, the habits of the public administration are unchanged — those who enter the Administrative Civil Service from some other part of the public service do so on terms spelled out by the administrators.

The result, increasingly apparent, is that the British government is denied the kind of advice and administration that circumstances now demand. The record of simple administrative errors stemming from innocence of technical matters grows with the passage of the months. It is not so long since the renegotiation by the Home Office of the international allocation of broadcasting frequencies robbed the BBC of facilities now plainly essential to its social function. More recently, the British government has been allowed to dither about the payment of the second promised tranche of £25 million to the semiconductor company INMOS (*Nature*, 5 June), apparently in ignorance of the nature of technical development in novel fields. (In the end, as the Prime Minister announced last week, the National Enterprise Board has been allowed to meet its moral obligation.) Unhappily, such conspicuous errors are almost by definition relatively minor. The influence of an ill-informed administration on the evolution of more substantial policies is harder to pin down. The chopping and changing in British energy policy over the past two decades, however, clearly carries the marks of technical innocence. So does the apparent assumption by several government departments that funds for research and development, or education, can be turned off and on as water from a tap. The truth is that, in such fields, uncertainty is more damaging than mere shortage of funds. But elsewhere, again apparently from lack of technical knowledge, the Civil Service conspires with the government to attempt to make water run uphill. How else is it possible to explain the devotion of successive governments (but not the present) to regional policies intended to share such prosperity as the country continues to enjoy more equitably between different parts of the country? The objective, of course, is admirable, but the results have been at best meagre, as economists have been saying all along.

It would of course be wrong to think that maladministration of this kind would vanish if more of the administration of the government's affairs were shouldered by scientists and other specialists. Scientists and other specialists do not have a monopoly of wisdom, and there is also something in the administrators' claim that good judgement in public administration comes with experience. This, however, is merely an argument in favour of the Fulton Commission's proposal that there should be a thorough merging of the scientific and the administrative Civil Services. While many scientists within the public service would no doubt wish to follow the public interest and their own in the pursuit of research and development, others would be able to contribute more effectively than is at present

0028-0836/80/320545-02$01.00

possible to the routine work of the public service, preventing the howlers which are at present perpetrated by the generalists and helping also to ensure that major issues of public policy are dealt with in a manner that is technically sound and, with luck, imaginative as well. One unconvenanted benefit would be that the hosts of advisory committees which at present litter Whitehall could be reduced in number — one of the present government's ambitions. Perhaps the first British Prime Minister who happens to be a scientist might take up the shamefully neglected cause of making the British Civil Service more competent.

Radiation standards not yet for changing

The chequered history (see page 550) of the report on low-level ionizing radiation, published last week by the US National Academy of Sciences, should not detract from its value. The report was commissioned by the Environmental Protection Agency and has been prepared by the academy's Committee on the Biological Effects of Ionizing Radiation. It is popularly known as BEIR III to distinguish it from an earlier report in 1972 and from the first draft of this document (released just over a year ago before all the members of the committee had had their say). The issues with which it deals are of great importance, not merely for regulatory agencies such as the Environmental Protection Agency, for those concerned with industrial health and safety (not only in the nuclear industry) but also for the public at large, rightly concerned that there should be a judicious assessment of the potential hazards of ionizing radiation, especially that produced by the nuclear industry. The public importance of the topic has of course been keenly appreciated for the past quarter of a century, with the result that attempts to calculate the hazards of radiation have been made by national governments, independent organizations such as national academies and even by the United Nations. The particular value of BEIR III stems from that feature for which it is likely to be most criticized — for by including the opinions of members of the committee dissenting on scientific grounds from the main report, it serves to dramatize the uncertainties that persist in this difficult field.

The abiding difficulty in the estimation of the consequences of radiation exposure is that of extrapolating downwards, from the often tragic experience of people who happened to be living in Hiroshima and Nagasaki in 1945, those who were treated with X rays for a variety of diseases such as rheumatoid arthritis or ankylosing spondylitis in the 1930s or those who worked as radiographers before the hazards of radiation were fully appreciated, to the rest of us, whose organs receive 100 mrem a year (in round numbers) from natural and unnatural causes — cosmic rays, natural radioactivity such as potassium-40, visits to the orthopaedics people, airline travel and the like. Hitherto, most serious studies of how the extrapolation should be carried out have been based on the assumption that the risk of damage is proportional to the dose of radiation. (The days have long since gone when it was permissible to talk of a "threshold" dose below which radiation entailed no risk of damage.) BEIR III breaks new ground by flirting seriously with the notion that the relationship between the risk of damage and the dose of radiation that produces it may not be linear after all, but rather quadratic, at least where the induction of some kinds of cancers is concerned. (On the genetic consequences of radiation exposure, BEIR III follows earlier studies in affirming that only the linear extrapolation is prudent in the present state of knowledge or, rather, ignorance.) This is why the report has engendered controversy among its authors even before publication.

Superficially, it is true, even to entertain the possibility that the rate of induction of some kind of cancer may be proportional not to D (where D is dose) but to $\alpha + \beta D + \gamma D^2$ (where α is the spontaneous rate, and β and γ are constants to be adjusted to fit the data) looks like a way of resurrecting the threshold hypothesis. For if γ is positive, extrapolation downwards from large to small D will suggest that the risk of harm by small doses of radiation, such as those attributable to krypton-85 in the atmosphere, for example, will be disproportionately less than those attributable to large doses.

The argument of BEIR III by way of justification is plausible but not conclusive. To their credit, the authors have acknowledged this to be the case. The conjecture that to cause a cancer it may be necessary to break the same DNA molecule at two places (not just one) before natural repair mechanisms have had time to do their work is modestly advanced, with as full a list of the objections as anybody could ask for. The experimental data bearing on this point which are marshalled by the report are impressive, but derive mostly from animal studies. The document acknowledges that the information available about the causation of human cancer is not "robust" enough to distinguish between the possible dose–response models, although there is some reason to think that skin cancer does not turn up at low doses of radiation, that the relationship between leukaemia induction and radiation dose among the Japanese bomb survivors is adequately represented by a quadratic relationship but that the risk of breast cancer is linearly related to the dose of radiation.

Inevitably, a quadratic rather than a linear relationship implies that the risk of cancer induction after exposure to small doses of radiation is reduced. BEIR III includes comparisons of the calculated risks based on the two assumptions which suggest that the risk of cancer induction after exposure to, say, 10 rads of ionizing radiation will be halved if the relationship between risk and dose is quadratic, not linear. Superficially, that represents a substantial change, for which reason it is relevant that the earlier calculations (like those of BEIR III) are accompanied by large (and unavoidable) errors; the new estimates, based on the quadratic assumption, do not lie all that far outside the errors of earlier calculations. A more serious difficulty (to which one of the dissenters, Professor Edward Radford, draws attention) is the element of arbitrariness in the way in which BEIR III had to calculate the parameters in its quadratic relationship between risk and dose from a few clumps of data relating to high acute exposures.

How, then, should the regulatory agencies respond to BEIR III? Some, no doubt, will be tempted to say that present regulations for occupational exposure to radiation might safely be relaxed, although not by very much. It will be a mistake, however, if BEIR III is taken as a licence for such a step. For the report itself is properly so hedged about with qualifications (and packed with interesting but complicated evidence to suggest how sensitivity to radiation may vary with age, sex and genetic constitution) that it cannot be regarded as the last work on the subject. Accordingly, the regulatory agencies should for the time being stick to the assumptions on which their calculations have hitherto been based while setting out more energetically to test the interesting proposal put forward by BEIR III. Perhaps the most conspicuous omission from the report is the committee's own assessment of the work that needs to be done more adequately to underpin its argument and conclusion. It is, however, plain that much can be done to test the conclusions of BEIR III. Animal experiments designed to test the risk of specific kinds of tumours after exposure to radiation could help to distinguish between the linear and quadratic hypotheses. BEIR III itself makes much of the results of the classic epidemiological study by Court-Brown and Doll on the incidence of tumours of people treated with X rays for ankylosing spondylitis. It is too much to ask that the regulatory agencies and the nuclear industries throughout the world should apply the same care to the study of the health of the only substantial group now exposed to relatively large doses of radiation—those occupationally exposed in nuclear plants?

Congress turns sour on technology fund

Washington

As part of a general effort to cut the foreign aid budget, Congress is threatening to veto the major US contribution to the new international fund for science and technology in developing countries which was set up following last year's United Nations Conference on Science and Technology for Development (UNCSTD).

The House of Representatives Appropriations Committee last week recommended the elimination from the 1981 budget request of a $10 million contribution which the Carter administration had proposed for the new fund. The committee also proposed changing the foreign aid bill so as to prevent any of the $130 million allocated to the United Nations Development Programme — the agency handling the fund — being used for this purpose.

UNDP officials hope that these recommendations will be rejected when the full House debates the foreign aid bill. Otherwise they fear that withdrawal of the US contribution could put the whole fund in jeopardy. This, they warn, would have repurcussions for relationships between the US and the many countries — particularly in Africa — which have already submitted project proposals to the fund on the understanding that adequate support has been promised.

Delegates to the UNCSTD conference in Vienna last August agreed to the fund as an interim measure. Initially the developing countries had proposed a more ambitious scheme for a $2,000 million to $4,000 million annual tax on technology transfers from the developed nations, but this was quickly rejected as unrealistic.

Promises were, however, made to explore the long-term prospects for such a scheme. Meanwhile a two-year interim fund was proposed under the auspices of the UNDP, with an initial target set at $250 million, of which the US indicated it would be prepared to cover 20 to 25 per cent.

In practice, even this target turned out optimistic. At a meeting in New York in March, total pledges of $36 million were made, primarily by Austria, Denmark, Norway, Sweden, The Netherlands and the US. (The UK made it clear in Vienna that it was not prepared to contribute: France and Germany are still negotiating conditions under which they may give up to $9 million more.)

Even though the total was less than had been hoped for, the UNDP decided that enough had been raised to get the fund off the ground. With the support of the UN General Assembly, the fund officially became operational in May. UNDP has already received over 550 applications from the governments of developing countries, and 70 projects have been selected as candidates for funding.

One African country has approached the UNDP for joint funding of a new metallurgical research institute, and another eight are already including possible support from the UNDP in schemes to integrate science and technology policies into their five-year economic plans.

UNDP officials argue that for the US to withdraw its proposed contribution — given its central role in engineering the Vienna compromise and steering attention away from the more far-reaching third world demands — would not only prejudice the future of the fund itself, but would also cast a cloud over all future negotiations on overseas aid.

The proposed $10 million US contribution has already been endorsed by the science committees and the foreign affairs committees in both the House and the Senate. Indeed some congressmen say they would have been prepared the support the $15 million contribution which President Carter had proposed in his original January request.

Despite this support, however, the appropriations committees are proving harder to convince. Commenting on its proposal that the US should not contribute to the fund, the House Appropriations Committee says that it took the action because the Administration had failed to provide adequate information on the activities of the fund.

This information is now being hastily provided, in the hope that at least some members of the Appropriations Committee can be persuaded to change their position. But the UNDP contribution has also become tied up with the conflict between the Congress and the Administration over the latter's plan to set up an Institute for Scientific and Technical Cooperation (ISTC) as a focus for research relevant to developing countries.

Last year Congress accepted the ISTC proposal in principle, but the appropriations committees failed to allocate funds after a bitter fight over the form that the institute should take, and its relationship to existing scientific and technological programmes in the Agency for International Development.

This year the Administration has again put forward the ISTC for funding. But despite plans to reduce its scope it seems increasingly unlikely that the institute will get off the ground.

Such a failure, embittered as it would be by the disputes which there have been between the Administration and Congress about overseas aid and the growing hostility of Congress towards multilateral aid programmes, imply that supporters of the UNDP have an uphill task ahead of them.

Compromise for Finniston?

On the principle that ministers cannot go on holiday until parliament has seen that their desks are clear, the British government was earlier this week preparing its much-delayed response to the report of the Finniston Committee on engineering education. The response will lose some friends and make some enemies, but is otherwise likely to be a compromise.

The central issue to have become apparent since the committee's report was published earlier this year is whether responsibility for the education of professional engineers, including the accreditation of university and other courses, the definition of professional standards and the certification of those claiming them, should rest with a new public body to be called the British Engineering Authority.

The Finniston Committee argued that there should be such a body, which would inevitably take over from the separate engineering institutions many of their existing educational and professional responsibilities. The committee also asked that such a body should be statutory, responsible to the minister responsible for industry — for the time being Sir Keith Joseph, Secretary of State for Industry. Only by such a device, the committee argued, could the reorganization of engineering education and qualification be carried out in such a way that industry could take notice. The committee also recognized that even the British government has, on paper at least, a long purse.

Since the publication of the report in February, the Department of Industry has invited comments from no fewer than 400 interested parties, most of whom have apparently replied. Many respondents, the Confederation of British Industries and the Committee of Vice-Chancellors and Principals for example, have however disappointed members of the Finniston Committee by warning the government against the notion that the engineering profession should be regulated directly by the government. This advice is likely to be the more influential because those who offer it also welcome structural changes in engineering education and qualification.

The favourite compromise seems to be that there should indeed be a new authority responsible for engineering education, but that it should be set up as an autonomous institution by the Privy Council, not by the government as such. To begin with, there should be a measure of direct financial help from the British government, but in the long run it might be appropriate that support should be channelled through bodies such as the University Grants Committee.

Radioactive waste

Windscale leak

The scathing report last week from the British Nuclear Inspectorate on the latest radioactive leak from the Windscale reprocessing plant raises familiar issues. Yet again, it seems, a substantial leakage of radioactivity, 100,000 curies this time, has arisen from relatively minor design faults and sheer human frailty.

One of the benefits of the arrangement under which the Nuclear Installations Inspectorate works directly to the Health and Safety Executive is, however, that its full report (Health and Safety Executive, £1.25) has now been made public. It emerges that the inspectors had seriously considered prosecuting British Nuclear Fuels Limited, or members of the senior staff at Windscale, for breaches of the operating licence. Instead, the inspectors have asked the company (which is state-owned) to take remedial action and plainly hope that publication of their report will be a more effective safeguard for the future. BNFL has duly eaten humble pie, with a statement reading like the public confessions common in China during the Cultural Revolution.

The chronology of this latest incident at Windscale begins in 1955 when a plant was built for bleeding off small quantities of highly active liquid waste from the reprocessing line as part of the research programme then under way at Harwell to glassify highly active waste. The UK Atomic Energy Authority (then the operator of Windscale) erected building 701 which contained a 1,400-litre stainless steel tank in which active waste could be aged for an appropriate length of time, and a device for transferring some of this material into 20-litre shielded flasks for transport to Harwell. There were arrangements for returning waste from the building to the main processing line, principally from a small 70-litre sump in the floor of the building.

After the last consignment of waste to Harwell in 1958, Building 701 seems to have fallen out of use and out of mind. For some years, workmen at Windscale followed the standard operating procedure of emptying the sump at regular intervals, but during the 1970s the practice had become irregular. BNFL told the inspectors that they assumed that the liquid collecting in the sump was not radioactive, but probably consisted of rainwater leaking through the roof of the building and of condensation inside. The inspectors complain that BNFL should have considered the chance that active waste was splashing over the movable vanes used in a valve arrangement to divert the stream of active waste in one direction or another.

Attemps to empty that sump during the 1970s were not always successful, now it seems because one of the two outlet lines had been mistakenly cut and blanked off in 1971. Curiosity about the level of liquid in the sump could not reliably be satisfied — the pointer on the face of the instrument recording the liquid level can apparently turn full circle and then keep on turning, so an over-full sump may seem nearly empty.

The leak was discovered during a survey of the Windscale site in 1978, and recognized to consist of fission products only two years old in March 1979 when the nuclear inspectors were informed. The inspectors say that for several years the sump had been overflowing and that radioactive material had found its way through the stainless steel cladding lining the bottom of the building to soak through the concrete foundation to the ground beneath.

The penance required from BNFL includes the reinstrumentation of building 701, its isolation and, eventually, its decontamination, the monitoring of radioactivity in the ground beneath the plant (where most of the activity is some three metres beneath the surface) and preparation for the physical isolation of the activity or even the removal of the contaminated soil.

Both parties to the investigation agree that nobody has been exposed to a significant radiation dose because of the leak.

European biotechnology

EEC proposals

The European Commission's proposals for the regulation of genetic manipulation, once widely feared for their restrictiveness, have turned out to be comparatively tame. The commission's "recommendation", submitted to the Council of Ministers this week, requires merely that experiments in genetic manipulation should be registered nationally. The proposals are thus much less constraining than the directive proposed in 1978 and later withdrawn.

A "recommendation" carries no legal force but, if agreed by ministers, has a certain moral force among the nine member states. Last week's recommendation argues that while hazards are now thought to be "non-existent or small" it would nevertheless be prudent to register experiments centrally in case so far undetected "long-term effects" exist. To deal with commercial objections about confidentiality, notification would be restricted to "the portion of the experimental protocol which is required for the evaluation of safety".

Compulsory notification already exists in the United Kingdom, and may do so in Germany if a proposed law on genetic engineering re-emerges after the October election. Elsewhere it is voluntary.

The commission would also set up a committee of experts, mandated by member states, to examine at least once a year the need for harmonization of regulations and to consider emerging knowledge of hazards. **Robert Walgate**

IWC whaling quotas

Politics wins out

The recent 32nd annual meeting of the International Whaling Commission (IWC) closed after a week of political struggle between those nations seeking a ban on commercial whaling (led by France, the Netherlands and the United States) and those, mainly the whaling nations (Canada, Chile, Iceland, Japan, South Korea, Peru, South Africa, Spain and the Soviet Union),arguing that such a ban could not be justified.

Any hope of a total moratorium was crushed at the beginning of the meeting, and for most of the week it looked as if agreement on quotas might never be reached. On the final day of the meeting, however, quotas were eventually agreed — 13,753 whales of all species can be taken in 1981–82 compared with 15,883 in 1980–81. The alternative of no agreement at all might have led to the demise of the whaling commission and a free-for-all, which would have been an even greater blow to the conservationists.

The purpose of the IWC's annual meetings is to reach agreement on the management of whale stocks for the next year based on the advice of its scientific committee. One of the problems is that the monitoring and prediction of whale population dynamics is fraught with difficulties, allowing interested parties to interpret the statistics as they wish.

The task of the IWC's scientific committee, which met a few weeks before the commission's main meeting, is to formulate a basis on which catch quotas can be set. It does this by estimating the current population of individual whale stocks and the ideal population which could be supported in the absence of interference by man. A population slightly below the ideal level will replace itself more rapidly than one at the ideal level because of increased resources per whale. The aim is to maintain populations at the level which shows the greatest replacement rate and hence gives the maximum sustainable yield (MSY). Under the IWC's new management procedure, a target yield, which provides guidance for setting catch quotas, is set at 90 per cent of MSY. The management procedure also stipulates that all catching should stop on any stock which falls to 10 per cent below the level at which it produces the MSY.

Estimated stock sizes and MSY and recommended catch limits

North Pacific, Western Division

	Males (11+)	*Females (10+)*
1910 stock × 10^3	157.9	175.0
1981 stock × 10^3	66.5	124.6
1981/1910	42.1%	71.2%
MSY level × 10^3	88.3	131.1
1981% MSY level	75.3	95.0
Catch limits	0	405

0028-0836/80/320548-02$01.00

The ideal population can be estimated only by knowing the current population and its rate of change. Almost all the data on the status of current stocks have come from whaling ships which have been providing information on the basis of catch per unit effort. This works on the principle that the difficulty of finding and catching a whale is inversely proportional to the total number of whales available. Changes from year to year in making a catch will reflect change in the population size and hence allow estimates of ideal population to be made.

IWC whaling quotas

North Atlantic	1980/81	1981/82		1980/81	1981/82
Sperm	273	130	*S. Hemisphere*		
Minke	2,543	2,554	Bryde's	264	264
Sei	100	100	Sperm	580	300
Fin	624	701	Minke	8,102	6,718
North Pacific			*Others*		
Bryde's	479	529	Bowhead	18	17
Sperm	1,350	890	Humpback	10	10
Minke	1,361	1,361			
Gray	179	179	Totals	15,883	13,753

Catch per unit effort, however, is not a reliable measurement on which to base calculations of population because it varies considerably with different whaling techniques. When allowances for handling time were recently taken into account, it was found that the depletion of population was being seriously underestimated.

One new way of modelling populations which overcomes some of the difficulties with catch per unit effort was proposed by John Beddington and J G Cooke of the University of York at the recent scientific committee meeting. It has already been applied to sperm whale stocks in the North Pacific with some success. The Beddington and Cooke model uses the fact that whaling distorts the distribution of length in populations as the basis for calculations of current and ideal populations (whaling ships tend to catch big animals leaving smaller ones behind). By examining the current length distribution of the catch and the change over recent years and by knowing the size of the catch, the current population and hence the ideal population can be calculated. This technique works well for species of whale, such as the sperm whale, which vary considerably in length.

One difficulty with the management procedure is that it only works well for species which have already been depleted where the catch is a fair proportion of the current population. The minke whale, for example, the most heavily exploited species, cannot be managed easily because its numbers are actually on the increase. Sperm whales also present problems, because unlike all other species, they are polygamous. Only large males over 25 years of age can hold harems so the damage to the sperm whale population of taking only the largest whales could be greater than at first suspected.

The deliberations of the scientific committee probably did not affect the outcome of the recent meeting as much as might have been expected. In spite of Beddington and Cooke's new evidence on sperm whales, which led the scientific committee to recommend that they should not be killed in the North Pacific, a quota of 890 was awarded to Japan. Some concession to the scientific evidence was made, however, by banning the killing of female sperm whales and all males over 45 feet long. Two other seriously endangered species also failed to get total protection: the humpback whale of the North Atlantic — Eskimoes in Greenland will be able to kill 10 next year — and the bowhead whale in the Bering sea where a small quota has been set for the benefit of Eskimoes in Alaska.

Judy Redfearn

More Soviet psychiatry

Physicist held

Vladimir Kislik, nuclear physicist, long-term refusnik and member of the European Physical Society, has been committed to a Kiev mental ward, apparently to prevent him from meeting western visitors to the city. Although this means of repression has of recent years been used against a number of political dissidents, including geneticist Zhores Medvedev and mathematician Leonid Plyushch, this is the first time that it has been used against a Soviet scientist who simply wishes to emigrate to Israel.

Kislik applied for an exit visa in 1972, but was refused on the grounds of access to state secrets while at his previous job at the Chelyabinsk Nuclear Reactor Plant. Following his application, he was dismissed from his research post at the Institute of Physics of the Ukrainian Academy of Sciences and since then has had to work as a bus-ticket seller, nightwatchman and the like. He attempted, however, to keep up his scientific reading and to organize a scientific seminar for other refusniks in his own home. In June 1976, however, he was beaten up by security police and threatened that he must close his seminar — or else face a criminal charge of black market activities. Meanwhile his name "disappeared" from the Soviet bibliographies and from references to the papers which he had published in his professional capacity.

He did, however, have one unpublished paper on the "Absorption of Helium by Irradiated Samples of Austenitic Steels". Before his dismissal from the institute, this research had been cleared for open publication. Kislik managed to send the paper by hand to the United States, where in 1977 it appeared in the *Journal of Nuclear Materials*

Shortly afterwards, an article appeared in the local evening paper *Vechernyi Kiev*, accusing Kislik of being a foreign agent and of smuggling out nuclear secrets. At the end of 1979, the accusation was revived, and he was informed by the Kiev Public Prosecutor, Ignatiev, that a file had been opened against him under Article 136 of the Ukrainian Penal Code "Violation of Authors' and Inventors' Rights" — in other words, plagiarism.

Since October 1979, Jewish emigration from Kiev has virtually ceased and routine police harassment of long-term refusniks has intensified. In April 1980, Kislik was prevented from travelling to Moscow for the refusniks' International Symposium on Collective Phenomena. One of the western visitors to the symposium, Professor Paul Kessler of the Collège de France, later visited Kislik in Kiev. After the visit, Professor Kessler reports, he was attacked by four strangers in plain clothes who gave him an "intentionally not too heavy" beating, which, he believes, was meant simply to intimidate him. A few weeks later, Kislik managed to make contact with some American geneticists who were attending a meeting in Kiev — an event which, some of his friends believe, was not unconnected with the latest harassment.

On 25 June, Kislik was picked up in the street and taken to the police station for an identity parade in connection with an alleged theft. On 4 July, he was arrested for alleged hooliganism and given 15 days detention. When this term was up, and he was not released, he threatened to go on hunger strike. The next day, 19 July, he was transferred to a psychiatric ward in the Pavlov hospital. Ironically, and to a certain extent in support of Soviet claims that Jews (as opposed to "Zionists") suffer no discrimination in the Soviet Union, the doctor in charge of the case is a certain Naum Lifshits.

Neuroscience

Snyder's pad

Washington

The Johns Hopkins Medical School in Baltimore has joined the growing ranks of United States research universities in announcing its intention to set up a new department devoted to neuroscience. This will be the first new department to have been established at the medical school for twenty years. Under the direction of the new department's chairman, Dr Solomon H. Snyder, who will become the medical school's first professor of neuroscience, its research will be concerned with the chemical and pharmacological aspects of brain function. Dr Snyder, joint winner of the 1978 Albert Lasker Basic Medical Research Award for his work on the actions of neurotransmitters and, in particular, on the functioning of opiate drugs, is this year's president of the American Society of Neurosciences.

The proposal to set up the department was made by an *ad hoc* group appointed by the medical school last autumn. The committee said that there were "compelling academic grounds" for a new department and pointed out that although knowledge in the field of neuroscience dovetailed with that in other disciplines, there was now a common body of knowledge and methodological approaches shared by people trained and working in neuroscience.

Bringing together the neurological aspects of various traditional disciplines into a single department will have organizational as well as academic advantages. According to Dr Steven Muller, president of Johns Hopkins University, "although Hopkins has universally recognized strength in several areas of neuroscience, the School of Medicine now needs the cohesive focus in neurobiology so necessary for the development of exciting and rigorous teaching programmes for medical students and for predoctoral and postdoctoral students in neuroscience".

One of the immediate research interests of the new department will be a study of effects of Huntingdon's disease on enzyme activity in the brain. This will form part of a nine-project research programme on the disease which last week received a grant of $1.8 million from the National Institute of Neurological and Communicative Disorders and Stroke.

David Dickson

Byelorussian graduates

Missing out

Young Byelorussian graduates are failing to take up their appointed posts in the Soviet national economy, according to a recent survey by the Byelorussian SSR State Committee for Labour.

According to Soviet practice, all young persons completing higher education must work for a prescribed period (usually three years), in whatever post the relevant ministry assigns to them. These posts can be anywhere in the Soviet Union, not necessarily in their own home republic. In Byelorussia, however, the system seems to have broken down. In 1978, says the survey, over 3,000 newly qualified specialists — just under 5% of the total — failed to turn up at their appointed enterprises.

In all, out of the 120,000 persons holding higher qualifications in agriculture 41,000 are now working in non-agricultural jobs, 10,000 with teaching qualifications are not teaching and 13,000 university and technical college graduates are working in branches of industry, building and transport unrelated to their education. Over 25% of the young specialists who have graduated in the past four years are now doing jobs which require no higher qualifications.

The ministries themselves, it appears, are partly to blame. A spokesman for the Byelorussian State Committee for Labour explained that many ministries distribute their young graduates at random, often switching them from the job for which they were originally destined letting them go off and find work for themselves, or terminating their assigned job earlier than scheduled. An increasing number of departments are refusing to employ graduates along the lines for which they have been trained. Cases of patronage and "protection" are also said to account for an unspecified number of graduates failing to fulfil their "civil obligations" of directed work.

Nor surprisingly, the professional skill of management workers in Byelorussian industry and agriculture is also said to be "rather low" and causing "great concern."

Vera Rich

Radiation risks

Twice lucky?

Washington

After a year of intense internal debate, the US National Academy of Science has issued a report revising its earlier estimates of the health risks of low-level radiation, and indicating that these may be lower than it had previously suggested.

In particular, academy scientists have qualified their support for the linear "no threshold" model for predicting dose–response relationships at low levels of radiation. They now say that, given all the uncertainties involved, a linear quadratic relationship is more likely to be realistic and that the linear hypothesis should be considered merely to define the upper limits of risk.

The report, which was prepared by the Academy's Committee on the Biological Effects of Ionizing Radiation (the BEIR Committee) and was commissioned by the Environmental Protection Agency, does not recommend specific exposure levels. But its findings are likely to reduce pressure on the agency to develop more stringent regulations.

The committee's conclusions, however, are still under fire. The chariman of the subcommittee on somatic effects, Dr Edward Radford, claims that support for the linear hypothesis was downgraded on the basis of a biased selection of data, giving too much weight to laboratory studies and not enough to epidemiological evidence. Another committee member, Dr Harald Rossi claims that the committee has not gone far enough in its revisions, and that the dangers are still being overstated.

The BEIR Committee first gave its support to the linear hypothesis in its initial report, published in 1972. Given the many uncertainties surrounding attempts to estimate the effects of low-level radiation, and in particular the impossibility of providing conclusive statistical evidence based solely on epidemiological studies, the committee proposed the linear hypothesis as a basis for regulation.

Since then, it has been used as the basis for standard setting by the EPA. But it has been challenged by the nuclear industry, which claims that it provides an unrealistic assessment of the health risks of nuclea power, and thus could lead to overly-restrictive legislation.

The BEIR committee came out with a revised version of its report last spring. It again endorsed the linear dose–response relationship as a basis for regulation and provided estimates of the several hundred additional cancer deaths per million population that would result from continuous exposure to one rad of radiation.

Publication of the report, however, brought into the open a fierce debate which had until then taken place within the committee over how much weight to give to

0028-0836/80/320550-02$01.00

different types of evidence — and the appropriate dose–response models which could threfore be justified.

Five members of the committee issued a dissenting statement, claiming that insufficient weight had been given to radiobiological data and that accepting the linear hypothesis as a basis for regulation, would result in regulations which would hinder the development of nuclear energy and the use of radiation in medicine.

When it became clear that additional members of the committee also had reservations, academy president Dr Philip Handler decided that the controversial section should be rewritten. The revised report was published in Washington last week, with dissenting statements from Drs Radford and Rossi.

The new report goes some way to establishing a compromise on what the academy calls the "ideological differences" between committee members over methods for estimating numerical risk values for cancer induction.

Whereas previously, for example, the committee had used data on general cancer incidence taken from survivors of the Nagasaki atomic bomb explosion, the new report gives this data less prominence than the cancer mortality data on survivors in both Hiroshima and Nagasaki, which suggests a more quadratic dose–response relationship at low radiation levels.

Similary, rather than giving estimates of predicted increased cancer mortality and morbidity based directly on the linear hypothesis for the effects of low LET (linear energy transfer) radiation — primarily X-rays and gamma rays — the new report presents a range of risk estimates based on linear, linear-quadratic and quadratic models. And it adds that the linear-quadratic is "most consistent with existing human epidemiological studies and radio-biological data and knowledge".

Dr Radford took no part in the rewriting process. He remains critical of the final results, claiming that the report ignores much new data in support of the linear hypothesis, with the consequent risk of understating the dangers of radiation.

Dr Rossi, too, remains dissatisfied. He claims that his own work and that of others on the effects of radiation on plant cells suggests that the linar hypothesis overstates the dangers. And that even though its prominence has been downplayed, it is still likely to be used in standard setting, to the disadvantage of the nuclear industry.

David Dickson

Calculations and measurements

What follows is a summary of the definitions in BEIR III relating to the somatic effects of ionizing radiation. The terms of reference of the study, set by the US Environmental Protection Agency, include an explicit reference to nonlinear effects. The report therefore includes a discussion of the small-scale effects of the interaction of radiation with matter along the following lines.

Radiation dose (D) is a quantity of energy deposited in matter; the unit is the rad (equivalent to 100 ergs of absorbed energy per gramme), soon to be replaced by the SI equivalent of the gray (or Gy), with 1 Gy = 100 rad. Charged particles (e.g. α particles) or uncharged and indirectly ionizing particles (e.g. X rays) differ from each other in the rate of "linear energy transfer" (LET) along their tracks; for a given particle, the LET is also a function of energy. The LET is low (a few keV per μm) for cosmic-ray μ-musons, high for α-particles.

Concerned as it is with nonlinear effects, BEIR III needs to introduce a microscopic analogue of the macroscopic dose D called "specific energy" z and intended as a measure of energy deposition by radiation in sub-cellular structures such as cell nuclei.

The deposition of energy along the track of a particle is not uniform on such a scale, because the interactions of radiation with matter entail interactions with discrete entities in the irradiated matter. Thus although (with appropriate units) the average value of z (written $\bar{z}$) must equal D, the microscopic intensity of energy deposition can vary dramatically with different kinds of radiation.

The report goes on to consider (but does not eventually adopt as an assumption) the proposition that for radiation to cause somatic damage, two "sublesions" must occur within some small range (say 1 μm) in a cell and within some specified interval of time. Then the frequency of "lesions" (E) will be $K(\overline{z^2})$ where K is a constant. Moreover, the mean square microscopic dose will be related to the macroscopic dose (D) by $\overline{z^2} = wD + D^2$ where w is a constant determined unambiguously by the statistical properties of z for the type of radiation concerned.

One consequence of this argument is that even the assumption that it takes *two* sublesions ("hits") within some microscopic region leads to a dose-effect relationship in which the risk of damage is of the form $\beta D + \gamma D^2$, but in that case β and γ should be related to each other by the statistical properties of the radiation concerned, whence the relative biological effectiveness of high-LET and low-LET radiation should be calculable.

With this said, BEIR III says that wherever possible empirical data have been fitted to curves with the form $(a_0 + \alpha_1 D + \alpha_2 D^2)$ exp $(-\beta_1 D - \beta_2 D^2)$ where all the constants are positive, a_0 represents the spontaneous rate of some effect and the exponential term (significant only at high doses) takes account of competition from cell death.

BEIR III includes a discussion of using human epidemiological data as a means of determining dose–response relationships empirically. Apart from familiar problems of bias (people exposed to diagnostic X-rays may be especially prone to cancer, for example), the report draws attention to the retrospective character of most epidemiological studies, the problems occasioned by the long latency period for cancer induction, the distinction between mortality and morbidity (and the possibility that the latter may be under-reported), differences of susceptibility between different genetic groups.

Numerical calculations of cancer caused by radiation yields rates per million people assumed to be taken from a population represented by life-tables for the United States population in the period 1969 – 71.

The BEIR report uses two alternative models for calculating the "excess" effects of radiation. Absolute risks from radiation exposure are represented by constant probabilities of cancer formation, or of death therefrom, for each year of life after the lapse of the latency period. Relative risks are calculated on the assumption that the effect of radiation exposure is to increase the formation of cancer, or of cancer mortality, in proportion to the spontaneous rate at the age at which the damage becomes apparent.

Like previous analyses of the consequences of radiation exposure, BEIR III leans heavily on data gathered over the years from the populations of Hiroshima and Nagasaki, but again it breaks new ground by seeking to separate the effects of gamma and neutron doses at the two explosions. The two explosions differed in that at Nagasaki the explosion exposed the population to much smaller neutron doses than that at Hiroshima.

To make the calculations of risk explicit, BEIR III considers three separate cases of radiation exposure: (a) a single exposure of a population represented by the US life-tables to 10 rad of low-LET radiation; (b) a continuous lifetime exposure at a rate of 1 rad per year; and (c) a pattern of exposure to 1 rad a year at ages chosen so as to simulate occupational exposure to radiation.

Different assumptions give very different results. Spontaneous cancer mortality for the standard US population is calculated at 16.38 per cent, and the consequences of a single exposure of the whole population to a dose of 10 rad turns out to be an extra 766 deaths (0.47 per cent) on the absolute risk calculation and an extra 2,255 deaths (1.4 per cent) on the relative risk basis, on the assumption that the dose-effect relationship is represented by a quadratic function including a linear term.

BEIR III is so far distributed in typescript form, but will be available in book form from the National Academy of Sciences later in 1980.

Alternative energy

Europe stirs

In Britain and France, there are now signs that governments are prepared to back alternative energy sources with real money. Last week, M Andre Giraud, the French industry minister, announced a 50 per cent increase of the solar energy budget. Hard on his heels, the UK government will announce this week a plan to spend £6.5 million on geothermal and wind energy projects.

With the latest increase, the French solar energy budget will amount to an annual £21 million. The *Commissariat à l'energie solaire* (Comes) estimates that France may produce 7.5 to 9 million tonnes of oil equivalent (mtoe) from biomass by 1990, more than 10 million mtoe by 2000 and ultimately 30 mtoe.

In 1990, solar heating is expected to provide 1.3 to 1.5 mtoe, geothermal energy 0.8 to 1 mtoe, and "*microcentrales*" (small solar power stations) 0.4 to 0.5 mtoe. Together with biomass, these sources will furnish 5 per cent of French energy needs compared with 1 per cent now.

Biomass is the centre of the French programme and forest wastes, used for methanol production and rural energy needs, its chief element. There is also a plan to use agricultural wastes and, in the process, to develop fermenters and distilleries which can be exported to Third World countries. There are somewhat pious hopes that these countries, using local biomass, would then re-export liquid and gaseous energy products to France, thus ultimately reducing French dependence on OPEC countries.

In Comes's vision, French agriculture would also be transformed, with more acreage devoted to energy crops and some 60,000 to 80,000 jobs created.

In Britain, the Department of Energy has recently estimated that some 8 per cent of Britain's energy requirements could come from biomass (including 2–3 per cent from burning domestic rubbish), while only two years ago the estimates were about 0.5 per cent. These estimates are however arrived at differently from the French, and represent a large number of small contributions from the energy-efficient use of farm and industrial waste, and finding sites for energy crops.

The major UK commitment announced by the Department of Energy this week is to geothermal "hot rocks" by means of a £7.2 million, three-year research programme at the Camborne School of Mines in Cornwall. The United Kingdom will provide £6 million and the European Commission £1.3 million for the project, which is intended to demonstrate the feasibility of a 30 MW (thermal) generator involving paired wells, 6,500 ft deep, and 2 million m^2 of fractured rock surface. The project is "complementary" to that at Los Alamos in the United States, using explosive fracturing rather than high water pressure to create the surface, project leader Dr A W Batchelor said this week. The entire land area of the United Kingdom could be exploited for geothermal energy production, said Batchelor, producing electrical energy at 10 per cent efficiency, if commercial drillings could be constructed to reach 7,000 to 8,000 metres depth. (Current deepest North Sea wells are 6,000 metres.)

A further grant of £450,000 goes to Dr Peter Musgrove of the University of Reading to develop a 25-metre diameter, 130 kW vertical axis windmill, the prototype of a 2–3 MW device. The North of Scotland Hydroelectric Board is showing great interest in wind energy, which is increasingly seen as the most advanced of the alternative sources in the United Kingdom.

In Germany, a question in the Bundestag last week led to the publication of figures which showed a decrease in the non-nuclear energy research programme for the first time since 1972. By 1979, spending in the programme had reached £164 million but it fell to £148 million this year. Within the decrease however, — alternative energy research managed to score a rise from £20 million (1979) to £25 million (1980). This year's budget includes £14 million on solar, £6 million on wind and £4 million on geothermal energy. Comparable figures for the Department of Energy in the United Kingdom are £1.7 million on solar, £1 million on wind and £2.1 million on geothermal.

Robert Walgate

Alternative technology

Water play

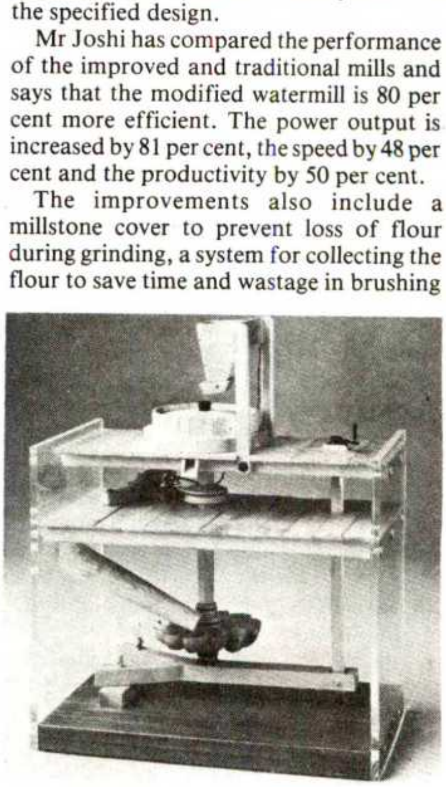
Villagers from two very different developing countries, Kenya and Nepal, are to benefit from the results of a project to improve the efficiency of watermills used to grind corn. The project has been stimulated by Jean Gimpel, a European historian of science and technology, who says that several international agencies are taking an interest.

Vertical axis watermills appear to be in common use in hilly regions of many developing countries (and can even be found in some industrialized countries). They have traditionally been used to grind corn for small communities of farmers. M. Gimpel, whose cause is the revival of traditional technologies in rural areas, first interested the Nepalese in modernizing traditional watermills by taking to Nepal a model of a watermill of improved design. Last year, the Research Centre for Applied Science and Technology (RECAST) at the University of Kirtiput set up a project to build a prototype mill in the Kathmandu valley under the supervision of Mr C. B. Joshi. M. Gimpel says that the Agricultural Development Bank of Nepal has been sufficiently impressed with the project to have distributed models of the prototype to all its branches. The bank has also set up a loan scheme for millers who want to improve their own mills.

The RECAST watermill succeeds chiefly by using well designed bucket-shaped vanes which can accept the full impulse of the water. Replacing the pin mounting of the turbine shaft with ball bearings also increases efficiency, as does enclosing the water feed to the mill in a covered chute. Gimpel and Joshi say that all the work can be done with local skills, mainly the carpenter's who can carve new paddles to the specified design.

Mr Joshi has compared the performance of the improved and traditional mills and says that the modified watermill is 80 per cent more efficient. The power output is increased by 81 per cent, the speed by 48 per cent and the productivity by 50 per cent.

The improvements also include a millstone cover to prevent loss of flour during grinding, a system for collecting the flour to save time and wastage in brushing the flour off the stone and electric light generated by a small dynamo driven by a bicycle wheel.



Although the improvements cost money, Mr Joshi estimates that the extra costs should be repaid more than three times within a year. He also says that the increased power output of the mills could be used to drive other machines — rice dehuskers, trip hammers and bellows and circular saws or lathes. He foresees small industries based around the mills, rather similar to the industrial complexes of eighteenth century England.

The Kenyan government, which has taken up the project since seeing models of the Nepalese mill at the United Nations conference on Technical Cooperation between Developing Countries in Nairobi in May, is hoping to have a small complex of several full-scale improved mills operating near Nairobi for next year's international conference on renewable energy.

Pre-Pleistocene climates

from Samuel M. Savin

ATTEMPTS to reconstruct the history of the world's climate and to understand its changes are among the oldest of geological problems. While enormous progress has been made in recent years, especially in understanding Cenozoic (0 to 65 Myr) climates, it is sobering to read Lyell's[1] 1837 summary of paleoclimatology and to realize for how long geologists have been struggling with similar climatic questions. One problem which continues to create difficulties is the host of variables which can be summarized under the term climate (e.g. average and seasonal variation of temperature, average and seasonal distribution of rainfall, aridity, wind, etc.) while only one, or a very few, are manifested in any single type of deposit. Furthermore, many of these climatic variables can only be documented in a qualitative or semi-quantitative fashion.

An exception to this state of affairs is the climate of the past million years or so. A great deal is now known[2] about the nature of glacial and interglacial stages and the timing of each. It has been possible to develop testable hypotheses of the causes of glacial-interglacial fluctuations and to develop models of glacial-stage atmospheric circulation[3].

Further back in time interpretation of climate becomes increasingly difficult. At a recent symposium on Pre-Pleistocene Climates*, J. Imbrie (Brown University) pointed to recent advances in Pleistocene climatology. Two types of models which are likely to prove especially useful are Global Circulation Models (GCM's) and models which can be thought of as sensitivity studies, designed to test the sensitivity of the climate to proposed changes in some controlling variable (e.g. insolation, atmospheric chemistry, continental and oceanic geometry, etc.). GCM's have been applied to the study of atmospheric circulation 18,000 years ago[3] with promising results. L. Gates (Oregon State University) discussed the kinds of geologic information needed if GCM's as well as simplified models are to be applied to the study of Mesozoic and Paleozoic climates.

Geologic information becomes increasingly generalized and climatic models must become correspondingly less detailed as we proceed backward in time. Pre-Jurassic deep sea sediments have been entirely swallowed up in subduction zones so the record of marine climate is found only in those continental shelf sediments that have survived erosion or metamorphism — a scattered record at best. However, so little is known about the climates of Paleozoic and Precambrian times that even a small amount of climatic data may answer key questions. For some parts of geologic history zero-dimensional climatic models, yielding average global temperatures, can be most useful. In earliest geologic time, for example, J. Pollack (NASA-Ames Research Center) noted that almost any acceptable theory of solar energy production yields solar output only 70 or 80 percent of the modern value. The geologic evidence, however, suggests that temperatures during at least much of the early Precambrian were as warm as, or warmer than today's. Any interpretation of the mechanisms controlling Precambrian climate must resolve this dilemma.

Deep sea sediments, when they are available, provide the most readily interpretable climatic information. The two most common approaches to obtaining paleoclimatic information from deep sea sediments are those based on paleontology and those based on oxygen isotope analyses. Haq (Woods Hole Oceanographic Institute) demonstrated his method of identifying acme events, or peak periods of environmentally (including climatologically) induced floral and faunal migration. Identifying such events involves obtaining fossil census data covering a broad geographical area. The unwieldy census data is reduced into a manageable number of factors, the dominance of each of which is presumed to be environmentally controlled. The migration of the factors through space and time is then interpreted in terms of variations in environmental conditions.

Oxygen isotopes have permitted detailed interpretation of surface and bottom water temperature history throughout the Cenozoic. While there is some debate, especially for the late Cenozoic, as to the extent to which isotopic variations reflect temperature change and the extent to which they reflect the growth and retreat of continental ice, isotopic fluctuations can be correlated remarkably well from place to place and clearly reflect climatic variations. Berger (Scripps Institute of Oceanography) characterized the Cenozoic isotopic record as showing step-like transitions from one state to another and attempted to discriminate between externally forced climatic changes and those generated internally within the earth-ocean-atmosphere system. He suggested, as did Thierstein (Scripps), that a number of events including the terminal Cretaceous extinction event and the rapid growth of Antarctic ice in mid-Miocene time belong to the latter class. Moore and Pisias (University of Rhode Island) examined the Cenozoic isotopic record, concentrating on variability rather than absolute values of temperatures. Using this annual approach they were able to show that the climate is substantially more variable at some times than others. Highly variable climates may turn out to be characteristic of less stable climatic systems, easily shifted from one state to another. The oxygen isotopic compositions of pre-Cretaceous fossils have frequently been altered by diagenetic processes. As pointed out by Savin, and by Hallam (University of Birmingham) the isotope record adds little, if anything, to our understanding of Jurassic climates. Uncertainties in the interpretation of the isotopic data are as large as or larger than uncertainties in non-isotopic estimates of Jurassic temperatures. Perhaps surprisingly, isotopes, especially of cherts, promise to be useful in providing constraints on early Precambrian temperatures. While the uncertainties in the isotopic temperature are indeed large, they are smaller than uncertainties in temperatures estimated by other means.

Samuel M. Savin is in the Department of Geological Sciences, Case Western Reserve University, Cleveland.

---

*The symposium was held on May 22, 1980 in Toronto at the Annual Meeting of the American Geophysical Union and was part of a study by the Geophysics Study Committee of the National Research Council. The aims of the symposium and study are to summarize the status of Pre-Pleistocene climatology and to identify key areas for future research. A final report will be published by the National Academy of Sciences in 1981.

0028-0836/80/320553-02$01.00

In assembling the climatic record on the continents it seems difficult to avoid the anecdotal approach. Terrestrial deposits are widely scattered and are subject to local variations in climate. Climatic variables other than temperature are far more important in affecting terrestrial deposits than marine. However, in spite of these difficulties, Wolfe (US Geological Survey) was able to show that Cenozoic climatic changes derived from North American plant fossils parallelled those of the North Atlantic from planktonic foraminifera. Eugster (Johns Hopkins University) showed a climatic reinterpretation of the Eocene Green River evaporites suggesting a climate similar to that of Holocene Southeastern California. Van Houten (Princeton University) assembled data on ancient laterites and calcretes from which he was able to draw consistent conclusions about climatic zonations. Crowell (University of California, Santa Barbara) assembled and critically evaluated evidence for Paleozoic and Precambrian glaciations. He offered a hypothetical series of plate reconstructions for Precambrian glacial stages not based on geophysical constraints but drawn so as to cluster glaciated regions in polar areas. Uncertainties in the paleomagnetic data are sufficient to permit considerable freedom in choice of continental positions. While lagging behind our knowledge of oceanic climates, knowledge of terrestrial climates is becoming more complete and techniques for obtaining that knowledge are becoming more sophisticated.

The oceans carry a significant amount of heat, and hence changes in oceanic circulation can be expected to have affected climate. Berggren (Woods Hole) presented a correlation between the climate of the past 200 Myr and the opening and closing of oceanic gateways (or barriers to circulation). At the time of the Eocene-Oligocene boundary there is a correlation between the opening of the Greenland-Norwegian Sea to the Arctic, the breaching of the Rio Grande Rise and the possible initial opening of the Drake Passage on the one hand and the marked cooling of oceanic bottom water and terrestrial climates on the other. He also pointed to a correlation between the elevation of the Isthmus of Panama 3 Myr ago and the onset of Northern Hemisphere continental glaciation.

In a field as complex and wide ranging as the history of climate throughout the history of the earth it is not surprising that the extent of our knowledge so often seems small. However, it was apparent at the symposium that great strides have been made in the past 15 years in pre-Pleistocene paleoclimatology, not only in the acquisition of climatic knowledge but in the development of new tools and techniques. □

Towards a submarine hydrology

from Marcus G. Langseth

The excitement generated by the discovery of hydrothermal fields at the axes of the Galapagos and the East Pacific rises notwithstanding, seawater movement within the crust also dominates geothermal heat transfer in the older and colder midoceanic ridge flanks. The pore fluids involved in this circulation system are at low temperature (usually less than 50°C at the top of the crust) and flow rates are slow (centimeters per year). If the high temperature hydrothermal zones at ridge axes are analagous to volcanic and geothermal zones such as Iceland, the low temperature circulation on the ridge flanks may be likened to groundwater movement. The phenomena of submarine hydrology may have little intrinsic glamour but their scientific and practical importance is nevertheless great. Several groups, particularly in the United States, are busily exploring ridge-flank thermal regimes and the past two years have seen some interesting and puzzling developments. Many of these emerged at the last three meetings of the American Geological Union.

The evidence that cold bottom-water circulates below the seafloor consists of temperature gradient measurements which show that temperatures at the base of the sedimentary layer are much less than those expected if the crust were in conductive equilibrium with the lithosphere. Anomalously low crustal temperatures are usually found where the sedimentary cover is thin (less than 200 meters) and where there are frequent exposures of the igneous oceanic basement. The inference is that bottom-water enters the igneous crust at these exposures and moves laterally below the sediments through a basement made permeable by extensive fracturing, thus carrying away much of the geothermal heat. It has been assumed that this circulation is driven by geothermal heat so that it is a kind of channelized convection, but recent observations have brought this simple model into question.

These observations were made on the flanks of the Mid-Indian Ocean Ridge by the Lamont-Doherty group late in 1977. They involve lines of closely-spaced temperature gradient measurements made with a temperature probe two to five meters long which is lowered into the sediments as it is towed over the bottom by a surface ship. Sonic reflection profiles over the same area throw light on the structure of the sediments. The heat-flow variations suggest that there is cellular convection in the crust and that some of the discharge and recharge may take place through the sedimentary cover. A group from the University of Washington, in a joint study with the Pacific Geoscience Centre in Canada, has made similar studies on the Juan de Fuca and Explorer ridges and found evidence for cellular convection and for the penetration of cold seawater beneath the sediments for distances of up to fifteen km from the nearest outcrops. Another survey on the flank of the Mid-Atlantic Ridge east of Brazil by the Lamont-Doherty group indicates that the crust is cooled up to twenty km from basement exposures requiring lateral flow rates in the range of 10^{-9} to 10^{-8}m/sec.

Particular attention has been paid to the two Low Heat-Flow areas of the Eastern Pacific, discovered in 1963, by Von Herzen and Uyeda in the Guatemala Basin southwest of Central America and at the equator southest of Hawaii. The areas are covered by thick pelagic sediments, 300m or more thick, yet their average heat-flow is less than one-third of the mean heat-flow from the earth. A Woods Hole group has now studied the Equatorial Low Heat-Flow Zone and found thermal evidence for an upward flow of porewater through the sedimentary blanket. The highest heat fluxes coincide with areas of rough basement which seem to focus the water flow.

Earlier this year, a Lamont-Doherty group made a detailed survey in the Guatemala Basin. Seismic profiling surveys showed a 400 m sedimentary blanket periodically broken by north-east trending ridges protruding through the cover and associated with fracture zones spaced 40 to 50 km apart. A line of temperature gradient measurements between two of the ridges shows anomalously low gradients even though the entire area between exposures is thickly sedimented. It appears that the basement in the Guatemala Basin is being 'ventilated' by this regularly spaced set of ridges.

During this survey, measurements of porewater pressure within the sediments were made by Dallas Abbott of the Lamont-Doherty Observatory. Anomalously, pore pressures are less than hydrostatic in sediments five meters below the seafloor and are accompanied by low

---

Marcus G. Langseth is in the Lamont-Doherty Geological Observatory, New York.

0028-0836/80/320554-02$01.00

temperature gradients. Abbott explained that these are exactly the circumstances that would be expected if there were a downward flow of porewater. She suggested that the low temperature in the thick sediments of the Guatemala Basin may indicate a slow drawdown of seawater through the sedimentary cover that reemerges at the ridges.

Whether the flow through the sediments is, however, significant is controversial. Nonlinearities of temperature profiles on the ridge flanks have been repeatedly observed. The Lamont-Doherty group, on the basis of their 1977 survey, attributed these to water flow through the sediments. At most stations temperature gradients decrease with depth, implying upward flow.

The flow rates are surprisingly high, tens of centimeters per year. Even if the permeability of sediments is among the higher values found in the samples, pressure gradients of the same order of magnitude as the hydrostatic are needed to drive the flows. The pressures cannot be achieved by thermal stresses associated with thermal convection but three possibilities remain: 1) the *in situ* permeability is much higher than laboratory measurements indicate; 2) there are unknown sources of pressure in the oceanic crust; or 3) the non-linear temperature profiles may have another explanation. Nonlinearity in temperature profiles can stem from many phenomena; for example an increase in conductivity with depth, changes in the bottomwater temperature and heat generation in the sediments. The present data are insufficient to decide between alternative explanations and as a consequence, there is much interest in other approaches demonstrating significant flow of sedimentary interstitial water.

Chemical gradients in sedimentary porewater will also vary with depth if the flow rates are of the same magnitude as the ionic diffusion rates. A combined University of Rhode Island and Woods Hole study, reported at the June 1979 American Geophysical Union Conference, found calcium-depth profiles in sediments in the Galapagos Hydrothermal Mounds field consistent with an upward flux of 0.3 to 15 cm yr^{-1}; whereas, profiles in an adjacent low heat-flow zone show seawater concentrations of calcium consistent with downward advection of water. However, sediments in this area are only about 20-30 m thick.

Porewaters from DSDP cores provide chemical profiles across thick sedimentary layers and a consistent pattern is emerging from measurements made by geochemists at the Scripps Institute, Lamont-Doherty Observatory and the University of Rhode Island. Sediments in older areas of the ocean show chemical gradients that preclude water flow through the sediments at thermally significant rates. However, in ridge flank areas, chemical gradients in the sediments are small or nonexistent, so vertical advection may be possible. The chemistry of interstitial waters promises to be one of the clearest means to detect water advection, particularly when coupled with temperature profiles.

The other means of investigating possible subseafloor flows is by *in situ* pore pressure measurements. The measurements of Abbott in the Guatemala Basin were the first such experiments attempted in deep-sea sediments. The measurements are difficult to carry out but initial results are repeatable and show significant pressure anomalies. Further tests of this new technique are planned.

Deep-sea drilling on the Costa Rica Rift during DSDP-IPOD Leg 69 showed there was a substantial drop in excess pressure across a 260 m thick sedimentary layer. One hole drilled through the sediments and into the basement showed a drawdown of water of about one meter per hour which persisted for at least 60 days. Pore pressures at the bottom of this hole estimated from extrapolation of pulse tests were nearly twenty bars below hydrostatic. Anomalously low pressures below the sediments may be a widespread phenomenon, as they have already been reported at two sites in the Mid-Atlantic Ridge on Legs 37 and 46 and Leg 60 in the Mariana Trough.

There are a number of ways by which the low pressures may be produced. They include; a fossil low pressure, perhaps from the lowered sea level of the last ice age; alteration reactions in the basement that cause a volume decrease and large-scale thermal convection with the low pressure field centred below the sediments. The possibility that the low pressures result from intrabasement reactions suggests that inward flow of water at outcrops can occur without discharge, a result that would agree with seafloor heat-flow observations.

The proposal that Challenger be available for an additional two years of Deep Sea Drilling could allow new data to be obtained on the hydrology of the oceanic crust. Particularly important will be pressure measurements in holes that penetrate through sediments into igneous basement. These measurements can be made with a packer, a tool that seals the annulus between the hole wall and the pipe, allowing bottom-hole pressures and *in situ* permeabilities to be determined. Temperature and porewater chemistry observations in the sediments and in the bottom of holes that penetrate basement will add the third dimension to the seafloor distributions provided by conventional seafloor methods.

One of the most promising approaches to the problems discussed here would be to use the Challenger to reenter existing holes. These holes are in thermal equilibrium and the experiments using the packer could be efficiently done in a predrilled hole. A sufficient number of reentry holes in both the ridge flank and in older seafloor exist to permit a variety of thermal and sedimentary environments to be sampled.

The questions about the extent and magnitude of circulation in the suboceanic crust have great relevance to problems of nuclear waste disposal in the deep seabed. The US Department of Energy is considering the burial of waste in durable cannisters within sediments such as the abyssal clays of the Northern Pacific which are assumed to be impermeable. Incomplete knowledge of the driving forces and extent of water circulation in the crust and sediments makes these assumptions questionable. However, should it turn out that low pressures in the oceanic crust are not associated with circulation that returns seawater to the ocean, then long-term disposal may become a possiblity. □

Membrane protein distributors

from M.J. Geisow

ON theoretical as well as experimental grounds, lipid vesicles have long been considered the likely carriers of proteins between the membranes of the cell. Rothman and Fine (*Proc. natn. Acad. Sci. U.S.A.* **77**, 780; 1980) have now demonstrated that a trans-bilayer glycoprotein, the small G protein of Vesicular Stomatitis Virus (VSV) is inserted into the membrane of coated vesicles during its migration to the surface of CHO cells. Furthermore — and of wide importance for studies of the transport of proteins synthesised on rough endoplasmic reticulum (RER) — intracellular transit of G from RER to the Golgi apparatus in which terminal sugars are added also takes place in clathrin-coated vesicles.

The character of the clathrin coat and its self-assembly in the plasma membrane may provide a basis for the specificity required in a membrane protein transport system. As early as the 1960's, Friend and Farquhar (*J. Cell. Biol.* **35**, 369; 1967) suggested that coated vesicles conveyed material to apical regions of the plasma membrane in rat vas deferens epithelial cells. The vesicles were seen in close association with the Golgi apparatus and cytochemical observations suggested that they might also transport lytic enzymes to lysosomes but supporting biochemical evidence was lacking until the experiments of Rothman and Fine.

Their choice of a viral protein to track the route of membrane proteins was a simplifying one as G is the only glycoprotein synthesised in CHO cells following VSV infection. In just the same way as native membrane glycoproteins, G

M.J. Geisow is in the National Institute for Medical Research, Mill Hill, London.

0028-0836/80/320555-02$01.00

is glycosylated in the endoplasmic reticulum and hexamannose units of the core oligosaccharide are replaced by terminal sugars in the Golgi apparatus. The pre-Golgi form of G is distinguishable from the post-Golgi processed protein by its sensitivity to endoglycosidase H (Endo H).

Coated vesicles purified from a large pool of VSV-infected cells contained G as well as the characteristic spectrum of vesicle polypeptides and G could be co-precipitated with clathrin using monospecific anticlathrin. Newly-synthesized G was detectable by pulse-chase labelling, in this case carrier vesicles derived from bovine brain allowed isolation of a small number containing radiolabelled G. A kinetic study of the transport of G in the vesicles was then possible, using Endo H to determine the amount of Golgi-processed protein.

It was clear that G was present in coated vesicles in transit to the plasma membrane since the vesicle fraction never contained more than 20% of the pool of labelled protein. More importantly, the specific activity of labelled G in the vesicles rose twice during the chase, showing the transport of first the Endo-H sensitive (pre-Golgi) glycoprotein and then the transport of the Endo-H resistant glycoprotein. The clearance of the post-Golgi form of G from the vesicles coincided with the appearance of G on the cell surface (55% of the label in 65 min).

G was demonstrated to be actually present within the coated vesicle membrane by uncoating vesicles containing ^{3}H-mannose-labelled G on metrizamide gradients. A single ^{3}H-labelled polypeptide corresponding to G floated up with the CV lipid vesicle fraction.

Coated vesicles are known to 'shuttle' rapidly within cells and short transit times are certainly in keeping with their functions as a transport system. The presumed cycling time of coated vesicles is much faster than the observed time for the total transport of pulse-labelled VSV G protein suggesting that many trips are made by the same vesicles or at least certain of their components. The difficulty of depleting some endocytic receptors which are known to be internalized in coated vesicles again suggests that they are re-used.

Of course, the recognition of the identity of the carriers still leaves open the question of how a given protein arrives at the appropriate cellular membrane, but at least this sorting problem has been brought nearer to the compass of current experiment. □

Adhesion of pathogenic microorganisms

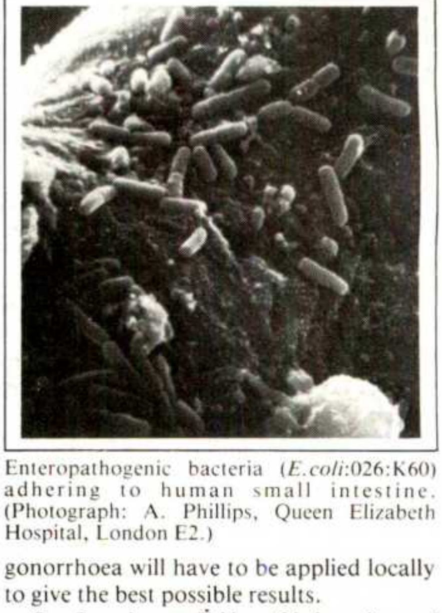
from Mary Lindley

MICROORGANISMS that enter the internal tracts of the body and come to rest on mucous membranes would seem to need a firm anchorage before invading or discharging their toxins into the underlying epithelium. Otherwise they would surely be swept away by the muscular activity of the tract or by the fluid passing through. Nevertheless, a link between adhesion and pathogenicity was recognised only slowly. The first clear evidence of the significance of bacterial adhesion came during the 1970s when veterinary scientists showed that certain strains of *Escherichia coli* must produce not only toxins but also an antigen, designated K88, in order to cause diarrhoea in piglets. Recognised by the ability to agglutinate red blood cells, K88 and the similar K99, produced by strains infecting calves and lambs, are hair-like fimbriae (also known as pili but unrelated to sex pili), which mediate adhesion to the intestinal mucosa. Analogous plasmid-encoded fimbriae, designated colonisation factor I and II (CFA/I and /II), have been described in certain *E.coli* from cases of human diarrhoea.

Thus a similar picture has begun to emerge for human diarrhoea, although the pace of work is hampered by the difficulty of finding a suitable system to study. At a recent symposium on adhesion and pathogenicity* D.C.A. Candy (Institute of Child Health, London) reported tests of adhesion of *E.coli* to human buccal epithelial cells and intestinal cells. This work has confirmed that CFA/I is important in adhesion to human small intestine. Investigation of an outbreak of acute diarrhoea in infants has lead to the isolation of a strain of *E.coli* producing a colonisation factor resembling CFA/II. There are also signs that some infants with protracted diarrhoea may be more prone than others to adhesion by *E.coli*, in the same way that some but not all piglets develop diarrhoea in response to *E.coli* carrying K88.

Apart from CFA/I and/II, strains of *E.coli* causing diarrhoea in man may carry antigens of a different sort — type 1 fimbriae (also known as common fimbriae). M.M. Levine and his colleagues (University of Maryland School of Medicine, Baltimore) are looking for a combination of all three that could form the basis of vaccine against infant and travellers' diarrhoea, analogous to that already used successfully for piglets. He suggested that a vaccine would probably include antigens such as CFA/I and/II plus type 1 fimbriae of perhaps three different antigenic varieties. The immediate task is to find antigens common to a sufficient variety of bacterial strains to provide a broad spectrum of protective antibodies when used as a vaccine.

Studies of *Neisseria gonorrhoeae* adhering to buccal epithelial cells, described by E.C. Tramont (Walter Reed Army Medical Center, Washington DC) have shown that fimbriae are the principal antigens mediating adhesion, again making them the obvious target for prophylaxis. Human antibodies against these fimbriae can be found in genital secretions from naturally occurring cases of gonorrhoea, albeit needed in very large amounts to block adhesion *in vitro*. One possible approach to prevention could be immunization to produce protective antibodies against fimbriae. The other approach discussed by Tramont would be to inhibit adhesion competitively by bathing the site of infection in fimbriae. Tramont believes that any vaccine against gonorrhoea will have to be applied locally to give the best possible results.



Enteropathogenic bacteria (*E.coli*:026:K60) adhering to human small intestine. (Photograph: A. Phillips, Queen Elizabeth Hospital, London E2.)

C. Svanborg Édén (University of Göteborg, Sweden) thinks that fimbriae also mediate the adhesion of those intestinal *E.coli* that infect the urinary tract. She has found that the extent of adhesion seems to be related to virulence, which is greatest in strains causing acute pyelonephritis, intermediate in those causing acute cystitis, and low in those producing no symptoms although they are detectable in the urine. Susceptibility to infection also seems to vary, and this, she suggested, may be associated with the density of receptors on the host cells. Candidates for those receptors are glycolipids related to globoside, which inhibit the adhesion of *E.coli* to urinary

Caligus coryphaenae Steenstrup and Lütken, female: top left, cephalon, ventral (30X); top right, frontal lunule (200X); bottom left, second antenna (200X); bottom right, a happy mouth tube (280X).

from R.J. Roberts

A recent Smithsonian Contribution to Zoology* by Cressey & Cressey has made a major contribution to resolving many of the problems of copepod taxonomy. There are more than a 1,000 known copepod species with very wide ranging structural diversity and the same hallowed, often inaccurate, drawings have appeared in text after text. The copepods are parasites of the economically important mackerel and tuna fish groups and when they occur in large numbers they can be a source of significant financial loss.

The scanning electron microscope pictures from the report, reproduced alongside, show various features of a parasite of the tunny. The bottom right-hand plate, which they designate "the happy mouthtube" shows something that parasitologists have long suspected — that copepods enjoy life even if their hosts do not. □

tract epithelium, whereas other glycolipids and monosaccharides do not.

N. Sharon (Weizmann Institute, Rehovoth) reminded the symposium that bacterial adhesion may be inhibited by simple sugars, particularly mannose in the case of various strains of *E.coli* and salmonella. This has suggested that mannose or mannose-like residues on the host cell form part of the receptor for the bacteria which attach to them. There is considerable evidence, said Sharon, that many strains of bacteria contain a lectin-like substance, specific for mannose, which may take the form of fimbriae or flagella or may be embedded in the outer membrane. (Adhesion mediated by CFA/I and/II, K88 and K99 is insensitive to mannose, while that due to type 1 fimbriae is sensitive.) He said there is good reason to believe that the mannose-sensitive attachment plays a role in pathogenicity, and he has found that α methyl-D-mannoside diminishes infection of the urinary tract of mice by virulent strains of *E.coli*.

Adhesion, often of a more transitory nature, is an obligatory step in the infection of cells by mycoplasma. S. Razin (Hebrew University of Jerusalem), describing work done in conjunction with W. Bredt (University of Freiburg), said that adhesion, chiefly in the respiratory tract, enables toxic products of mycoplasma metabolism, such as ammonia and hydrogen peroxide, to reach concentrations sufficient to damage the cells. He said that sialic acid residues form the receptors of the cells, while the binding sites on the mycoplasma are apparently membrane proteins. Adhesion seems to depend on the metabolic state of the mycoplasma, with the electrochemical ion gradient across the membrane also being influential.

Another parasite, the protozoan responsible for amoebic dysentery, has come under closer scrutiny as a health problem of the developing world. The trophozoite stage of *Entamoeba histolytica* begins the infectious process by adhering to intestinal epithelial cells, and from there can penetrate into the circulation, adhering to red blood cells and phagocytosing them. D. Mirelman (Weizmann Institute) reported that a lectin found in the trophozoite is apparently involved in the adhesion. He thinks the lectin is separate from the amoeba's toxin, for the two activities can be demonstrated in different fractions obtained from the trophozoite.

For the merozoite stage of the malaria parasite, adhesion to red blood cells is an essential part of the cycle of invasion, multiplication, release and reinvasion that produces characteristic symptoms of anaemia and fever in the host. Adhesion seems to be mediated by specific receptor molecules on merozoite and red cell — evidence includes the specificity of each species of merozoite for either young or old red cells of certain host species and for a particular blood group antigen. R.J. Howard (National Institute of Allergy and Infectious Diseases, Bethesda), discussing work with *Plasmodium vivax* and *Plasmodium knowlesii*, pointed out that characterization of the molecules involved in recognition is hampered because the morphological changes occurring during the cycle are likely to affect the receptors.

D.F.H. Wallach (Tufts-New England Medical Center, Boston) recalled that after invasion, a merozoite matures and multiplies within a vacuole. At the same time the host red cell's cytoskeleton is destroyed and its surface membrane is altered by modification of component proteins and insertion of others synthesised by the parasite. The new proteins are immunogenic in the host, and two of them are involved in protective immunity and have antigenic features common to several species of *Plasmodium* that cause malaria in mammals. This lack of species specificity should make such proteins an attractive target in the search for a vaccine against malaria.

Although the details of adhesion and its relationship to pathogenicity are likely to be hard won, the potential rewards in terms of prevention and treatment of disease are clearly considerable. Vaccines are an obvious outcome to hope for, but other approaches are possible. E.H. Beachey (University of Tennessee College of Medicine, Memphis) reported that small, sublethal concentrations of various antibiotics can disrupt the adhesion of some *E.coli* and *Streptococcus pyogenes*. Especially effective are antibiotics that act on the ribosomes or the cell wall, and Beachey presumes that they interfere with the synthesis or assembly of the fimbriae. This suggests the possibility of combating bacteria with doses of antibiotics sufficient to prevent adhesion but not necessarily to kill them; such low doses would avoid problems of toxicity. As the details of adhesion become better understood, more such relationships should emerge. □

Virus crystallography comes of age

from Stephen C. Harrison

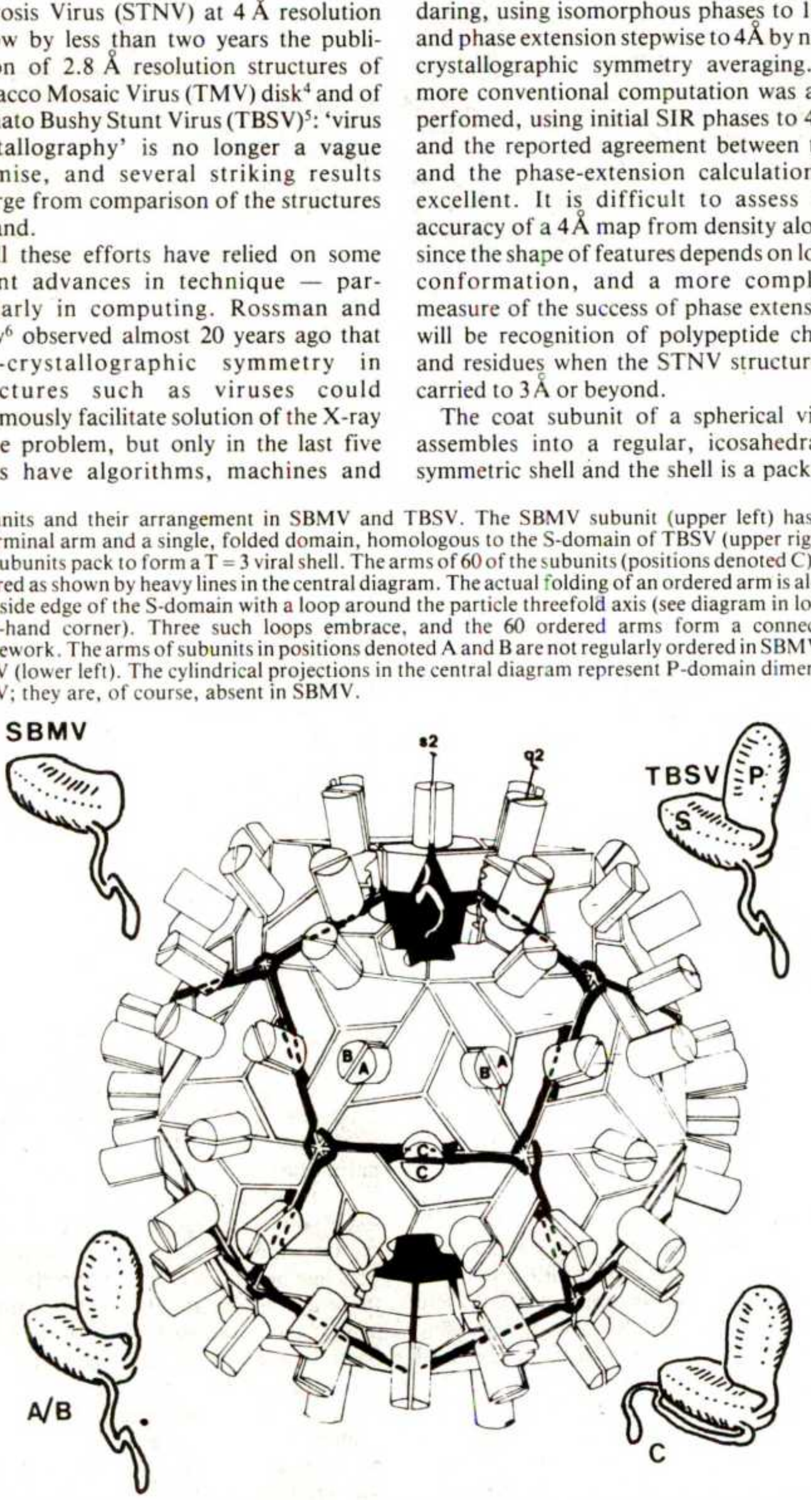
VIRUS particles are simple paradigms for all sorts of sub-cellular assemblies, and detailed views of their organization have long been sought. X-ray diffraction studies of virus crystals began at almost the same time as crystallographic investigation of small proteins[1], and a certain mystique of the 'ultimate' in large unit cells grew up around them. The reports in *Nature* by Abad-Zapatero *el al.* [2] of Southern Bean Mosaic Virus (SBMV) at 2.8 Å resolution and by Unge *el al.*[3] of Satellite Tobacco Necrosis Virus (STNV) at 4 Å resolution follow by less than two years the publication of 2.8 Å resolution structures of Tobacco Mosaic Virus (TMV) disk[4] and of Tomato Bushy Stunt Virus (TBSV)[5]: 'virus crystallography' is no longer a vague promise, and several striking results emerge from comparison of the structures at hand.

All these efforts have relied on some recent advances in technique — particularly in computing. Rossman and Blow[6] observed almost 20 years ago that non-crystallographic symmetry in structures such as viruses could enormously facilitate solution of the X-ray phase problem, but only in the last five years have algorithms, machines and programs been available to carry out the lengthy iterative calculations[7]. In principle, these iterations should converge from any initial approximation to the phases; in practice, however, experimental errors in observed structure amplitudes and approximations in the computational scheme require a non-random starting point. The work on TMV disk, TBSV and SBMV have all relied on the standard method of isomorphous replacement to provide this start. The STNV solution is rather more daring, using isomorphous phases to 10 Å and phase extension stepwise to 4Å by non-crystallographic symmetry averaging. A more conventional computation was also perfomed, using initial SIR phases to 4 Å, and the reported agreement between this and the phase-extension calculation is excellent. It is difficult to assess the accuracy of a 4 Å map from density alone, since the shape of features depends on local conformation, and a more complete measure of the success of phase extension will be recognition of polypeptide chain and residues when the STNV structure is carried to 3 Å or beyond.

The coat subunit of a spherical virus assembles into a regular, icosahedrally symmetric shell and the shell is a package for nucleic acid[8]. Moreover, in most structures the same subunit is found in several conformationally distinct positions, genetic economy requiring a larger coat than can be constructed from just sixty (i.e. one icosahedral quota). These architectural conditions demand a way of incorporating nucleic acid that adapts an inherently nonrepeating structure (the loops and stems of folded RNA) to a regular surface lattice. In structures with more than 60 subunits, they further demand a subunit that can adopt alternative bonding arrangements and hence also a mechanism for avoiding ambiguity.

In TMV, which has been resolved at 4 Å by diffraction from orientated gels[9], three nucleotides are bound into a groove-like site on each subunit. The coat is an 'unwinding protein' and imposes its own helical order on the RNA backbone. One might imagine by analogy that each protein subunit of a spherical virus could bind to an exact length of nucleic acid. If the binding sites were located on a part of the protein fixed in the surface lattice, the RNA would be piecewise icosahedrally ordered, and portions of it would be visible in a suitable electron density map. This model can be ruled out in TBSV and apparently now in SBMV, where no clear RNA-related features appear. In both cases, however, a significant portion of the protein subunit (about 60 residues) is also invisible in the map, implying absence of a unique spatial relationship to the rest of the chain. This portion lies at the N-terminus, and it is a plausible candidate for a nucleic-acid binding sequence. If so, we can imagine two RNA packing modes that might interact with a flexibly-linked binding domain: (1) Viral RNA *in situ* could have a more or less defined tertiary structure, requiring binding regions on the protein loosely tethered to the rest of the subunit, in order to seek out appropriate sites on a non-icosahedrally-symmetric nucleic-acid structure; (2) RNA stems and loops could be compactly but essentially randomly close-packed in the particle (some 60 to 70% of the RNA in such viruses is probably in double-helical stems[10]), again requiring flexibly-linked protein regions for interaction with appropriate RNA structures or sequences. Crystallographic structure determination necessarily yields an average over the operations of the space group, and in SBMV and TBSV, a unique RNA structure would be blurred by the high symmetry of the lattice postion on which the particle lies. In STNV, the asymmetric unit comprises an entire particle, and Unge *et al.* point out that

Subunits and their arrangement in SBMV and TBSV. The SBMV subunit (upper left) has an N-terminal arm and a single, folded domain, homologous to the S-domain of TBSV (upper right); 180 subunits pack to form a T = 3 viral shell. The arms of 60 of the subunits (positions denoted C) are ordered as shown by heavy lines in the central diagram. The actual folding of an ordered arm is along an inside edge of the S-domain with a loop around the particle threefold axis (see diagram in lower right-hand corner). Three such loops embrace, and the 60 ordered arms form a connected framework. The arms of subunits in positions denoted A and B are not regularly ordered in SBMV or TBSV (lower left). The cylindrical projections in the central diagram represent P-domain dimers in TBSV; they are, of course, absent in SBMV.



Stephen C. Harrison is Professor of Biochemistry at Harvard University.

0028-0836/80/320558-02$01.00

crystallographic symmetry alone does not exclude determination of RNA configuration. Such a determination would require not only a unique RNA conformation, but also sufficient asymmetry imposed thereby on the shell that consistent orientations appeared throughout the crystal. The present map is ambiguous on that point, but a high degree of order does not appear likely.

The N-terminal 15 residues cannot be traced, and the general appearance of internal density is not immediately recognizable as a single structure. It is useful in this connection to recall that the uniqueness of the secondary structure has not been established for viral RNA, although the correlation of nuclease sites and predicted single-stranded regions in 'flower diagrams' of the MS2 sequence suggest a general regularity[11]. In any one stock of virus, a given RNA molecule is likely to differ from the mean sequence at a number of positions[12]. Moreover, the compactness of the configuration in the virus appears to be imposed by the shell, rather than by its own sequence, since RNA of the size of the genomes in these viruses has a much larger radius of gyration under conditions of physiological ionic strength than that of the cavity into which it is packed[13]. Indeed, the degree of compaction is striking: from figures given by Unge *et al.*, the volume available to STNV RNA implies an inner cavity with space for about 1.2 g H_2O per g RNA; the packing of TBSV RNA is comparably tight. A model of more or less random close packing of roughly parallel RNA stems is appealing, since very efficient packaging can be achieved without any significant demands on RNA structure or sequence. But it will not be simple to prove such a picture.

The most surprising of recent results is probably the similarity of the SBMV subunit to the S-domain of TBSV. Various evolutionary speculations can be made, but from the point of view of assembly and its control, there are two more immediate conclusions that should be emphasized. The first is the identical way in which these two T = 3 structures solve the ambiguity problem alluded to above. A portion of the polypeptide chain, just N-terminal to the compact domain(s), is ordered on sixty subunits and disordered on the remaining 120. The sixty ordered arms effectively serve as an internal, T = 1 framework: they interdigitate around icosahedral twofolds. This scaffold, formed by a flexibly linked part of the subunit chain determines the size and curvature of the particle. The choice between alternative bonding patterns at interfaces that must so adapt is dictated by the symmetry and geometry of the network of arms. One might imagine cases where the network would be formed of a distinct protein — could this be the case with cores in bacteriophage head assembly[14] or VP2 and VP3 in polyoma and SV40[15]? The second direct conclusion that emerges from comparison of TBSV and SBMV is the significance of modularity in the design of assembling subunits. In SBMV as seen in the paper of Abad-Zapatero *et al.*, the subunit has three functional parts: an unseen (RNA-binding?) N-terminal piece, the framework-like arm (including sequences in the intertwined β-annulus), and the major folded domain. In TBSV, there is an additional folded domain (the P-domain). Clearly the P-domain is not essential for particle stability, since it is missing in SBMV. It does appear to be a strong twofold 'clamp', and the hinge between it and the S-domain is required for subunits to conserve these two fold interactions while still adapting to the T = 3 surface lattice.

With these advances now at hand, what about the crystallography of other viruses and large assemblies? SBMV and TBSV show quite dramatically that the spatial arrangement of modules in a subunit protein is characteristic of the assembly, but not necessarily of the isolated polypeptide; the remarkable interdigitation of N-terminal arms could not have been anticipated (or even seen) in the structure of the subunit alone. The possible consequences for those who would like to visualize a ribosome, for example, are sobering: high-resolution structures of large assemblies may not readily be constructed from structures of component parts. There is, however, a converse advantage of flexibly-linked modules: in cases where function is a property of a particular module of a large protein, proteolytic dissection and piecewise crystallization is a fruitful and helpful strategy. This is the case, for example, with influenza virus haemagglutinin[16] and may well be appropriate for the presumptive RNA-binding, N-terminal portions of SBMV or TBSV. □

Open-ended fusion systems

from R. F. Post

JAPAN, among all of the highly industrialized nations, is the most dependent on imported energy. Japan is also a nation that owes its advanced technology both its present economic strength and its hopes for future economic growth. Given these circumstances it is not surprising that nuclear fusion research has been singled out for special attention by the Japanese government. Fusion, for which the primary fuel is heavy hydrogen, extractable at low cost from water, would be an extremely attractive long-term energy source. It is against this backdrop that a specialized scientific meeting dealing with a particular approach to fusion, so-called open-ended magnetic confinement systems was convened in Japan in April.*

Open-ended fusion systems are a class of fusion 'magnetic bottles' in which the field lines of the externally-generated magnetic field (needed to confine the hot fusion plasma) enter at one end of the bottle and exit from the other end. Open-ended magnetic bottles are in contrast to ones such as the tokamak, where the field lines remain entirely within the doughnut-shaped confinement chamber.

R. F. Post is Deputy Associate Director for Physics in the Magnetic Fusion Division of the Lawrence Livermore National Laboratory, University of California.

An example of an open-ended system is the simple mirror machine, in which the field lines form a tubular bundle constricted at both ends (the mirrors). The charged particles of a fusion plasma, once trapped between the mirrors, continue to gyrate back and forth along the field lines, being repeatedly reflected by magnetic mirrors in the same way that charged particles are trapped, between the north and south magnetic poles, in the Van Allen radiation belts that surround the earth.

Present interest in the mirror approach to fusion power stems in part from an inherent advantage that some kinds of mirror fields possess in their ability to suppress the so-called MHD or fluid-like turbulences in magnetically confined plasmas. From this property derives the remarkable ability of specially-shaped mirror fields (called 'magnetic wells') to stably confine very high plasma pressures for a given magnetic field intensity. To this inherent advantage has recently been added a new feature — the tandem mirror idea — an idea that shows promise of greatly improving the economic prospects of mirror fusion systems relative to older mirror approaches. The tandem mirror

---

The 'International Symposium on Physics in Open-Ended Fusion Systems' was held at the new University of Tsukuba, Japan in April 1980.

0028-0836/80/320559-02$01.00

consists of two small conventional mirror cells located at each end of a large central confinement chamber around which is wound a simple solenoidal magnet coil. The hot plasmas in these end cells create positive electric potentials that act to electrostatically 'plug' the end leakage of charged particles from the central cell far more effectively than is possible with a single mirror at each end acting alone. Though invented in the USSR and, independently, in the US about four years ago, the first tandem mirror device to be constructed and operated (Gamma-6; 1978) was built at Tsukuba University, Japan, preceding the larger experiment (TMX; 1979) brought on line at the Lawrence Livermore Laboratory.

The scientific validity of the tandem mirror idea for enhancing mirror confinement was made clear in papers by Kawabe (Tsukuba) and Grubb and Drake (Lawrence Livermore Laboratory) who described experiments in the Tsukuba Gamma-6 and Livermore TMX experiments, respectively. Work in progress (TMX) includes more detailed measurements of particle and energy transport, the role of microinstabilities and their suppression, and the study of plasma pressure limits as determined by MHD effects. Baldwin (Livermore) then described recent developments in tandem mirror theory, including the important new idea (originated by Baldwin and Logan) of the thermal barrier. In a tandem mirror, a thermal barrier is a specially designed cell that, through the generation of a locally-negative potential region, can act to thermally isolate the end plug from the central cell. Thermal isolation then would permit the heating of plug electrons to higher temperatures than those of the central cell, with resultant increased plug potential at lowered plug plasma density — a major economic advantage.

The use of radiofrequency fields to enhance the confinement of open-ended systems has been a major topic in fusion research in Japan for many years. Pioneered at Nagoya under the direction of K. Takayama, this work led to the construction at Nagoya of a large mirror-cusp device, RFC-XX. Itatani (Nagoya) described preliminary results with this machine, in which enhancement of confinement of moderate temperature plasmas by factors of 5 or more (over the confinement observed with r.f. turned off) were seen. Whether good confinement of higher temperature plasmas can be achieved is not yet resolved. RFC-XX however appears to be the most advanced facility for the study of such questions in any fusion laboratory.

An important sub-class of mirror systems are those where the phenomenon of field-reversal is invoked to improve confinement. In a field-reversed mirror — a form of the so-called "compact toroid" configuration — the internal diamagnetic currents of the mirror-trapped plasma are made to be sufficiently intense to reverse the direction of the magnetic field near the axis within the plasma, thus closing the magnetic lines on themselves within the plasma interior and thereby inhibiting plasma losses through the mirrors. Interest in such configurations, which dates back many years to related systems (such as the electron ring ASTRON of Christofilos), comes from their geometric simplicity and, especially, from their extremely efficient use of the external field. The field-reversed mirror shares with the tandem mirror the generic idea that properties of the plasma are used to improve its own confinement. The Symposium provided a forum for the discussion of most of the FRM work now in progress, including, for example, work at the Los Alamos Laboratory on field-reversed configurations produced by a coaxial gun (Sherwood; Los Alamos) and field-reversed electron rings (Fleischmann; Cornell).

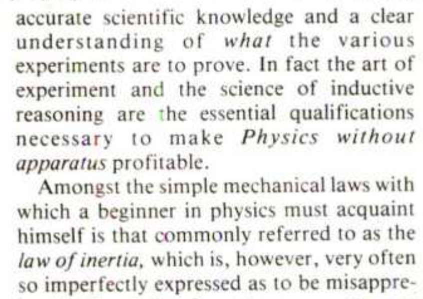
Some of the most unusual mirror devices were described in the papers concerning work at Novosibirsk (Ryutov, Koidan). In addition to the AMBAL tandem mirror, now under construction, there are two other mirror devices: PSP-2, a device in which mirror confinement is enhanced by electrically-induced plasma rotation, and GOL-1, a device using multiple mirror cells and operating at very high plasma density. Both of the latter innovative devices owe much in their origin to the former Director of the Novosibirsk fusion group, G. I. Budker, who died July 4, 1977.

Judging from the lively discussion at the conference, and from the enthusiasm of the participants, interest in open-ended systems is increasing not only in Japan but world wide. In the case of the Japanese effort, it seems equally clear that their contributions to research on open-ended magnetic fusion systems will become increasingly important over the next few years. ☐

100 years ago

PHYSICS WITHOUT APPARATUS

It is almost a proverb in science that some of the greatest discoveries have been made by the most simple means. It is equally true that almost all the more important facts and laws of the physical sciences can be illustrated and explained by the help of experiments made without special or expensive apparatus, and requiring only the familiar objects of common life for their performance. The greatest exponents of popular science — and amongst them notably Faraday — delighted in impromptu devices of this kind. It is indeed surprising how throughout the whole range of natural philosophy the hand of the master can turn to account the very simplest and rudest of apparatus. A silver spoon, a pair of spectacle lenses, a tumbler of water, and a few sheets of paper suffice to illustrate half the laws of geometrical optics. A few pieces of sealing-wax, some flannel, silk, writing paper, pins, and glass tumblers will carry the clever experimenter a long way into the phenomena of electricity. These are things which any person can procure, and which any person can be taught to use. But their right use depends on the possession of accurate scientific knowledge and a clear understanding of *what* the various experiments are to prove. In fact the art of experiment and the science of inductive reasoning are the essential qualifications necessary to make *Physics without apparatus* profitable.



Amongst the simple mechanical laws with which a beginner in physics must acquaint himself is that commonly referred to as the *law of inertia*, which is, however, very often so imperfectly expressed as to be misapprehended. It requires force to move matter, not because matter is inherently lazy or sluggish, but because it possesses *mass*. The greater the mass of matter in a ball, the harder work is it to send it rolling. Force is also required to stop matter that is moving, the reason again being that a mass moving under the impulse of an impressed force possesses a certain moving energy which cannot be at once reduced to nothing. In either case — either to move a mass or to alter the motion of a mass — force must be employed and energy expended. Of this law of inertia many examples might be given: and there are many curious facts which this law serves to explain. Some of the most striking of these are those in which the effect of sudden forces is different from that which might have been expected. In Fig. 1 we give an illustration of an experiment of this nature. A wooden rod — say a broomstick — has a couple of needles fixed into its ends, and it is then supported upon two wineglasses resting upon two chairs. If a heavy poker is now brought down very violently upon the middle of the stick it will break in two without the needles or the glasses being broken. A feeble or indecisive blow will fail to do this, and will break the glasses or the needles, or both. Here the moving energy of the heavy mass, the poker, is suddenly transferred to the middle of the stick, so suddenly that it is broken asunder before the thrust has *time* to reach the fragile supports. From *Nature* 22 5 August, 320 & 321, 1880.

REVIEW ARTICLE

New findings in methane-utilizing bacteria highlight their importance in the biosphere and their commercial potential

I. J. Higgins, D. J. Best & R. C. Hammond
Biological Laboratory, University of Kent, Canterbury, Kent CT2 7NJ, UK

Recent results, showing that the ubiquitous methane-utilizing bacteria (methanotrophs) can partially oxidize and, in some cases, extensively metabolize complex organic compounds, call for a reappraisal of their role in the cycling of elements in the biosphere. Possible environmental implications and opportunities for industrial exploitation are discussed.

ABOUT half of the substantial, but not precisely known, proportion of total organic carbon degraded by anaerobic microflora is converted to methane. The amount of the hydrocarbon released into the atmosphere, however, represents only about 0.5% of total carbon turnover[1]. The disparity between this figure and the large amounts of methane produced by the methanogenic bacteria is due mainly to the activities of aerobic methane-utilizing microorganisms (methanotrophs), situated between the anaerobic sediments responsible for methane production and the atmosphere, and partly to the microbial oxidation of methane anaerobically. On this basis alone, organisms responsible for the oxidation of methane are therefore of major importance in the carbon cycle and much current research effort is being devoted to an understanding of their physiology and biochemistry. Our present knowledge has been comprehensively reviewed in recent years[2–6] and our purpose here is not to reiterate this information but rather to survey important new findings implicating methane-oxidizing bacteria in transformations of substances which are not their growth substrates, particularly multi-carbon compounds, and to highlight possible consequences and applications of these microbial activities.

The ubiquity of methane-utilizing bacteria is attested to by the variety of sources from which various workers have been able to isolate them[7]. The many strains isolated in the last 15 years are predominatly aerobic Gram-negative bacteria, growing only on methane or, in some cases, on methanol or dimethyl ether. They can be divided into two distinct groups (types I and II) based on the morphology of their internal membranes and the nature of their carbon assimilation pathways. In recent years, however, facultative methane-oxidizing bacteria, apparently similar to type II obligate methanotrophs, have been isolated[8,9] and some yeasts have been implicated in methane oxidation[10]. Evidence for the involvement of fungi and algae in this process is more equivocal. Although microbial utilization of methane is primarily an aerobic process, it has been shown recently that some species can oxidize it anaerobically. In particular, energy for growth can be obtained by coupling methane oxidation to carbon dioxide with sulphate reduction to hydrogen sulphide[11]. A small amount of methane oxidation may also be accomplished by methanogens[12].

Mechanisms of methane oxidation

In the current context we are particularly concerned with the aerobic, obligate methanotrophs because of recent advances in our understanding of the mechanisms of methane oxidation in these bacteria. It has been known for many years that these microorganisms oxidize methane to carbon dioxide by a route involving successive two-electron oxidation steps via methanol, formaldehyde and formate. Carbon is incorporated into cell material at the oxidation level of formaldehyde by type I species, which use the ribulose monophosphate pathway (Quayle cycle), and in type II species, using the serine pathway, as formaldehyde and carbon dioxide[2–6]. Both groups of bacteria can grow only on a restricted range of reduced C_1 compounds and, in their selectiveness resemble the so-called obligate autotrophs. Nevertheless, it has long been known that such bacteria, either as washed suspensions or in culture, will partially oxidize simple substrate analogues, such as ethane, propane and butane, to the corresponding alcohols, aldehydes and fatty acids[13]. This was presumed to reflect some lack of specificity in the enzymes involved in methane oxidation. Subsequently, it was shown that carbon monoxide, ammonia and ethene are also oxidized[14–16]. However, there is now known to be a surprisingly vast range of multi-carbon compounds, often not closely related to the natural substrates, which are oxidized by methanotrophs[17–19]. Although this capacity varies between species, the following types of compound are oxidized by washed cell suspensions: long-chain alkanes (up to at least hexadecane), alkenes, aromatic and alicyclic hydrocarbons, phenols, long-chain and alicyclic alcohols, pyridine, multi-ring compounds and chlorinated aromatic hydrocarbons. In each case only a limited number of products (sometimes only one) are formed as a result of this unexpected activity, showing that there is, nevertheless, some mechanistic specificity. In some cases the products are simply hydroxylated derivatives, suggesting that a reaction analogous to the oxidation of methane to methanol has occurred. Commonly, there is further oxidation of these hydroxylated compounds to yield aldehydes and carboxylic acids. Many of these biotransformations have been shown to occur in both the presence and absence of methane[17].

'Fortuitous metabolism'?

These activities have been described as 'fortuitous metabolism' (ref. 18), implying that they are merely due to the lack of specificity of oxidative enzymes, whose primary function is to effect the oxidation of methane to carbon dioxide. Such extraordinary lack of enzyme specificity would be extremely unusual if it were entirely fortuitous and we argue here that this phenomenon has developed and been retained because of its survival value to these species. It may well also be of environmental importance and could prove of commercial value, as evidenced by the recent filing of a number of patents on this subject[20–26].

We now have some understanding of the enzymological basis of this lack of specificity and it mainly reflects the properties of enzymes initiating methane oxidation, methane monooxygenases (MMOs). In common with some other

0028-0836/80/320561—04$01.00

monooxygenases, these enzymes have proved difficult to purify but oxygenase involvement was clearly indicated by the ^{18}O-incorporation experiments described by Higgins and Quayle[27]. Subsequently, cell-free activities were studied in a number of species, but substantial purification has been reported in only two, *Methylococcus capsulatus* (Bath) and *Methylosinus trichosporium* OB3b. The system seems to be best characterized in the former species and there is some uncertainty concerning the true nature of the system in the latter[3,4]. There is evidence, however, that growth, and perhaps storage conditions, may markedly affect the characteristics of the enzyme of *M. trichosporium*[28]. Since the first report of cell-free MMO activity by Ribbons and Michalover[29], several workers have reported that such activities are not totally specific for methane, higher gaseous alkanes, alkenes, ammonia and carbon monoxide also being oxidized[30–33]. The range of substrates for MMOs was dramatically extended by Colby *et al.*[34], who showed that cell-free extracts of *M. capsulatus* (Bath) oxidized a wide range of hydrocarbons and related compounds. It has since been shown that enzymes from other species are also relatively nonspecific, but in some cases the specificity is more restricted[18]. Although these findings account for the ability of whole organisms of some methanotrophs to introduce an oxygen atom into many compounds, they do not explain the further oxidation of some of these initial products to, for example, aldehydes and carboxylic acids. These further oxidation processes for simple analogues of methane no doubt reflect lack of absolute specificity of the methanol- and formaldehyde-oxidizing enzyme systems. In the case of more complex hydroxylated products, recent evidence suggests the involvement of other enzymes with no known roles in C_1 metabolism. For example, a number of species contain a broad-specificity, secondary alcohol dehydrogenase[35]. It was thought that intact cells of *M. capsulatus* (Bath) had a rather limited oxidizing capacity[18] but it is now known to be more extensive (H. Dalton, personal communication).

Transformations effected by *M. trichosporium*

Recent work in our laboratory has revealed not only that intact *M. trichosporium* can effect the partial oxidation of a relatively wide range of hydrophobic organic compounds but also that the transformations, in some cases, involve more extensive or even non-oxidative metabolism[17]. Examples of transformations observed are shown in Table 1. With the exception of benzoic acid formation from toluene, the simple oxidation reactions are due entirely to MMO activity. The formation of benzoic acid from toluene and of other acids and aldehydes shown involves MMOs plus other oxidoreductase enzymes. Dechlorination of substituted aromatic compounds and shifts in the positions of ring substituents may be manifestations of the different mechanisms of action of MMOs or may involve other enzyme activities. Debromination reactions have also been reported[36].

Two cases are shown in which dechlorination is associated with covalent attachment of a methyl or alkanoate group to an aromatic ring. We currently have no understanding of these reactions but it is conceivable that they are, in part, due to the lack of specificity of MMOs and they may indicate some type of free radical mechanism[37], or involve other enzyme activities.

In the current context, two of these examples are of special importance, namely the transformations of ethylbenzene and 1-phenylheptane. In each case, products arise as a result of side-chain oxidation and degradation. With the former compound, α-oxidation must be involved, whereas in the latter, the degradation process probably involves β-oxidation. In addition, recent experiments with 1-[^{14}C]-n-hexadecane also suggest that *M. trichosporium* can slowly degrade long-chain alkanes; after incubation with washed cell suspensions in rigidly aseptic conditions, about 5% of the radioactivity was recovered in carbon dioxide (D.J.B., unpublished data).

Although it is well known that most methanotrophs require methane or some other reduced C_1 compounds for growth, the question arises of whether they can obtain supplementary carbon and/or energy from other sources. Clearly, ω-oxidation of alkanes, followed by further oxidation to fatty acids which are subsequently β-oxidized will yield reducing equivalents, which might be used for energy transduction, and acetate for possible incorporation into cell material. Radiolabelling experiments have shown that products of oxidation of several gaseous alkanes and also acetate, the product of β-oxidation, are incorporated into cell material by methanotrophs[38–41]. The findings of Wadzinski and Ribbons[39], using *Methanomonas methanooxidans*, are of particular interest. Acetate, present in the medium during growth on methane, greatly increased the growth yield and it was incorporated into cell material, especially into amino acids, as well as, in part, being oxidized to carbon dioxide by a tricarboxylic acid cycle.

Possible evolutionary reasons for the lack of specificity of methane monooxygenases

A wide range of hydrocarbons and related compounds are continually released into the environment in substantial amounts. They are natural products present in most living organisms, they arise by seepage from subterranean oil and gas deposits and are pollutants due to man's activities. There are also many hydrocarbon derivatives that are xenobiotic products of the chemical industry. Despite controversy concerning specific compounds regarded as pollutants, most hydrocarbons and hydrocarbon-like materials currently turned over in the biosphere are not novel but have been substantial components of the carbon cycle throughout most of evolutionary history. It follows, therefore, that such compounds have always been present in the environment of methanotrophs. As methane is invariably present in their natural habitats, it is not surprising that many of them have developed an obligate requirement for C_1 compounds for growth. These organisms are not in direct competition for survival with heterotrophs. They are, however, in competition with each other for available methane and it is probable that any mechanisms which might develop and enable them to utilize ancillary carbon and/or energy sources would generally be of selective value either to supplement their metabolism or facilitate survival under severe methane limitation.

Although some of the simple oxidation reactions catalysed by methanotrophs and by their MMO activities are of no obvious survival value, for example, the epoxidation of propene, others seem to be responsible for initiating useful metabolism. We would argue, therefore, that there has been selection pressure for the development of broad-specificity MMOs and other oxidoreductases. This selection pressure must be sufficient to outweigh any disadvantage of such lack of specificity. These disadvantages include truly fortuitous oxidations yielding neither energy nor products of value to these bacteria. Indeed, in these conditions, reducing equivalents would be wasted, as MMO requires a source of reducing power, which may be derived from the further oxidation of methanol, its analogues or storage polymers. In addition, some products may prove toxic. Because it is clear that these oxidations occur in the presence of

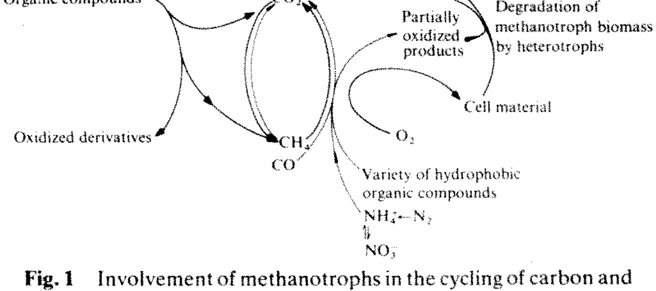

Fig. 1 Involvement of methanotrophs in the cycling of carbon and nitrogen in the biosphere.

Table 1 Examples of biotransformations effected by resting whole organism suspensions of *Methylosinus trichosporium* OB3b

Type of reaction	Compound	Products
Oxidation	$CH_3CH=CH_2$ Propene	$CH_3CH{-}CH_2$ (O bridge) Propene oxide
	 Benzene	 Phenol
	$CH_3(CH_2)_{14}CH_3$ Hexadecane	$CH_3(CH_2)_{14}CH_2OH$ Hexadecan-1-ol
	 Toluene	 *p*-Hydroxy-toluene  Benzoic acid
Oxidation and degradation	 Ethyl benzene	 *o*-Hydroxy-ethylbenzene  *p*-Hydroxy-ethylbenzene
		 2-Phenylethanol
		 Phenyl acetic acid  Benzoic acid
	 1-Phenylheptane	 1-Hydroxy-1-phenylheptane  1-Phenyl-heptan-7-al  1-Oxo-1-phenylheptane  Cinnamic acid  Benzoic acid
Oxidation and dechlorination	 *m*-Chlorotoluene	 Benzyl alcohol  Benzyl epoxide[*]
Oxidation, dechlorination and condensation	 *m*-Chlorotoluene	 *m*- or *p*-methyl benzyl alcohol
Oxidation and condensation	 *m*-Chlorophenol	 An hydroxyphenylheptanoic acid[*]
Oxidation and rearrangement	 *m*-Cresol	 *m*- and *p*-hydroxybenzaldehyde
	 *o*-Cresol	 5 Methyl-1,3-benzene diol

* Tentative identification.

methane, disadvantages may also arise through competition between methane and other potential substrates for the active site. At first sight, an equally plausible explanation for lack of specificity would not involve evolutionary arguments but would be dictated by some mechanistic requirements of MMO. However, there is substantial evidence against this view. For example, the MMO of one species, *Pseudomonas methanica*, shows greater specificity than those of other species[18] and higher alkane monooxygenases that have been investigated are relatively specific. On the balance of the evidence, therefore, many of these metabolic activities are probably not fortuitous and instead have substantial metabolic significance.

It has generally been accepted that heterotrophic organisms are responsible for mineralization of hydrocarbons, their derivatives and related xenobiotics[42]. If these recently discovered, extensive metabolic activities of some species of the ubiquitous methanotrophs prove to be widespread amongst the group, it is likely that they play a significant part in the mineralization of complex, organic material, in addition to their already documented, major role in the carbon cycle. Methanotrophs are also involved in the nitrogen cycle, being able to fix atmospheric nitrogen, oxidize ammonia and reduce nitrite[3].

It is clear from this discussion that methanotrophs are important in the biosphere (Fig. 1), yet only 15 years ago they were regarded, even by most microbiologists, as obscure, uncooperative, perhaps unimportant microorganisms, as evidenced by the fact that, before 1970, only three species had been isolated and well authenticated[7]. Today, in spite of the efforts of many research groups and the isolation of some 200 strains of methanotrophs, their significance is still not widely recognized, and this fact, in part, provoked the writing of this article.

Some of the oxidative biotransformations catalysed are difficult and/or expensive to effect by conventional chemical means. The whole organism activities are relatively stable and many products are either not further degraded or are degraded only slowly. It is therefore possible that some of these species will prove valuable as industrial catalysts, exploiting intact bacteria or enzymes derived therefrom[20–26].

Two important recent developments may facilitate such industrial exploitation. First, genetic manipulation of these strains is proving possible[43] and second, using cell-free preparations, processes may be devised in which reducing equivalents for the MMOs are supplied electrochemically, thereby dispensing with any requirement for expensive pyridine nucleotide coenzymes[44–46].

We thank Mr D. Scott for helpful discussion and the SRC and ICI Limited for financial support.

Anorthositic magmas and the origin of proterozoic anorthosite massifs

Robert A. Wiebe

Department of Geology, Franklin and Marshall College, PO Box 3003, Lancaster, Pennsylvania 17604

Many anorthositic plutons of the Nain complex were formed from highly feldspathic parental magmas, which were probably generated by melting or factional crystallization of tholeiite at 15–22 kbar. Their existence suggests a high geothermal gradient and thick continental crust during the mid-Proterozoic.

PROTEROZOIC anorthosite massifs have long presented three major problems to geologists interested in crustal evolution: (1) what were the parental magmas of the anorthosite intrusions[1]; (2) what is the tectonic significance of the broad belts of these intrusions; and (3) why were most of these complexes emplaced during a restricted interval of the Proterozoic[2]? Solution of the first problem is probably an essential precursor to solving the other two. This article summarizes new evidence for the existence of a suite of highly feldspathic magmas parental to anorthositic rocks in Labrador.

The bulk composition of anorthosite massifs is generally much more feldspar-rich than any known magmas[3]. Has fractional crystallization of plagioclase from normal basaltic or andesitic magmas produced these highly feldspathic plutons, or have

0028-0836/80/320564—04$01.00

these plutons been formed by unusually feldspathic magmas? If basaltic magmas were parental, complementary mafic and ultramafic intrusions must also formed. Gravity surveys indicate that many of these complexes lack hidden mafic and ultramafic bodies[4,5], and even where such mafic intrusions are apparently associated[6], it has not been shown that they are comagmatic with the anorthosites. If andesitic or other intermediate magmas were parental, then complementary plutons of mafic and granitic rocks should be present. Large volumes of granite are commonly associated with anorthosites, but it is not clear that they are comagmatic with the anorthosites. Many granites seem to have been formed from separate melts generated from continental crust[7,8]. The alternative to a 'normal' parental magma is an unusual, highly feldspathic magma. Although several works have suggested parental magmas of this type on the basis of extensive field study[9,10], the evidence has not been sufficient to establish a consensus that such feldspathic magmas did indeed exist and were parental to massif anorthosites. However, recent studies of three anorthositic plutons in the Nain complex of Labrador, outlined below, provide clear evidence that each of these plutons had a distinct, recognizable anorthositic parental magma. These anorthositic magmas together with high-alumina basalts[11,12] indicate that a highly feldspathic magma series was responsible for the formation of the Nain and probably other Proterozoic anorthosite complexes.

Nain complex

The Nain complex is a typical Proterozoic anorthosite massif of area ~15,000 km^2 located along the coast of Labrador. It is ideal for study because it lacks later deformation and metamorphism and because contact relations are well displayed in coastal outcrops. Nearly half of the complex consists of anorthositic intrusions (colour index = 0–20); as many as 20 major anorthositic plutons may be present. Some are highly differentiated and layered; others are homogeneous and massive. Most have average plagioclase compositions between An_{70} and An_{40}. Minor amounts of gabbroic and troctolitic rocks are present[11,13]. Minor ferrodioritic rocks represent late stage differentiates of the anorthosites and mafic intrusions[14]. Somewhat less than half of the Nain complex consists of granite, most of which approaches minimum-melt composition and does not seem to be comagmatic with the anorthosites[15].

Field evidence for anorthositic magmas

Two anorthositic plutons in Nain have fine-grained anorthositic margins. (Strictly, the intrusions should be termed leuconorite because they have colour indices[16] in the range 10–18). One of the chilled margins represents a gradation in average plagioclase grain-size from 3 cm about 5 m in from the contact to 2 mm at the contact with country rock. The other chilled zone shows less variation and is less abrupt. These fine-grained rocks are compositionally equivalent to the coarse-grained anorthositic rocks with which they are associated. Plagioclase in all rocks is characteristically subhedral to euhedral with weak normal and oscillatory zoning. Mafic phase are orthopyroxene and inverted pigeonite with minor ilmenite, magnetite and apatite. The mineralogy suggests that the parental magma must have been relatively dry.

Fine-grained anorthositic dykes are associated with a third intrusion. They were injected into and preserved within a highly refractory xenolith of basic granulite[8]. Average grain size in many of the anorthositic dykes is 1–2 mm while the associated anorthosite has plagioclase in the range 1–7 cm.

The highly feldspathic and relatively dry magmas proposed here could exist only at high temperatures, and such temperatures are indicated by field relations along contact zones. Where anorthosite has intruded quartzofeldspathic gneisses, there is abundant evidence that the gneisses have been partially melted within 10–20 m of the contact. Granitic melt has locally mixed with anorthositic magma or crystal mush along some contacts, and locally derived granitic veins have cut or mixed with dykes emanating from the anorthosite. Hypidiomorphic textures are common in banded gneisses near the contact. Euhedral overgrowths occur on corroded plagioclase, and interstitial areas of alkali feldspar include small euhedral crystals of quartz and biotite. In contrast to these textures, gneisses farther from the anorthosites have allotriomorphic granular textures. Berg[17] has estimated that the depth of emplacement in this area was equivalent to a pressure of about 4 Kbar and that the country rock may have been only 200–300 °C before emplacement. An anhydrous magma, which was as feldspathic as the chilled rocks, must have had a liquidus temperature of ~1,300 °C. If the magma were emplaced at the temperature, the contact zone would have adjusted rapidly[18] to ~800 °C, well below the solidus of the feldspathic magma and above the beginning of melting of the gneisses.

Not all contacts of anorthosites with country rock are characterized by chilled feldspathic margins and remobilized gneiss. Most other contact zones can be explained by emplacement of plagioclase-rich crystal mush with mafic interstitial liquid and by processes of crystal–liquid fractionation along the contact.

All analyses determined by X-ray fluorescence; recalculated to 100% anhydrous.

* Composition represents the average of 17 analyses of coarse-grained rocks from the interior of the pluton. This composition is very similar to that obtained for fine-grained anorthositic rocks within a chilled contact zone. These latter compositions were not used because of minor contamination by granitic melt in the contact zone.

† Composition represents the average of 17 analyses of coarse-grained rocks. This composition is very similar to that obtained for fine-grained anorthositic dykes related to this pluton[8].

‡ Composition is based on the average of two nearly identical relatively fined-grained samples within 50 m of the intrusive contact. (REEs for two samples are listed in Table 3.)

§ Less than detection limit.

Geochemical evidence for anorthositic magmas

The chilled margins and dykes each have chemical compositions which are nearly identical to the compositions of the coarse-grained, homogeneous and massive anorthositic intrusions with which they are associated. One can thus argue that the average compositions of these intrusions must approximate their parental magmas. Estimates of the compositions of these parental magmas (Table 1) are based on the compositions of the chilled rocks or on averages of samples from the interior of the pluton. These three magmas are all highly aluminous ($Al_2O_3 = 21$–25%) with SiO_2 between 53% and 56%. Each has a distinct Mg/Mg+Fe which varies with normative anorthite. Incompatible elements (such as, K, P, Rb, Ba and Zr) all increase as anorthite decreases. Normative colour index (wt %) varies from ~14 for the most calcic magma to ~19 for the most sodic.

Figure 1 and Table 2 present rare-earth element (REE) data for one intrusion and its associated fine-grained dykes. All analysed rocks contain approximately the same amount of plagioclase (roughly 80–90%).[8] The remarkably constant REE content of the fine-grained dykes contrasts strongly with the variation shown by the coarse-grained rocks. The average REE content of the coarse-grained rocks approximates the REE abundance in the dykes. The similarity in REEs (as well as major and other trace elements[8]) between dykes and coarse-grained rocks strongly supports the other data which indicate that the parental magma of this intrusion was anorthositic and similar in composition to the dykes.

REEs have also been determined for rocks which approximate compositions of the parental magmas of the other two intrusions (Table 3). Two values for each pluton have been averaged and plotted on the same diagram with the average REEs of dykes related to the first pluton (Fig. 2). These REE patterns and abundances are taken to be characteristic of the magmas which have produced these three anorthositic plutons. All three have a similar light REE enrichment with a small positive Eu-anomaly. The magma with highest An (Kheovik) has the lowest REEs, and the magma with lowest An (Uivakh) has the highest REEs. There does not seem to be a systematic variation in the size of the Eu-anomaly and the Eu-anomalies are much smaller than most reported for anorthosites. Although the small positive Eu-anomalies might be interpreted as being due to minor feldspar accumulation[19], field relations preclude that interpretation for these rocks. Except for slight depletion in heavy REEs, the REE abundances of these anorthositic rocks fall within the range of values for Hawaiian basalts[20]. In terms of REEs and major elements these anorthositic rocks closely resemble anorthosite parental magmas estimated by Simmons and Hanson[21].

Origin of anorthositic magmas

Highly feldspathic magmas provide an immediate explanation for the existence of the Proterozoic anorthosite massifs. However, the source and genesis of these magmas remain significant problems. The fact that An and Mg/Mg+Fe vary sympathetically suggests that these magmas were in equilibrium with both plagioclase and pyroxene and that they therefore represent cotectic compositions. Available experimental data suggest that an appropriate cotectic with at least 75–80% plagioclase is present at pressures in the range 15–22 kbar in olivine-free tholeiitic compositions[22,23]. If they represent partial melts, their highly feldspathic compositions suggest that feldspar was in the source area and that a high proportion of the feldspar was melted. Light REE enrichment and small positive Eu-anomalies also suggest major melting of feldspar[21]. A pure feldspar source (for example, Archean anorthosite) is extremely unlikely because of the sympathetic variation of Mg/Mg+Fe with normative An in the three magmas. Direct derivation by partial melting of the mantle seems unlikely because of the low Mg/Mg+Fe (ref. 21).

Alternatively, the feldspathic magmas reported here may have been derived by fractional crystallization from tholeiitic magma[24]. Possible distribution coefficients for REEs[21] indicate that fractional crystallization of clinopyroxene could lead to a magma enriched in light REEs and depleted in heavy REEs, and develop a positive Eu anomaly from a liquid initially lacking one. Cotectic crystallization of plagioclase would also increase REEs and could be responsible for the smaller Eu of the Uivakh magma. Proterozoic dykes which cut the Nain complex have recently been found to carry megacrysts of high-Al orthopyroxene and cumulate nodules of plagioclase and two

pyroxenes. The composition of these minerals suggest that they would represent lower crustal cumulates responsible for the fractionation from basaltic to anorthositic magma.

If these magmas have been generated from tholeiitic compositions, the need for a feldspar-rich cotectic suggests a tectonic environment characterized by a relatively high geothermal gradient and thick crust. An intracontinental rift zone might provide conditions necessary to generate these anorthositic magmas, and recent workers have argued that the Proterozoic anorthosite massifs have developed in such an environment[2,17,24].

Conclusions

The anorthositic magmas proposed here are documented by chilled margins and fine-grained dykes. They have compositions essentially identical to the coarse-grained, massive, homogeneous anorthositic intrusions with which they are associated. Although only three different magmas have been documented so far in Nain, it seems highly probable the many other similar but distinct plutons of massive anorthositic rocks will prove to have crystallized from other batches of feldspathic magma. There is also abundant evidence that high Al basaltic magmas make volumetrically significant contributions to the anorthosite complexes[11,12,24].

The anorthositic rocks within the Proterozoic complexes, therefore, seem to have been generated by magmas ranging in composition from high-Al basalt[11,24] to the highly feldspathic magmas reported here. These magmas define an entirely new association which is clearly distinct from previously known basaltic and calc-alkaline series. This unique magma association implies that unique tectonic and thermal settings are responsible for the generation of the Proterozoic anorthosite massifs. If most of these massifs prove to have ages in a restricted time period (for example 1,400–1,500 Myr), as present evidence suggests[24], then the conditions necessary to generate that magma series must have been most common in that period. Recognition that unusually feldspathic magmas are involved in anorthosite genesis should aid in evaluating how tectonic style, crustal thickness, and the geothermal gradient evolved in Proterozoic time.

High-salt d(CpGpCpG), a left-handed Z′ DNA double helix

Horace Drew, Tsunehiro Takano, Shoji Tanaka, Keiichi Itakura* & Richard E. Dickerson

Division of Chemistry and Chemical Engineering, California Institute of Technology, Pasadena, California 91125
*City of Hope National Medical Center, Duarte, California 91010

*The DNA tetramer d(CpGpCpG) or CGCG crystallizes from high-salt solution as a left-handed double helix, the Z′ helix. Its structure differs from that of the other known left-handed helix, Z-DNA, by a C1′-*exo *sugar pucker at deoxyguanosines rather than C3′-*endo, *and these represent two alternative solutions to the same steric constraint arising from the* syn *glycosyl bond orientation. The apparent molecular basis for the Z to Z′ transition in going from intermediate to high salt is substitution of a bound anion for water at guanine amino groups, and consequent charge repulsion of anions and backbone phosphates.*

THE predominance of right-handed DNA helices of the A and B families was called into question recently by the discovery[1] that the double-helical DNA hexamer d(CpGpCpGpCpG) is a left-handed helix, and one in which the repeating unit is two base pairs rather than a single step. This 'Z helix' has since been found to explain the X-ray patterns from certain fibres with alternating purine–pyrimidine sequences[2]. We now report that the high-salt form of the tetramer d(CpGpCpG) (hereafter to be termed CGCG) also adopts a left-handed conformation, similar to but not identical with the Z helix.

We, like Wang[1], chose alternating CG oligomers of DNA for study because it has been known for some time[3–6] that

0028–0836/80/320567—07$01.00

alternating poly (dC-dG) undergoes a reversible, salt-induced conformation change with a midpoint at about 0.7 M MgCl$_2$ or 2.5 M NaCl (essentially the same ionic strengths); the exact nature of this change has been a matter of interest. We have reported that such a transition with a change in ionic strength of the surrounding medium can also be observed with the tetramer CGCG in the crystalline state itself[7]. Hexagonal crystals of a low-salt form can be grown by diffusion of ethanol into aqueous solutions of CGCG (for experimental details as well as crystallographic survey data, see ref. 7). High-salt crystals are grown by vapour diffusion from solutions containing DNA, MgCl$_2$ and 2-methyl-2,4-pentanediol (MPD). The hexagonal low-salt crystals that form initially in this latter method crack into smaller blocks as the MgCl$_2$ concentration approaches 1 M. These blocks and the crystals that nucleate subsequently show the orthorhombic X-ray pattern of the high-salt form. Conversely, high-salt crystals that are placed in a more dilute solution convert immediately from the orthorhombic to a slightly disordered version of the hexagonal X-ray pattern[7]. Although the diffraction intensity distribution is quite different in the two forms, the transition is apparently small enough to be accommodated within the crystal lattice packing. Unit cell dimensions suggest that the transition involves a shifting of the double helices relative to one another along the *c* axis, with the lateral packing of helices being relatively unaffected, as in Fig. 3 of ref. 7. The structure of the high-salt form is now known and is the subject of the present article.

Structure analysis

Crystallization data and preliminary X-ray survey results have already been reported[7]. High-salt crystals are orthorhombic, space group C222$_1$, with cell dimensions $a = 19.50$ Å, $b = 31.27$ Å, $c = 64.67$ Å, and with one CGCG double helix (two CGCG monomer strands) per crystallographic asymmetric unit. The empirical formula of $C_{38}N_{16}O_{22}H_{46}P_3$ per strand leads to a molecular weight of 1,172, and the measured crystal density of 1.6 g cm^{-3} indicates that the crystals are only 49% DNA by weight. The structure was solved by the method of single isomorphous replacement. Diffusion of various ions and complexes into pre-grown CGCG crystals failed to produce a usable isomorphous derivative. Instead, two covalent heavy atom derivatives were prepared by *de novo* synthesis of the tetramer, with 5-bromocytosine in place of one of the cytosines at the first or third position, using the triester synthesis[8]. The derivative with bromine at the third position (3Br-CGCG) crystallized isomorphously with the native compound, whereas that with bromine at the first position (1Br-CGCG) did not. In the light of the final structure, we now can see that insertion of bromine at the beginning of the molecule interferes with stacking of adjacent double helices up the *c* axis, whereas 3Br-CGCG has no such impediment to stacking. Single isomorphous replacement phases[9] calculated from the 3Br derivative yielded a mean figure of merit of 0.42 to a resolution of 2.7 Å. These phases were used to calculate a 'best' or least r.m.s. error electron density map[10]. A Kendrew wire model served as the starting point for Jack–Levitt refinement[11]. The completed structure consists of 158 non-hydrogen DNA atoms and 86 ordered solvent atoms per asymmetric unit. The current residual error or *R* factor for 1,900 reflections ($>2\sigma$) to a resolution of 1.5 Å (beyond which the pattern fades rapidly) is 19.9%.

The CGCG double helix

As shown in Fig. 1, two CGCG strands in the high-salt crystals form a short left-handed antiparallel double helix with Watson–Crick base pairing. As in the Z helix reported for the CGCGCG hexamer[1], cytosines retain their customary *anti* orientation about the C–N glycosyl bond, with the sugar ring turned away from the O2 carbonyl oxygen of the cytosine ring, and guanines adopt an unusual *syn* conformation with the sugar ring bent towards the guanine N3 ring nitrogen. The sugar–phosphate backbone therefore has a zigzag path, with two steps along the chain as the true helical repeat. The helical rotation between repeating units or pairs of base pair steps is −60°. The minor

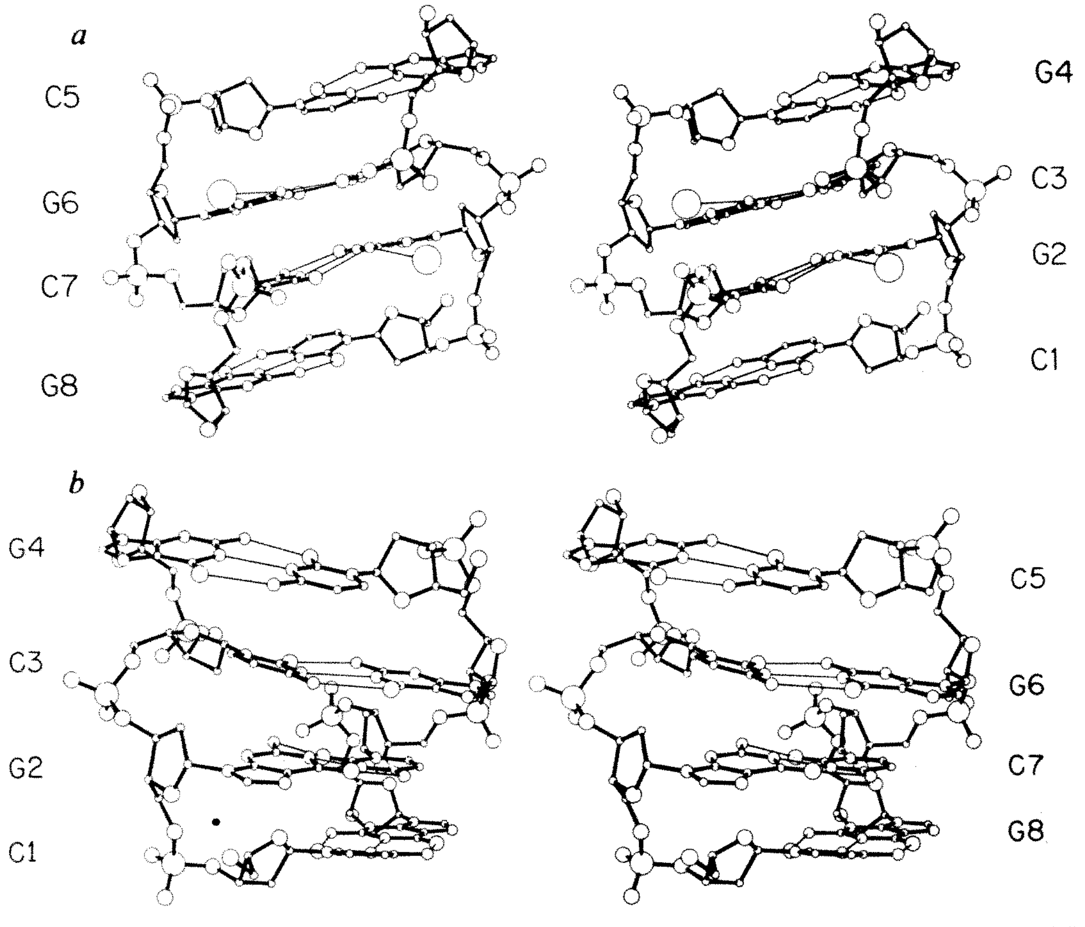

Fig. 1 Stereo pair drawings of the high-salt CGCG double helix. Cytosine and guanine bases are labelled C1 to G8 to the left and right of the two stereo images. Two chloride ions are shown in *a* as large spheres coordinated to the N2 amides of guanosines G2 and G6. Other spheres in order of decreasing radius represent P, O, N and C. The phosphorus atoms along the backbone are referred to as P2, P3 and P4 in one strand and P6, P7 and P8 in the other. *a*, View into the minor groove, down the approximate 2-fold axis. *b*, Oblique view from the outside, in the direction that would correspond to the major groove in the right-handed helices.

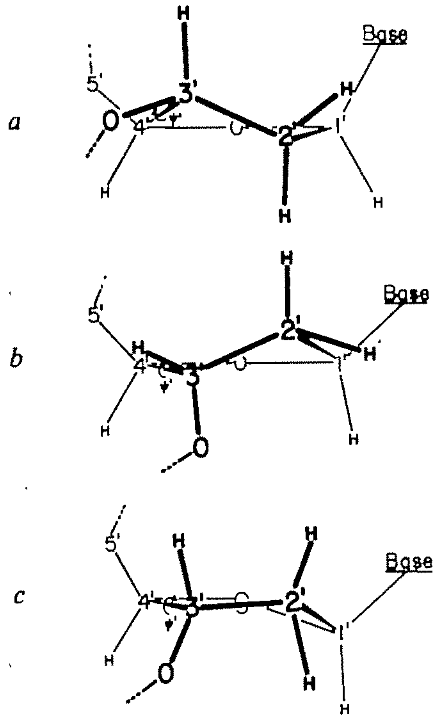

Fig. 2 Deoxyribose ring conformations: *a*, C3'-*endo*; *b*, C2'-*endo*; *c*, C1'-*exo*. The value of the C4'–C3' torsion angle ψ' is clearly defined by the positions of atoms O3' (attached to C3') and C5', and is 82° (*a*), 144° (*b*), and 120° (*c*) for the conformations drawn here.

groove containing the guanine amino and cytosine carbonyl groups (Fig. 1*a*) is the only true groove in the helix, because what corresponds formally to the major groove with guanine carbonyl and cytosine amino groups (Fig. 1*b*) is pushed out to the surface of the helix so that it is not a groove at all. The *syn–anti* alternation of glycosyl bonds may limit all such zigzag left-handed helices to alternating purine–pyrimidine sequences, because placing a pyrimidine base in the *syn* conformation brings its O2 carbonyl oxygen close enough to the O1' oxygen of deoxyribose to disturb their first hydration shells and permit dipole–dipole repulsion.

The low-salt CGCGCG hexamer[1] and the present high-salt CGCG tetramer differ slightly in the tilt of base planes to the helix axis and base repeat spacing along the helix axis. In the hexamer the bases are tilted 7° away from perpendicularity to the helix axis and the average rise per residue along the axis is 3.7 Å. In the tetramer the base plane tilt is 9° and the average rise per residue is 3.8 Å. These differences are associated with a more fundamental change in sugar conformation at deoxyguanosine. In the hexamer the sugar pucker is C2'-*endo* at cytosines and C3'-*endo* at guanines. The tetramer also has C2'-*endo* sugars at cytosines, but at guanines the conformation is C1'-*exo*. This latter is a conformational variant of C2'-*endo*, and quite distinct from C3'-*endo* (Fig. 2). Hence, to a crude first approximation, the sugar pucker is repetitive along the CGCG chain rather than alternating as in CGCGCG.

The evidence for sugar pucker comes less from direct observation of the rings themselves than from the geometry of the backbone chain. As the X-ray data for the tetramer do not extend to atomic resolution, every atom in the deoxyribose ring cannot be resolved and positioned accurately from electron density alone. A better guide to sugar puckering is the torsional angle about the C4'–C3' bond in the five-membered ring (ψ' in Fig. 2). The X-ray results allow this angle to be specified with considerable accuracy, as the C5'-C4'-C3'-O3' linkage is an extended chain with well resolved atoms. This torsional angle is directly related to the sugar pucker as shown in Fig. 2: ~82° for the C3'-*endo* configuration, 144° for C2'-*endo* and an intermediate 120° for C1'-*exo* (ref. 12). In the CGCG structure it averages 141±4° for the four cytosine positions, and 122±1° for three of the four guanines; at one of the 3'-terminal guanines, G8, the final O3' oxygen is disordered, so its ψ' value of 141° is not representative of the ideal helical structure.

The C1'-*exo* conformation can be regarded as a slightly 'bent' C2'-*endo*, and this deformation can be seen from the tetramer structure to arise from a close contact between the N3 nitrogen atom of a guanine ring and the C2' atom in the sugar ring that is in *syn* orientation to it. This distance averages 3.1±0.1 Å in the crystal, with a C1'-*exo* pucker. Forcing the ring back into a C2'-*endo* conformation would push these atoms 0.4 Å closer together, leading to an unacceptably short non-bonded contact. The observed tetramer backbone, therefore, represents the best that can be done using a repetitive C2'-*endo*-like sugar pucker, in the presence of alternating *syn* and *anti* glycosyl bonds. The alternation of 2'-*endo* and 3'-*endo* present in the CGCGCG hexamer[1] represents a different solution to the same steric problem.

We have termed our structure the Z' helix because it differs from the Z helix to about the same degree, if in a different way, as the A' helix with 12 base pairs per turn[13,14] does from the A helix with 11 (ref. 15). Transitions between both pairs, A to A' and Z to Z', can be induced by changes in salt concentration. A similar salt-induced transition is observed between the two principal members of the third family of helices, B with 10 base pairs per turn and C with 9⅓ (refs 16–18). From this viewpoint it might have been more consistent for the C helix to be termed the B', but consistency in an evolving scientific nomenclature is a goal scarcely to be hoped for.

Unlike CGCGCG, the molecular helix axis in CGCG does not coincide with a crystallographic axis, and the molecules are not stacked in such a way as to simulate a continuous helix. In Fig. 3, the two molecules are related by a 2-fold axis normal to the plane of the paper through the centre of the diagram. Horizontal 2-fold axes above and below these molecules also relate them to other molecules not shown at the top and bottom of Fig. 3. An elongated solvent peak of eight electrons occupancy extends between positions 3.5 Å away from the N2 amino groups of guanines G4 on the two molecules shown, and the distance from the amino group suggests that this is a partial-occupancy, disordered chloride site rather than water. At the other end of each molecule, the amino group of guanine G8 is coordinated to a water molecule at 2.7 Å distance rather than to Cl$^-$, and a network of solvent molecules crosses each horizontal 2-fold axis to connect to another molecule not shown. Each molecular helix

d(GpC)	16 5 Å	15 Å
Ref.	This work	1

As the repeating unit in each helix is two consecutive bases, C and G, all helix parameters given have been expressed in terms of this repeat, rather than individual bases. Idealized parameters for the Z' helix have been obtained using a helix-building program provided by John Rosenberg.

* $d = 0.5\,(a^2+b^2)^{\frac{1}{2}}$, where *a* and *b* are crystal cell dimensions.

† *c*/6, where *c* is the cell dimension along the helix axis.

‡ Variants Z_I and Z_{II}, respectively[27]

§ Reported as C3'-*endo*, but with torsion angles closer to C2'-*exo* (ref 12)

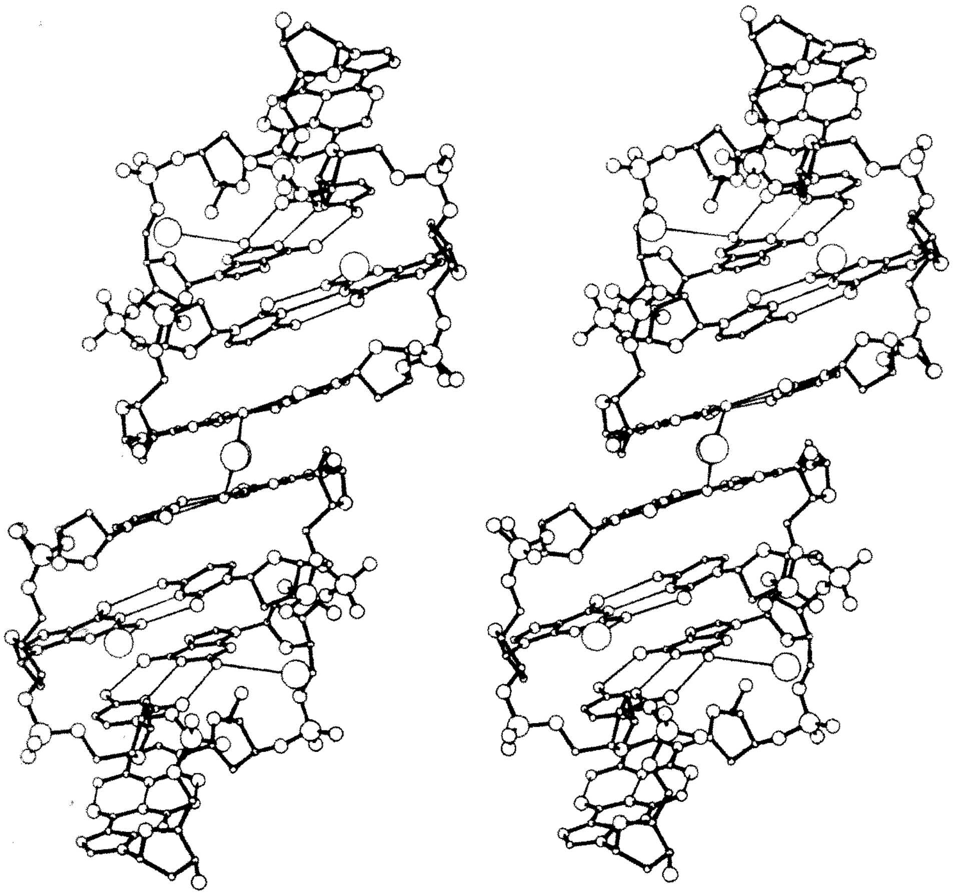

Fig. 3 Stereo drawing of stacking of neighbouring molecules along the *c* axis (vertical). These two molecules are related by a crystallographic 2-fold axis normal to the plane of the drawing through the central bridging chloride ion (large circle). This ion is actually a cigar-shaped peak elongated vertically from one guanine plane to the other, and could represent statistical occupancy of two sterically exclusive coordination positions to the two G4 guanine rings.

axis is tilted 14.3° away from the crystallographic *c* axis, which is vertical in Fig. 3.

In addition to this mismatch of molecular helix axes, the two molecules shown are not stacked in a way that continues the helical twist. For this to be true, the lower two base pairs of the top molecule in Fig. 3 should be rotated by −60° relative to the upper two base pairs of the bottom molecule. The observed rotation is only −30°, and the reason for this smaller rotation is that it maximizes base pair overlap between molecules. The absence of linking phosphate groups permits this more favourable stacking with base pairs almost eclipsing one another, whereas within a helix the GpC base stacking involves a 32° twist. The combination of a 60° helical twist within each molecule and a 30° non-helical twist between molecules turns the *c* axis into a pseudo-4_3 screw axis, leading to a strengthening of $(0, 0, l)$ reflections with $l = 4n$ and weakening of the others, as was noted from the first survey X-ray photographs[7]. The molecular packing is exactly as was predicted in Fig. 7 of ref. 7, except that the lateral 2-fold axes run between molecules rather than through the molecular centres. The 2-fold symmetry of the two halves of any one molecule is only approximate.

The idealized Z′ helix

To establish the helix axis and other helical parameters as shown in Table 1, the rotational and translational parameters that best mapped the first CG half of the molecule onto the second half had to be found analytically. As with CGCGCG, there are six repeating units per turn of ideal continuous helix. The rise per repeat and the tilt of base planes to the helix axis are both slightly greater in CGCG than in CGCGCG, but the most conspicuous differences are the deoxyguanosine sugar puckering, mentioned earlier, and the phosphate separation distances listed in Table 1.

Figure 4 shows three CGCG molecules stacked on top of one another with their helix axes coincident and with −60° rotation between them to simulate one complete turn of Z′ helix. Although each molecule is correct as observed, this idealized arrangement of them has no relationship to the actual molecular packing in the crystals. Zigzag lines connect the phosphorus atoms, including missing phosphates necessary to turn the three molecules into a continuous helix. As was noted for the Z helix, each cytosine deoxyribose ring has its oxygen atom packed against a guanine ring one step farther along the chain. Each base plane in Fig. 4 is puckered or twisted, and the observed deformations imply a steric repulsion by this close-packed sugar oxygen. A careful examination of Fig. 2 of ref. 1 reveals a similar apparent repulsion between guanine rings and deoxyribose oxygens in the Z helix, and this may be a characteristic feature of these left-handed zigzag structures.

Ion binding and helix conformational change

CGCGCG was crystallized from low-salt conditions and CGCG from high salt. The explanation for their observed difference in backbone conformation, and also for the salt dependence of the transition, may lie in the presence of bound chloride ions in the CGCG structure. DNA itself is a polyanion; if one assumes a charge of −3 on each CGCG strand and the observed crystal packing, then the crystals are 2.0 M in negative charges which must be neutralized by cations. By comparison, crystals of CGCGCG with an assumed −5 charge per strand and the published cell constants[1] are 2.6 M in negative charge, which sets a lower limit on the compensating cationic charge molarity.

Table 2 Solvent binding to base amino groups in CGCG

Base no.	N-to-solvent distance (Å)	Refined total electrons	Probable identity
Minor groove:	N2 of guanines		
G2	3.6	16	Cl^-
G4	3.5	8	Cl^-
G6	3.2	11	Cl^-
G8	2.7	5	H_2O
Major groove:	N4 of cytosines		
C1	—	—	—
C3	3.1	4	H_2O or Cl^-?
C5	3.2	7	Cl^-
C7	3.6	8	Cl^-

Although CGCGCG was crystallized from low-salt solution conditions, it is by no means in a low-salt or low-ionic strength environment within the crystals themselves, and this may be significant for the helix conformation in the crystal. CGCGCG might better be described as an intermediate salt structure.

As mentioned earlier, high-salt CGCG has additional chloride anions bound within the crystal structure, and these are listed in Table 2. In the minor groove, two sites of occupancy 16 and 11 electrons are found 3.6 Å and 3.2 Å away from the N2 amino groups of guanines G2 and G6 (Fig. 1*a*). An elongated 8-electron peak bridges N2 amino groups of guanines G4 on adjacent molecules as depicted in Fig. 3. Two more partial-occupancy chloride sites are coordinated to amino group N4 of cytosines C5 and C7 on the 'major groove' surface of the molecule. Hence, allowing for partial occupancy and other possible minor sites, we estimate that there are approximately four bound chlorides per double-stranded helix or two per monomer. This leads to a total negative charge molarity from DNA plus chloride of 3.7 M, which again places a lower limit on compensating cation molarity.

The phosphate group connecting bases G6 and C7 in CGCG is rotated out and away from the narrow groove relative to its position in CGCGCG, in a manner which suggests electrostatic repulsion between it and the chloride bound to G6 (Fig. 1*a*). The phosphate connecting G2 and C3 is rotated away from the chloride bound to G2 in a similar manner, and together these account for the 1.5 Å increase in GpC phosphate separation in the Z′ helix shown in Table 1. By contrast, in CGCGCG the phosphate and the guanine N2 amino groups are actually bridged by a hydrogen-bonding water molecule, as shown schematically in the left half of Fig. 5. This difference in phosphate position is sufficient to account for the increase in torsion angle ψ' from 82° in CGCGCG to 122° in CGCG, and the change in sugar conformation at guanine from C3′-*endo* to C1′-*exo*. It is significant that Pohl and Jovin[3] did not see a salt-induced conformational change in either poly(dI-dC) or poly(dA-dT), both of which lack the N2 amino group in the minor groove. Patel's observation that poly(dI-dC) shows only a single phosphorus NMR resonance[19] rather than the two found with poly(dG-dC)[20] indicates that the (dI-dC) polymer is not already in a zigzag left-handed helix in the conditions examined. It may be that the loss of the solvent interaction in Fig. 5 tips a delicate free energy balance in favour of a right-handed helix.

This is the first single-crystal study of an alteration in double-helix geometry produced by binding of ions, but not the first time that such mechanisms have been invoked to explain transitions monitored by circular dichroism or other methods. Both the A to A′ transition[13,14] and the B to C[16-19] may involve specific ion binding, and there may be a certain amount of parallelism in the behaviour of the three principal families of nucleic acid double helices: A, B and Z.

Why a left-handed helix at all?

To date, X-ray, circular dichroism, laser raman and/or NMR evidence has been found for a salt- or alcohol-induced transition that probably involves a right- to left-handed helix change, with poly(dG-dC) (ref. 3) and poly(dI-Br^{5}dC) (ref. 20), but not with

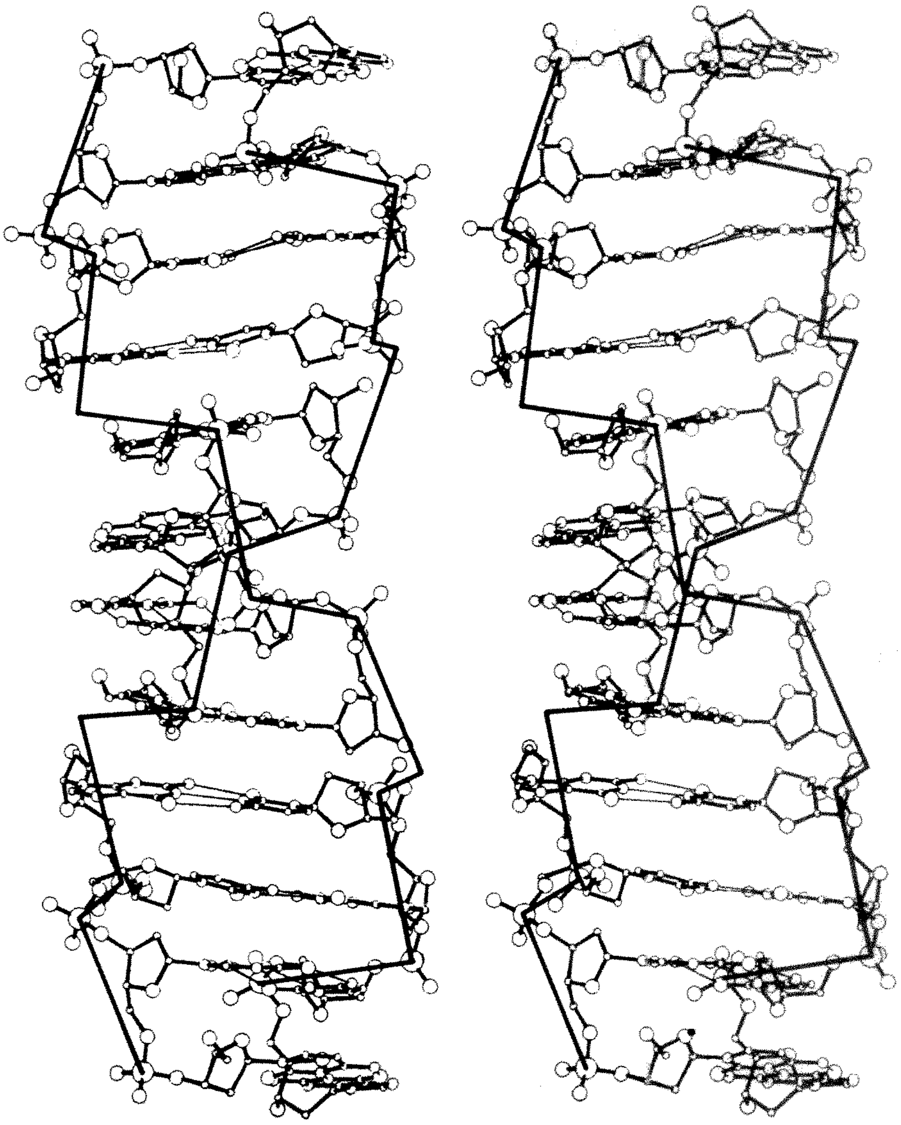

Fig. 4 Stereo view of stacking of three CGCG molecules on top of one another in such a way as to simulate a continuous 6-fold Z′ helix. Zigzag lines connect the phosphate backbone of an ideal helix, including the absent phosphates between molecules. The base plane normal is tilted 9° to the helix axis. The nearest phosphates on opposite strands are only 8.1 Å apart across the minor groove. The 'major groove' is pushed to the outside of the helix and is not a groove at all. Base plane puckering is such as to suggest steric repulsion by adjacent cytosine deoxyribose oxygen atoms. This is an isometric drawing with the viewing point at infinity; previous stereo figures have been perspective drawings with a finite viewing distance.

Table 3 Nucleic acid double-helix geometry

Family	A		B		Z	
Helix sense	Right		Right		Left	
Glycosyl bonds	*anti*		*anti*		*syn/anti*	
Sugar pucker	C3′-*endo*		C3′-*exo* (or C2′-*endo*)		Alternating	
Helix	A	A′	B	C	Z	Z′
Bases per turn	11	12	10.4–10*	$9\frac{1}{3}$	12	12
Rotation per base	32.7°	30°	34.6°–36°	38.6°	−60°/2	−60°/2
Pitch (Å)	30.9	36	33.8	31	44.6	45.7
Rise per base (Å)	2.8	3.0	3.38	3.31	7.43/2	7.61/2
Lateral packing diameter (Å)	23	23	19.3	19.2	18.1	18.4
Base tilt	16°–19°	10°	−6°	−8°	−7°	−9°

*Fibre diffraction experiments indicate 10 base pairs per turn, but solution measurements[31] and theoretical calculations[32] favour a slightly larger non-integral value. The entire B–C family probably represents a continuum of rotation angles in the range 34°–39°.

poly(dI-dC) itself, poly(dA-dT), poly(dA-Br^{5}dU), poly(dA-I^{5}dU), the ribonucleic acid poly(rG-rC), or any sequence lacking a purine/pyrimidine alternation[3,20]. It is not difficult to see why zigzag left-handed helices might be limited to such alternating sequences: the steric repulsion mentioned earlier between cytosine and a *syn* deoxyribose ring may be sufficient. However, why should even poly(dG-dC) adopt a left-handed geometry in preference to a right-handed helix of the A or B families, and why the apparent discrimination between various possible alternating sequences?

Properties of the six principal helices in the three helix families are compared in Table 3, and their known interconversions are schematized in Fig. 6. The three sectors of the circle about the B helix represent the three ways of bringing about transitions: lowering the humidity of fibres or films, increasing the alcohol concentration, or raising the ionic strength by increasing the salt concentration. Transitions within one family seem to be salt dependent and may even involve specific ion binding. This is certainly true for anion binding in the Z to Z′ transition, as the X-ray results have demonstrated. Ivanov[17] has also observed a correlation between the relative abilities of alkali metal cations to induce the B to C transition, the radii of the hydrated cations and the width of the minor groove as the helix winds down from 10 base pairs per turn to $9\frac{1}{3}$. Little information is available about the A to A′ transition in DNA, but in RNA the transition is salt induced. All these interconversions within families are probably non-cooperative as they occur gradually over a reasonably broad range of conditions.

The transitions between the B helix and A or Z families are sharper and are cooperative in nature[4,21]. This is not surprising, because a major change in backbone conformation at one point along the helix will make it easier for neighbouring regions to adopt the same changes, and for the transformation to propagate along the helix. Only the B to C conversion is appreciably temperature sensitive: with a ΔH° of −10 kcal, the C form is increasingly favoured as the temperature falls[22,23]. In contrast, the B to A and B to Z transitions are essentially isoenthalpic and independent of temperature[3,21].

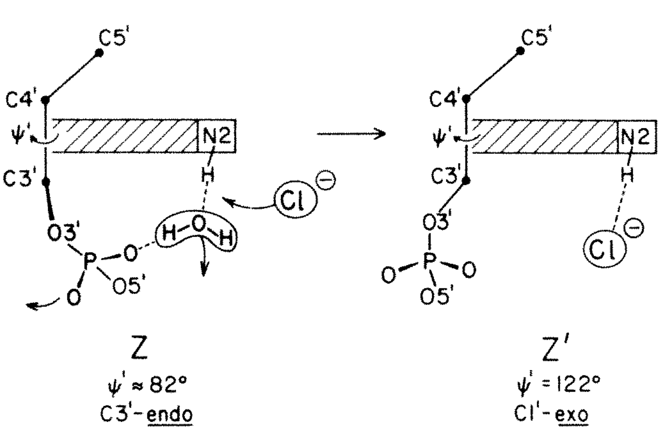

Fig. 5 Interactions between deoxyguanosine O3′ phosphate and N2 amino group in the Z helix of low-salt CGCGCG (left) and Z′ helix of high-salt CGCG (right). In CGCGCG the two groups are bridged by a water molecule, whereas in CGCG the phosphate is repelled by a bound chloride. This can account for the observed increase in ψ′ (the C4′–C3′ torsion angle) from 82° in CGCGCG to 122° in CGCG, and the change in sugar pucker from C3′-*endo* to C1′-*exo*.

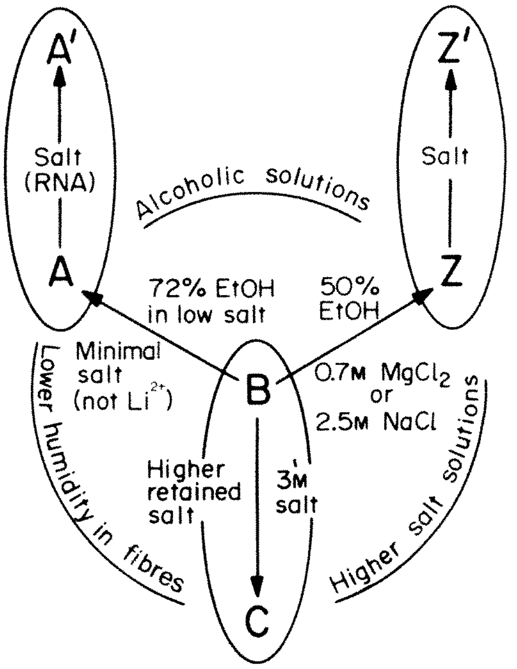

Fig. 6 Families of double helices and transitions between them. Transitions between members of one family, within oval outlines, are influenced by salt concentration. Transitions between families can be brought about by changing relative humidity and salt content in fibres or films, or changing ionic strength or solvent polarity in solution. Critical salt and ethanol concentrations, from refs. 3, 6, 17, are expressed as midpoints rather than endpoints of transitions. The B to Z transition, involving a change in helix sense, may be restricted only to certain alternating purine/pyrimidine sequences.
